The present contribution extends the developments in [8] to include the effect of nonlocal damage for ductile failure. The main prototype for the effective material is the Johnson-Cook model, accounting for deformation and strain rate hardening and temperature degrading effects. In the damage modeling we are concerned with:

1. the energy dissipation rate describing a damage coupled to plasticity driving dissipation to the fracture area production process [8].

2. the description of energy dissipation due to fracture area production, involving area production due to “damage convection” and “damage nucleation” in the temporal evolution of the damage field [9]. In addition, a “gradient” fracture area production effect is obtained due to spatial growth of the damage field.

3. the formulation of nonlocal condition for onset of the plasticity driven damage evolution.

Thereby, the model constitute a novel control of the ductile failure process. In fact, this model can partly remove the pathological mesh dependence and have a stable behavior without the additional gradient effect [8, 9]. A major incentive of the present investigation is to consider the convergence and stability properties in the FE-application considering both damage rate and gradient dependence in the fracture area production.

In line with Lemaitre concept for continuum damage evolution, the model is formulated so that the damage evolution is driven by the stored free shear energy and plastic work of the effective material. This effect is described by degrading the isochoric portion of the free energy in terms of the scalar damage variable $0 \leq \alpha \leq 1$. In order to enhance the ductile failure modeling capability, an initiation criterion is introduced to monitor the contribution of the plastic work to damage force. As to the nonlocal damage evolution model, the global fracture area functional defines the total fracture

area through the fracture area density γ [9], which takes on values based on damage state, the rate of damage and gradient damage.

$$\dot{\gamma} = \frac{1}{l_c}\left(\alpha\dot{\alpha} + \boldsymbol{H}\cdot\dot{\boldsymbol{H}}\right) + \frac{1}{v^*}\dot{\alpha}^2 \geq 0 \tag{1}$$

where the parameters involved are the internal length parameter l_c and the fracture area progression speed parameter v^*, controlling the damage evolution. The interpretation is shown in Figure 1a, considering schematic isolevels of the damage state and evolution. Note the directional dependence of the nonlocal damage through the damage flux vectors $\boldsymbol{H}$ and $\dot{\boldsymbol{H}}$. From Eq.(1) there are three mechanisms governing the fracture area evolution: The first two mechanisms, $\alpha\dot{\alpha}/l_c$ and the gradient damage term $\boldsymbol{H}\cdot\dot{\boldsymbol{H}}/l_c$, are due to growth (or convection) of existing damage induced voids, whereas the term $\dot{\alpha}^2/v^*$ represents void nucleation [8]. Clearly, the conventional completely rate independent fracture area evolution is obtained when the damage propagation speed parameter $v^* \to \infty$ [8, 9].

Split Hopkinson tests are considered to show the predictive capabilities of the model [10]. Figure 1b shows our preliminary results of the localized deformation patterns for the rate sensitive damage evolution model [8] and the combined damage rate and gradient dependent damage model. Clearly, in the present case of shear failure the gradient damage effects becomes pronounced due to the extreme localization when considering the local rate dependent model.

SOME RECENT PROGRESS ON PHASE-FIELD MODELING: FATIGUE, R-CURVES, AND LARGE STRUCTURES

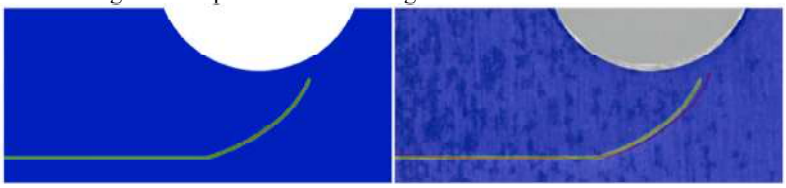
Summary Phase-field modeling approaches for fatigue crack growth, R-curve behavior, and large-scale structures are presented. For fatigue, a modified J-integral is developed to demonstrate how the phase-field approach can be used to generate Paris-Law type crack growth rates. A steady-state finite element method is then applied to generate fits of the phase-field theory to measured crack growth rate data. Full transient simulations are performed and compared to experimental measurements on samples where crack turning is induced by the presence of a hole in the vicinity of the crack. To model R-curve behavior plasticity is introduced into the formulation and adaptive refinement is used to capture different length scales. Finally, modifications to the damage functions are introduced to allow for the analysis of large-scale structures and some issues are identified and discussed.

PHASE-FIELD MODELING OF HIGH CYCLE FATIGUE

The most well-known phenomenological relationship between fatigue crack growth and mechanical loading is the so-called Paris-law. Paris et al. [1] found that the fatigue crack growth per cycle, da/dN, is governed by the stress intensity factor range, ΔK, that is, $da/dN = f(\Delta K)$, and it can often be assumed to follow a simple power-law relation called the Paris-law: $da/dN = C(\Delta K)^n$ in which C and n are material constants. Since the Paris-law is a phenomenological description based on linear elastic fracture mechanics, it is possible to enhance phase-field methods for brittle fracture to allow for fatigue crack growth without the need to include the complications of plastic deformation around crack tips. Hence, the primary goal of this work is to extend the phase-field approach to reproduce the macroscopic fatigue crack growth behavior that is either driven by cyclic loading or monotonic loading, i.e. static fatigue. Cyclic fatigue conjures notions of applied forces or displacements that are increased from zero to some maximum value and then decreased to some minimum value, with such a cycle repeating as the crack grows and the sample eventually fails. The present model *does not* require the full time integration of the details of individual cycles that would track the full history of loading and unloading. For high cycle fatigue this would require explicit solutions for millions of cycles. Instead, we regard the Paris-law as a *kinetic law* governing the relationship between the crack growth driving force and the crack growth rate. Hence, instead of applying cyclic loads explicitly within the model, the loading is applied *statically* as ΔK and the crack trajectory evolves according to the partial differential equations of the phase-field model, suitably modified to reproduce the correct $da/dN = f(\Delta K)$ behavior. We use the J-integral to aid in determining the relationship between the phase-field kinetic law and the Paris law and we then apply the theory within the finite element method to predict the crack growth [2]. One example of the results of the theory compared to an experimentally measured fatigue crack path is shown in Figure 1.



(a) (b)

Figure 1. The crack path from (a) the phase-field simulation and (b) an overlay of the results for the crack path with the experimental observation.

PHASE-FIELD MODELING OF R-CURVE BEHAVIOR

The modeling of R-curve behavior using the phase-field approach was performed to compare to the results obtained for the R-curve behavior predicted with cohesive zone models. Here, the bulk material behavior is modeled with isotropic hardening J_2 plasticity, and the phase-field evolution equation is driven by the elastic stored energy in the material. A new adaptive mesh refinement scheme was developed in order to resolve the disparate length scales associated with the large elastic region required to model small-scale yielding, the size of the plastic zone, and the size of the phase-field region surrounding the crack. Figure 2 shows the results for a R-curve for a specific set of material parameters, and Figure 3 shows the evolution of the plastic zone up until steady state crack growth is achieved.

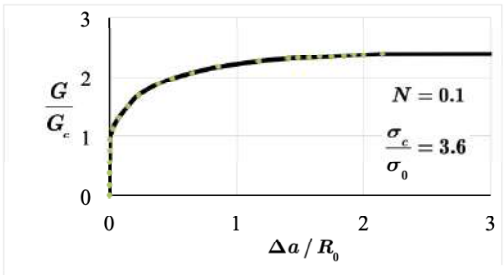


Figure 2. R-curve bahavior predicted by the phase-field approach with plasticity and phase-field driven by elastic energy.

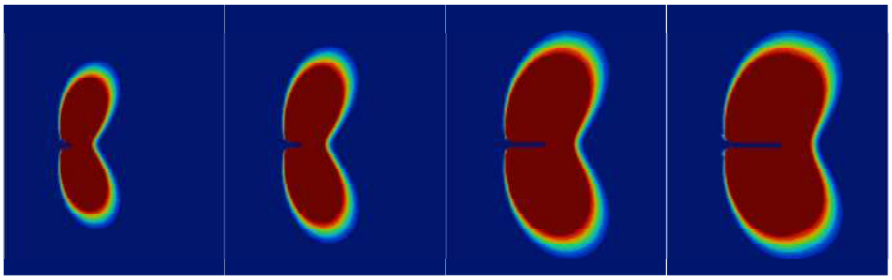

Figure 3. The evolution of the plastic zone associated with the R-curve behavior shown in Figure 2.

PHASE-FIELD MODELING OF LARGE STRUCTURES

Phase-field fracture theories contain a small length-scale interface region around the cracks. In fact, this length-scale, ℓ_0, is set by the material properties, specifically the peak stress, σ_c, and fracture toughness, G_c, such that $\ell_0 = 3G_cE/8\sigma_c^2$. Unfortunately, this length-scale can be very small. In a brittle material it can be on the order of nanometers, and for a ductile material it can be on the order of a fraction of a millimeter. Furthermore, the numerical solution of the phase-field equations requires that the discretization of the model can resolve this length scale. Clearly, such resolution makes the application of the phase-field theory to meter-sized structures difficult in two dimensions and prohibitive in three dimensions. Hence, all of the attractive features of the phase-field formulation are for naught if it cannot be applied to the analysis relevant large scale structures. Most of the academic research so far has focused on the generality and the accuracy of results, rather than computational cost. It is on this avenue of inquiry that we focus this study. The insight that we have uncovered is that the very small process zone length-scale that is set by the material properties can be decoupled from the phase-field length scale that must be numerically resolved within the calculations by the appropriate choice of the function that degrades the elastic load carrying capacity of the material. Specifically, the function used is the exponential form introduced in [3]. Furthermore, as is relevant for improving the computational cost, the phase-field length scale can be made orders of magnitude *larger* than the material length scale. We will present new results for this approach and explain the limitations on how far the decoupling can be pushed on a given mesh discretization. Figure 4 shows results for this new approach.

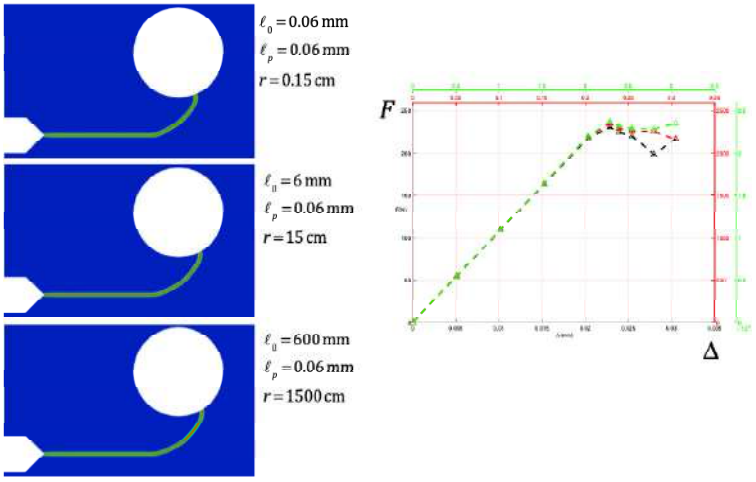

Figure 4. Simulations on increasingly larger compact tension specimens with a hole. In all cases the material process zone length scale is taken as a physically reasonable value of 0.06mm, but the phase-field length scale is allowed to vary such that the mesh density required to resolve the fields around the hole can also be used to resolve the phasse-field distribution around the cracks, which is 1, 100, and 10,000 times as large as the process zone length-scale going from top to bottom. Both the crack path agreement and the scaling of the load deflection curves are in agreement with the requirements of linear elastic fracture mechanics.

SYSTEMATIC INVESTIGATION OF FRACTURE BEHAVIOR OF COMPOSITES IN THE VICINITY OF TOUGH-BRITTILE TRANSITION

Uttam S. Kachhwah*[1] and Sivasambu Mahesh[1]
[1]Department of Aerospace Engineering, Indian Institute of Technology Madras, Chennai 600036 India

Summary The Monte Carlo simulation plane transverse to the composite direction has been studied for various parameters such as patch size, variability of fibre strength, and the stress transfer coefficient. Limitation of patch size is overcome by FFT algorithm used by Ankit Gupta *et al*. and hence it has been possible to explore the tough-brittle transition existence marked by previous researchers. Patch size and other constraints imposed on simulation have shown different trends during cluster analysis and a counter fitting model respectively, which has helped take an assertive decision to scan peaks on moments ratio vs stress transfer coefficient plots. Two-parameter based probabilistic tight cluster growth model is developed to capture the empirical strength distribution and also extrapolated to map the survival probability.

INTRODUCTION

Composite structures are light in weight and high in strength due to which it has been widely used in aerospace applications as well as ground structures (e.g. Composite flywheel material design for high-speed energy storage) where anisotropicity in strength is our primary concern. Increasing demand of high strength and reliable composite in the market has narrowed down the probability failure tolerence. Keeping this into mind, studies based on cluster formation statistics (unstable cluser growth) and model fitting parameters are carried in the present study. Final rupture of materials depends upon how crack grows and interact each other. The correlation of crack growth depends on many factors such as fibre strength variability (weibull moduli), ρ, stress transfer coefficient, β, and patch size, N. Smaller weibull moduli corresponds to the formation of scattered breaks whereas strong correlation in cluster formation is observed for higher weibull moduli. Another factor, β decides the intensity of load shared amongst intact fibres. Two load sharing extremum which exists are, first: equal load sharing (ELS) where aditional load is borne by all the intact fibres equally, second: local load sharing (LLS) wherein only neighbors share additional load dropped by a broken fibre. All remaining set of β, between these two limits, have also been explored in order to comment on the point where fracture mode changes suddenly. In breif, two modes of failure, tough and brittle mode is separated by a point calculated by R.C. Hidalgo *et al* [3] and S. Pradhan *et al* [4] using the method of moment for cluster analysis and is given at around $\beta = 2.2 \pm 0.1$ and its equivalent value by [4], respectively. In this paper, empirical distribution results, model fit based on tight cluster growth, and cluster moment analysis results are presented. Empirical data is obtained from two-parameter based weibull distributed fibre strength formula,

$$F(\sigma) = 1 - exp(-\sigma^{\rho}) \tag{1}$$

where σ is normalized strength per fibre and F is failure probability. Re-writing Eq. 1 for strength expression,

$$\sigma = [-log(1 - F(\sigma))]^{1/\rho} \tag{2}$$

PROBABILISTIC MODELS

Probablistic model and weakest-link analysis on weibull plot are explaind in two subsections explaining tough and brittle fracture mode.

Tough mode - This mode is generally observed for high variability of fibre strength; uncorrelated crack growth is the main cause. A relatively larger bundle of loose threads is considered as ELS patch and can be captured exactly by gaussian distribution done by Daniels [5] whereas for smaller patch size McCartney and Smith [6] have developed a recursion formula, discussed in [1]. Final failure of tough composite does not occur by a single running crack but due to the coalesence of small cracks into a comparitively big well-rounded fissure which makes the composite weaker for higher loads. One way of defining tough regime is cluster calculation which will be discussed in the result section.

Brittle mode - It's imprudent to explain brittle fracture mode alone in a single way however, qualitatively one can say that a crack formation which leads to the final rupture of composite with no additional load application possible is termed as brittle failure. Brittle failure in composites occur with no apparent deformation before fracture like other materials. Most likely cases where brittle mode dominates are due to selection of parameters from the higher $\beta - \rho$ plane. The existence of critical cluster or weakest-link, used interchangeably, can be seen pictorially on weibull paper where all curves collapse into a single curve. When a patch comprises a critical cluster whose size is less than the size of the patch itself, the failure under this mode can be regarded as the weakest-link phenomenon which becomes independent of the number of fibres. These two modes are quantified using cluster statistics calculation and few questions are also raised on interpretation on genesis of peaks during the method of moment application analysis.

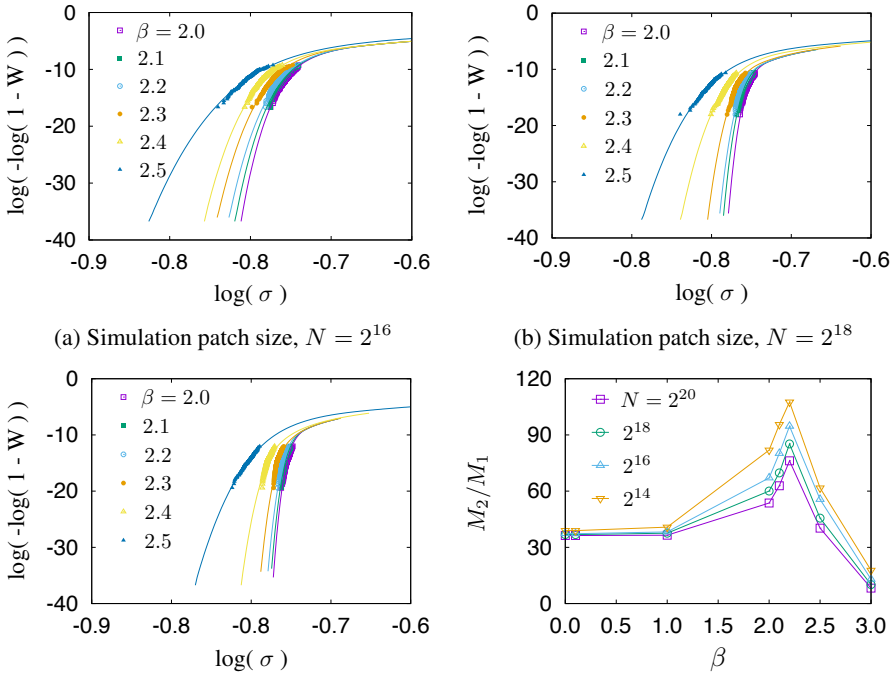
RESULTS AND DISCUSSION

Strength distribution of intermediate β fibre bundles are discussed for three different N, shown in Fig.1. A best fit for each β distribution is obtained by running the model based on tight cluster formation [6]. Variability in fibre strength plays significant role on the selection of ELS bundle size, M, taken as model fitting parameter. For higher ρ, crack grows in a tight cluster manner $\forall\ \beta > 2.0$, whereas for lower ρ, in order to make them grow in the same fashion entire patch needs to be divided into N/M number of ELS-bundle [2] of size M where $1 \leq M \leq N$. To esnure the minimum amount of overload on neighboring ELS bundle, appropriate value of M has been opted with in given limit. M increases with decreasing ρ and increaing patch size untill it reaches to the critical cluster size. $N_{sim} = 256$, Monte Carlo simulation have been performed for each set of $N \in \{2^{14}, 2^{16}, 2^{18}, 2^{20}\}$, $\beta \in \{2.0, 2.1, 2.2, 2.3, 2.4, 2.5\}$, and $\rho = 2.0$. Fig.1(a, b, c), do not show any sudden jump near $\beta = 2.1$, whereas Fig.1(d), has shown a clear peak at $\beta = 2.2 \pm 0.1$. As we can see that the gap between curves are changing gradually from $\beta = 2.0$ to 2.5 unlike peaks observed during cluster analysis; this just contradicts the previous study on tough-brittle transition point. Our empirical strength distribution has considered mutual break interaction thus making simulation realistic unlike others however, change in stress concentration has just altered the failure probability (not presented in this article).



(a) Simulation patch size, $N = 2^{16}$

(b) Simulation patch size, $N = 2^{18}$

(c) Simulation patch size, $N = 2^{20}$

(d) Variation of the cluster moment ratio

Figure 1: (a), (b), and (c) are weakest-link plot on weibull paper for various β and $\rho = 2.0$. A gradual change in empirical distribution can be clearly seen unlike sudden jump nearby $\beta = 2.1$. Model fits exactly well to the empirical distribution following monotonicity in M across β and ρ. (d) is the varaition of ratio of second and first cluster moment (M_2/M_1) over the desired range of β.

CONCLUSIONS

Monte Carlo simulations have been performed thoroughly for various β coefficeints and $\rho = 2.0$. Brittle region of fracture mode is still unclear for other varaibility of fibre strength, which is also an important parameter to be considered in the simulation part. Our next goal is to set a model which can capture the lower probability of failure perfectly and analyse thoroughly for various ρ values. From the Fig.1(a, b, c), it's clear that, for any arbitrary $\beta > 2.0$ and $\rho = 2.0$ in the limit of $N \to \infty$ mode of failure is brittle fracture.

POROELASTIC EFFECTS ON TIME AND RATE DEPENDENT FRACTURE OF GELS

Yalin Yu[1], Nikolaos Bouklas[2], Chad M. Landis[1], and Rui Huang[1]*
[1]Department of Aerospace Engineering and Engineering Mechanics, University of Texas, Austin, TX 78712, USA
[2]Sibley School of Mechanical and Aerospace Engineering, Cornell University, Ithaca, NY 14853, USA

Summary Fracture of polymer gels is often time and rate dependent. The underlying mechanisms include local fracture processes, viscoelasticity, and solvent diffusion (poroelasticity). This paper focuses on the effects of poroelasticity, for which a modified J-integral is adopted to define the crack-tip energy release rate for crack growth in gels. For a stationary crack, the energy release rate is time dependent, with which delayed fracture can be predicted based on a Griffith-like fracture criterion. For steady-state crack growth in a long-strip specimen, the energy release rate is a function of the crack speed, with rate-dependent poroelastic toughening. With a poroelastic cohesive zone model, solvent diffusion within the cohesive zone leads to significantly enhanced poroelastic toughening as the crack speed increases. We present numerical results and discuss implications for experiments.

INTRODUCTION

Recently, polymer gels have been exploited as a class of soft active materials with potential applications in soft machines and soft robotics. These applications have motivated development of smart and tough gels. However, it remains a challenge to accurately measure the fracture toughness of polymer gels [1], and fundamental understanding of the fracture mechanisms in gels is still lacking. In particular, fracture of polymer gels is often time and rate dependent. For example, in an experimental study on steady-state crack growth in gelatin gels, Baumberger et al. [2] found that the effective fracture energy was rate dependent and increased with the crack speed (so-called "velocity toughening"). Recently, Tang et al. [3] conducted fracture experiments of polyacrylamide hydrogels under monotonic, static, and cyclic loads; they observed time-dependent, delayed fracture below the critical load for fast fracture but above a threshold load. In this paper, we present a set of theoretical and numerical results concerning the poroelastic effects on the time and rate dependent fracture of polymer gels, including both delayed fracture and steady-state crack growth.

J-INTEGRAL AND ENERGY RELEASE RATE

Based on a nonlinear poroelastic theory of polymer gels, a modified J-integral was derived by Bouklas et al. [4] to calculate the energy release rate for crack growth in poroelastic gels, where the energy dissipation by solvent diffusion was subtracted from the classical J-integral. It was shown that the modified J-integral is path independent for both transient and steady-state crack growth in poroelastic gels [4-8]. With the modified J-integral as the crack-tip energy release rate, a Griffith-like fracture criterion is proposed. In the case of a stationary crack, the modified J-integral is time dependent [4,5], and the onset of crack growth may be predicted when the modified J-integral reaches a critical value, namely, $J^*(t) = \Gamma_{c0}$, where Γ_{c0} is the fracture energy for initiation of crack growth. For steady-state crack growth, the modified J-integral is a function of crack speed $\dot{a}$ [6-8] and must be equal to the fracture energy at the same crack speed, namely, $J^*(\dot{a}) = \Gamma_{SS}(\dot{a})$, where $\Gamma_{SS}(\dot{a})$ is the rate-dependent steady-state fracture energy.

DELAYED FRACTURE

Consider a specimen with a stationary center crack (Fig. 1a), subject to uniaxial tension by either displacement or load (traction) controlled step loading under plane strain conditions. The initial state of the gel is assumed to be stress free and homogeneously swollen. The specimen may be immersed in an external solution so that all of the boundaries (including the crack faces) are in contact with the external solution where the chemical potential $\mu = 0$ is assumed. Alternatively, if the specimen is not immersed, we assume that all of the boundaries are impermeable to solvent diffusion. For simplicity, only the results from the linear poroelastic analysis [5] are discussed here, whereas the nonlinear results [4] are qualitatively similar.

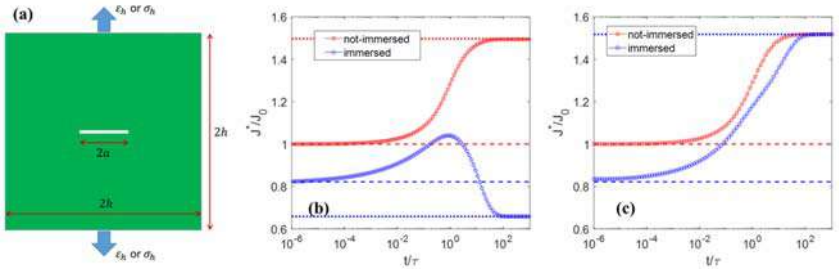

Fig. 1: (**a**) Schematic of a stationary center-crack model. (**b-c**) Normalized energy release rate versus the normalized time under displacement and load control, respectively. The horizontal dashed and dotted lines are the short-time and long-time limits.

By dimensional considerations, the energy release rate can be written as

$$\frac{J^*}{J_0} = \Lambda\left(\frac{t}{\tau}, \frac{h}{a}, \nu\right), \tag{1}$$

where $J_0 = \frac{K_{I0}^2}{4G}$, $\tau = a^2/D^*$ is the characteristic diffusion time with an effective diffusivity D^*, and ν is Poisson's ratio (drained). The dimensionless function on the right-hand side is determined numerically by a finite element method, as shown in Fig. 1. For linearly poroelastic materials, analytical solutions for the energy release rate were found at the short- and long-time limits [5].

According to Fig. 1, except for the immersed case under displacement-controlled loading, the energy release rate (J^*) increases monotonically over time. In these cases, the crack would grow immediately if the short-time limit of the energy release rate is greater than the fracture toughness, but would never grow if the long-time limit is lower than the fracture toughness; in between, delayed crack growth is predicted. Taking J_0 as the applied loading parameter, the delay time is predicted when $0.66\Gamma_{c0} < J_0 < \Gamma_{c0}$ for the not-immersed case and when $0.66\Gamma_{c0} < J_0 < 1.22\Gamma_{c0}$ for the immersed case under load control. The numerical results are qualitatively consistent with recent experiments by Tang et al. [3], who observed delayed fracture of polyacrylamide hydrogels when the applied energy release rate (J_0) was below the critical load for fast fracture and above a threshold value.

STEADY STATE CRACK GROWTH

For steady-state crack growth, an infinitely long strip specimen with a semi-infinite crack was considered, first under plane strain conditions [7] and then under plane stress conditions [8]. The steady-state crack model has two relevant length scales: the specimen half-width h and the steady-state diffusion length $l_{ss} = D^*/\dot{a}$. The ratio between the two length scales defines a dimensionless number, $\mathrm{Pe} = \frac{\dot{a}h}{D^*}$, called the Péclet number. For a linearly poroelastic long-strip specimen, the normalized energy release rate for the steady-state crack growth can be written as

$$\frac{J^*}{J_e} = \Lambda_{ss}(\mathrm{Pe}, \nu). \tag{2}$$

where $J_e = 4G\varepsilon_\infty^2 h$. The dimensionless function on the right-hand side was determined numerically, as shown in Fig. 2. Analytical solutions for the steady-state energy release rate were found at the slow and fast crack limits [7,8]. In all cases, the crack-tip energy release rate is smaller than the classical J-integral applied at the remote boundary ($J^* < J_e$), because part of the supplied energy has been dissipated by solvent diffusion in the poroelastic specimen. The poroelastic toughening depends on the normalized crack speed.

A cohesive zone model was developed to partly account for the rate-dependent fracture processes in gels [6,8]. For the immersed case, significantly enhanced poroelastic toughening is predicted (Fig. 2c) for relatively fast crack growth ($\mathrm{Pe} > 100$), due to solvent diffusion within the cohesive zone. This is consistent with "velocity toughening" observed in experiments [2]. On the other hand, for the not-immersed case, with no solvent diffusion in the cohesive zone, the effect of poroelastic toughening decreases as the normalized crack speed increases.

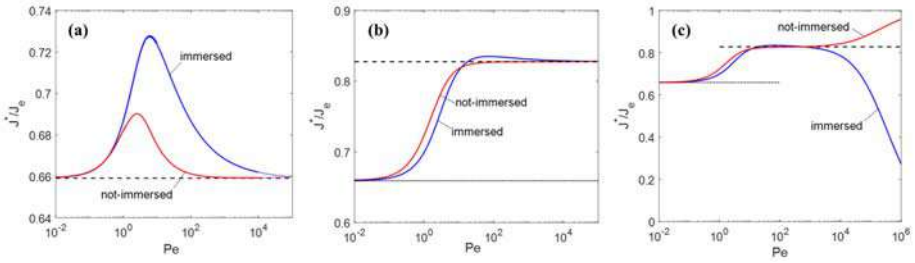

Fig. 2: (**a-b**) Normalized energy release rate versus the normalized crack speed ($\mathrm{Pe} = \dot{a}h/D^*$) for steady-state crack growth under plane strain and plane stress conditions, respectively. The dotted and dashed lines are the slow and fast crack limits. (**c**) Plane stress results with the cohesive zone model.

CONCLUSIONS

A modified J-integral method is developed for calculating the crack-tip energy release rate for fracture in poroelastic gels, with which Griffith-like fracture criteria are proposed for delayed fracture with a stationary crack and for rate-dependent steady-state crack growth. While the method is generally applicable for linear and nonlinear poroelasticity, analytical and numerical results are presented here based on linear poroelasticity only. Future studies may extend to nonlinear poroelasticity with large deformation.

[1]Department of Civil and Systems Engineering, Johns Hopkins University, Baltimore, USA

Summary This work focuses on the fracture strength of brittle lattice materials under tensile loads. We design three-dimensional lattices with controlled morphological characteristics and synthesize them using stereolithography. We perform tensile experiments to failure and connect the measured strength to key microstructural features. Micromechanical numerical models are used to simulate the experiments and estimate the effect of base material properties and loading conditions to the macroscopic strength. Finally, we propose an energy-based method for analysing the fracture mechanics of lattice materials. We show that using this approach does not require any assumptions on the stress and displacement fields near the crack tip. The accuracy of the method is illustrated by predicting the strength of 2D lattices and comparing the estimated critical stresses with direct numerical simulations.

INTRODUCTION

Cellular solids have excellent mechanical, thermal and acoustic properties and have thus been widely used in a variety of engineering applications including thermal shielding, acoustic insulation and shock absorption [1]. Recent advances in additive manufacturing have enabled the synthesis of novel cellular materials and micro-lattices with unprecedented properties. While there has been a large volume of work focusing on the nonlinear mechanics associated with the compressive behavior of these materials, their fracture properties under tension remain relatively unexamined [2-3]. The design of new materials with superior combinations of strength and toughness, by manipulating material architecture, requires a strong understanding of the connection between key microstructural characteristics and fracture properties. Here, we combine additive manufacturing, characterization and modelling of 3D-lattice materials in order to measure their fracture strength and establish its connection to the underlying microstructures. We finally present an energy-based method to calculate the critical load in lattices that have a crack. We examine the accuracy of our method by comparing analytical estimates of critical stresses to numerical simulations.

TENSILE FRACTURE OF 3D BRITTLE LATTICE MATERIALS

In this work we focus on 3D lattices with different average node-connectivities leading to their mechanical behavior varying from bending- to stretching-dominated. Kelvin, octet and BCC lattice specimens are synthesized in a stereolithography-based printer with 50μm layer thickness using a high-temp photocurable resin (see Fig. 1a). The strength of the base material is measured using micro-tensile tests in struts. The results show a typical brittle polymer behavior with an average tensile strength of 63 MPa and a corresponding failure strain close to 3%. A series of uniaxial tension experiments are conducted on all lattices with relative densities ranging from 3% to 15%. A typical response of a Kelvin lattice with two relative densities (6% and 12%) is shown in Fig. 1. One notices that the response becomes nonlinear for nominal strains larger than 1%. The material stiffness is gradually decreasing and at a critical load damage initiates at some area within the domain and then instantaneously propagates through the whole specimen. The corresponding macroscopic stress drops to zero and all elastic strain energy is released. Several experiments are used to establish strength as a function of key microstructural characteristics for all lattices. Numerical models are developed that are able to capture the lattice materials' strength and are then used to examine the effect (a) topology, (b) material distribution and (c) base material behavior to the macroscopic lattice strength.

ENERGY-BASED FRACTURE MECHANICS FOR LATTICES

We next consider lattices materials with pre-existing cracks and try to predict their fracture strength under macroscopic loads. In this case, the failure mechanism is greatly affected by the behavior of the lattice material around the crack region. In contrast to traditional fracture mechanics of monolithic solids, where the stress and displacement fields are described by the stress intensity factors, defining the corresponding fields in lattice materials remains an open challenge. The complex microstructure can strongly alter the stress behavior ahead of an existing crack as well as its propagation under external loads. Here we propose an energy-based method that combines modelling and theory in order to predict the critical macroscopic failure stress. For simplicity, we focus first on a 2D triangular lattice (see Fig. 2a) under mode I loading conditions and made of a perfectly-brittle material. We measure the strain energy difference $U = E_1 - E_2$ between the cracked and the intact lattice. The calculation of the elastic strain energy stored in the cracked model requires the measurement of the crack profile $\delta(x)$ (see Fig. 2b). Hence, the energy release rate $G(\sigma_0, E^*, \rho^*, \alpha) = \partial(E_1 - E_2)/\partial\alpha$ can then be formulated as a function of remote stress, lattice material properties and crack length.

The fracture energy $\Gamma = \Gamma(\sigma_f, E, \rho^*, \alpha)$ is a function of the base solid properties, the lattice microstructure and the crack length and can be measured using the energy of the broken ligaments as the crack propagates. The criterion for crack propagation corresponds to the energy release rate being equal to the fracture energy $G(\sigma_0, E^*, \rho^*, A) = \Gamma(\sigma_0, E, \rho^*, A)$. Using this equality the critical macroscopic stress $\sigma_c = \sigma_c(\sigma_f, \rho^*, \alpha)$ can then be estimated. We note here that the stiffness of the underlying solid in this case does not affect the fracture strength. The accuracy of the method is verified against numerical calculations. In the numerical model, all struts are discretized with beam elements and the crack propagates once the stress in any element ahead of the crack reaches the base material strength σ_f. Both central-crack and single-edge-notch models are examined and the results are shown in Fig. 2c. The theory seems to agree well with the simulation for a range of different densities and crack lengths. We will show that contrary to other techniques that assume an infinite lattice material [4], the current methodology remains accurate even for finite size domains. It does require however, as in the case for classical continuum fracture mechanics, an a priori knowledge of the crack propagation direction.

Finally, we use our energy-based approach to estimate the critical fracture strength of different materials and connected it to their macrostructure. We will present results from both stretching- and bending-dominated lattices under general loading conditions.

A PHASE FIELD FRACTURE MODEL FOR POROUS ROCKS

Ralf Denzer*[1] and Alex Spetz [2]
[1]Division of Solid Mechanics, Lund University, Lund, Sweden
[2]Department of Construction Science, Geotechnical Engineering, Lund University, Lund, Sweden

Summary In this contribution, we present a modified phase-field model for simulating the evolution of mixed mode fractures and compression bands in porous rocks and the comparison to experimental results. For the purpose of validation, the behaviour of samples of artificial rock, with either a single or double saw cuts, under uniaxial plane strain compression has been numerically simulated. The simulated results are compared to experimental data, both qualitatively and quantitatively. It is shown that the proposed model is able to capture the commonly observed propagation pattern of wing cracks emergence followed by secondary compaction bands driven by compressive stresses. Additionally, the typical types of complex crack patterns observed in experimental tests are successfully reproduced, as well as the critical loads.

INTRODUCTION

Numerical phase-field fracture models have the appealing numerical property that a crack can propagate at least in principle arbitrarily through a mesh without being restricted to mesh lines, e.g. when using cohesive zone interface elements, or using enrichment techniques in cracked elements such as the extended finite element method. In phase-field fracture models, a crack is indicated by a scalar order parameter, which is coupled to the material properties in order to model the change in stiffness between broken and undamaged material.

Quasi-static brittle fracture mechanics can be formulated in a variational setting [2]. A numerical implementation of the regularized approximation of the variational formulation was first described in [1]. In [4] the interpretation of the phase-field parameter in the context of a gradient damage model was presented. The phase-field fracture model has since been extended in a number of directions, e.g., including dynamic fracture, coupled thermo-mechanical-driven, high-order phase-field approaches.

However, these contributions assume that the critical energy release rate for different fracture modes are the same, which is not the case for rocks and rock like materials [7]. In fact, in rock-like materials, the critical energy release rate for Mode I and Mode II can differ significantly. In [8] a phase-field fracture model that distinguish between the critical release rates for Mode I and Mode II is proposed. Moreover, porous rocks, e.g. sandstone and volcanic rock often displays fractures in compression, referred to as compaction bands [6].

PHASE-FIELD FRACTURE MODEL FOR POROUS ROCKS

Following [3], the phase-field fracture model is characterised by a coupled set of local equations,

$$\mathbf{0} = \mathrm{div}\boldsymbol{\sigma} + \boldsymbol{f} \tag{1}$$

$$0 = \frac{\dot{d}}{M\mathcal{G}_c} + 2d[1-\eta]\frac{\mathcal{H}}{\mathcal{G}_c} + \frac{1}{2\ell_0}[d-1] + 2\ell_0\Delta d \tag{2}$$

where $\mathcal{G}_c$ is the critical energy release rate, $\mathcal{H}$ represents the crack driving part of the elastic energy density and the kinetic coefficient or mobility parameter M is a non-negative scalar function $M = M(\boldsymbol{\varepsilon}, d, \nabla d, \dot{d})$ introduced to control the crack velocity. The most simple assumption, $M =$ constant lead to the standard Ginzburg-Landau evolution equation.

To take different critical energy release rates for Mode I and Mode II as well as formation of compaction bands into account we propose a generalisation to the ratio $\frac{\mathcal{H}}{\mathcal{G}_c}$ in the evolution equation (2) to

$$\frac{\mathcal{H}}{\mathcal{G}_c} = \frac{\mathcal{H}_I^+}{\mathcal{G}_{cI}} + \frac{\mathcal{H}_{II}^+}{\mathcal{G}_{cII}} + \frac{\mathcal{H}^-}{\mathcal{G}_{band}} \tag{3}$$

with $\mathcal{H}_I^+ = \frac{1}{2}K\langle \mathrm{tr}[\boldsymbol{\varepsilon}]\rangle^2 H(\mathrm{tr}[\boldsymbol{\varepsilon}])$, $\mathcal{H}_{II}^+ = \mu \mathrm{tr}[(\boldsymbol{\varepsilon}_d^+)^2]H(\mathrm{tr}[\boldsymbol{\varepsilon}])$ and $\mathcal{H}^- = \frac{1}{2}K[\mathrm{tr}[\boldsymbol{\varepsilon}] - \langle \mathrm{tr}[\boldsymbol{\varepsilon}]\rangle]^2 + \mu \mathrm{tr}[(\boldsymbol{\varepsilon}_d^-)^2][1 - H(\mathrm{tr}[\boldsymbol{\varepsilon}])]$. Where the parameters $\mathcal{G}_{cI}$, $\mathcal{G}_{cII}$ are the critical energy release rates for Mode I and Mode II respectively and $\mathcal{G}_{band}$ the energy release rate for compaction bands forming due to compressive stresses. H is the Heavyside function and ε_d is the deviatoric part of the linearized strain tensor. the definition of $\varepsilon^{\pm}$ are given in [3].

The spatial discretisation of the weak forms of eqn. 1 and 2 is performed by means of the Galerkin method, using C^1-continuous NURBS basis functions as the finite dimensional approximations to the function spaces. We utilise a staggered scheme to solve the displacements and phase-field separately. The staggered approach allows for robust solution of the incremental update of both the displacement and phase fields. An implicit Euler backward method is used for the numerical time integration of the evolution equation of the phase-field parameter d.

NUMERICAL RESULTS

As an example we study an rectangular sample made out of an artificial porous rock under uniaxial compressive load under plane strain conditions. Figure 1a)-c), see [5], depicts evolution of the crack pattern. Note, that the sample has an initial saw cut inclined under 45°, indicated by the blue line in the pictures. In comparison we show in Figure 1d)-f) the evolution of the phase-field parameter d from the numerical simulation for the corresponding load states. We observe a very good agreement of the simulated crack patterns and the experimentally observed ones.

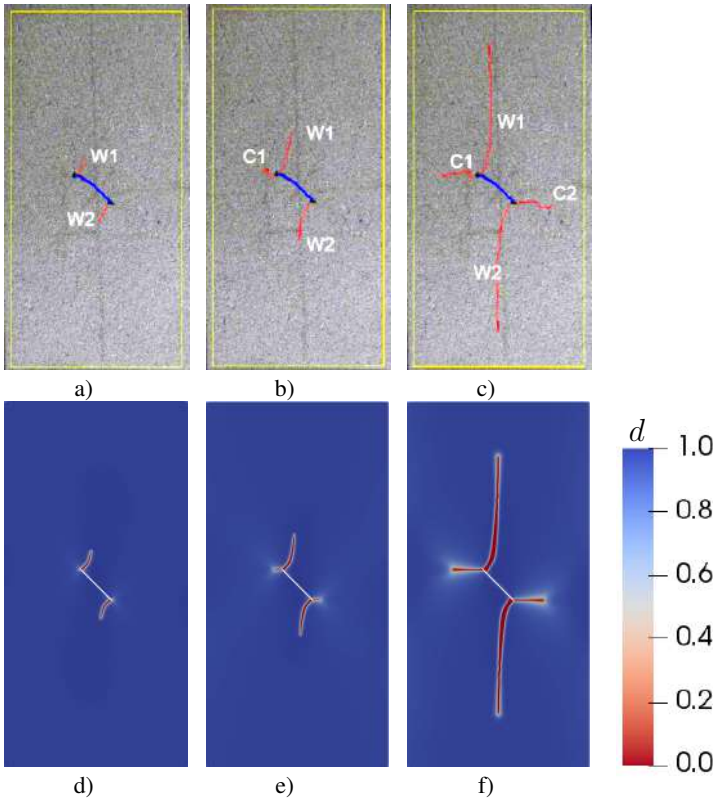

Figure 1: Comparison of experimental results a)-c) of the crack pattern at and d)-f) the phase-field parameter from the numerical simulation for the corresponding load states.

In our contribution we will discuss more details of the proposed phase-field fracture model, show further numerical results for samples with two saw cut and also Meuwissen samples having two U-notches with an vertical offset. Additionally, we discuss also the quantitative comparison between simulated and experimental load-deflection curves.

Summary Predicting the resistance-to-failure from the solid structure at the atomistic scale remains unsolved, even in the simplest situations of perfectly brittle fracture. By examining numerically crack growth in electrical analogues of brittle crystals, we shed a new light on this question: Fracture toughness is found to be significantly higher than expected from Griffith's relationship between fracture and specific surface energy. This discrepancy finds its origin in the matching between the continuum displacement field at the engineering scale and the discrete lattice of solids at the atomic scale. We will show how to use the specific asymptotic form taken by this field near crack tip to infer this matching, and subsequently to predict toughness from the atomistic parameters. The implications will be discussed.

INTRODUCTION

Predicting when rupture occurs is central to many industrial, societal and geophysical fields. For brittle solids under tension, the problem reduces to the destabilization of a pre-existing crack. Material's resistance-to-failure is then defined by two dependent material constants (one is proportional to the square of the other): fracture energy and fracture toughness. Nowadays, there exists well-established standard test methods allowing the accurate experimental determination of these material constants. Conversely, their relation with the atomistic parameters of the considered solid remains unsolved, even in perfectly brittle situations where fracture occurs via successive bond breaking, without involving further elements of dissipation. The cornerstone in this context was provided by Griffith [1], which identifies the fracture energy with the free surface energy (energy of the chemical bonds crossed by a fracture surface of unit area). Unfortunately, this conjecture does not fit with the observations: Fracture energy is always measured to be anomalously high, even in perfectly brittle crystals (silicon or mica for instance, see. e.g. [2]). The study reported here aimed at uncovering the origin of this discrepancy.

METHOD & RESULTS TO BE PRESENTED

We examined numerically how crack propagates in a two-dimensional lattice of fuses arranged periodically (triangular, square or honeycomb geometry, see e.g. figure 1A). Such model digital materials, indeed, (i) possess fully prescribed and tuneable "atomic bonds"; (ii) break in a perfectly brittle manner, by the successive breakdown of fuses, and (iii) satisfy isotropic linear elasticity under antiplane deformation at the continuum scale [3]. Fracture energy was determined in these digital materials and, as in real elastic solids, it was found to be significantly larger than Griffith specific surface energy, by a factor depending on the lattice geometry.

To understand the origin of this discrepancy, we looked at the spatial distribution of the displacements within the digital materials (Figure 1B). At the continuum-level scale, the displacement field displays a mathematical singularity at the crack tip. As such, it takes a generic asymptotic form [4], referred to as Williams' series expansion. The difficulty is to position the singularity origin properly in the discrete lattice at the atomic scale. As an illustration, placing it at the center of the next bond to break (O_{guess} in figure 1A) makes the Williams's series expansion describe the measured field fairly well, except in the very vicinity of the crack tip [figure 1C]. Unfortunately, this near-tip zone is precisely the one setting whether or not the next bond breaks!

However, as we will see in the presentation, it is possible to make use of the Williams' form taken by the displacement field near crack tip to infer accurately the singularity positioning in the discrete lattice, and then to predict fracture toughness from the atomistic parameters [5]. It is then possible to derive an analytical method to predict fracture toughness and fracture energy in our digital materials and the obtained values coincide exactly to those obtained numerically. We will discuss how to extend the analysis to genuine elastic (plane stress) crack problems and predict toughness in 2D and 3D materials. Implication will be finally discussed.

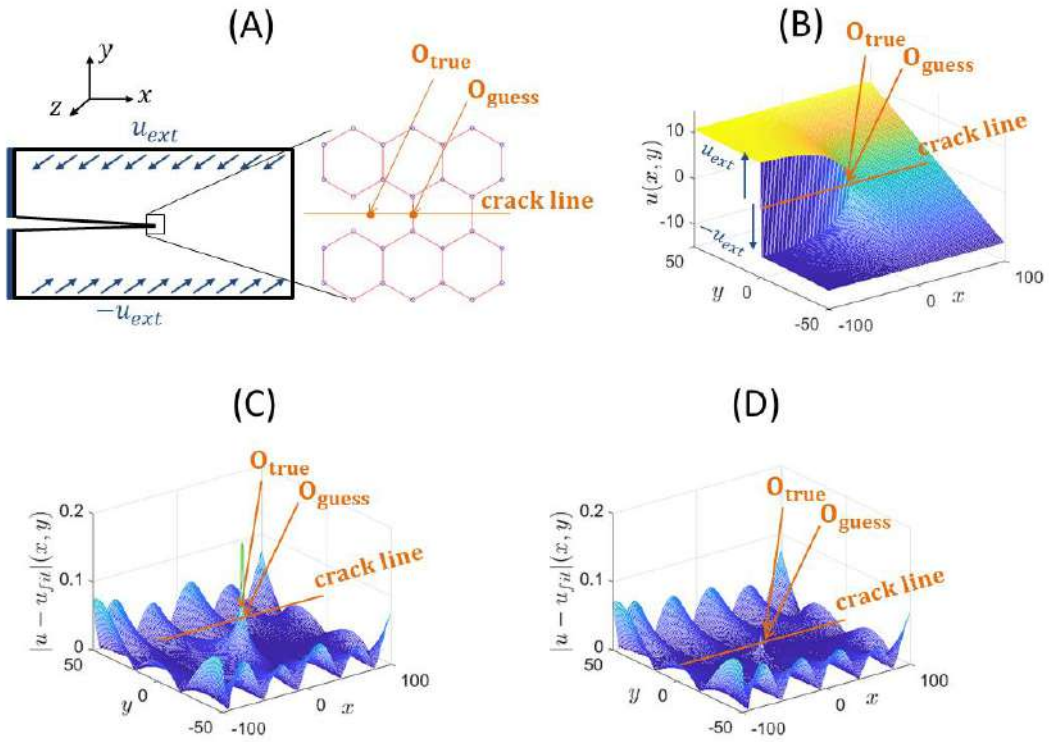

Figure 1, panel A: Sketch and notation: A crack is introduced into a two-dimensional electric crystal (here honeycomb lattice). The crack is parallel to x-axis, lies in the middle of the crystal ($y3 = 30$) and stops in the center. The cracked crystal is loaded by imposing a constant potential u_{ext} (opposite signs) to the left/ top and left/bottom edges. Panel B: measured displacement field. This should obey Williams asymptotic singular form. The difficulty is to place the singularity properly in the discrete lattice. Panel C: Absolute difference between the displacement field $u(x,y)$ measured in panel B and Williams asymptotic form, $u_{fit}(x,y)$ obtained after having placed the singularity at the center of the next bond to break (O_{guess} in panel A). The fit is very good everywhere, except in the vicinity of the crack tip. Panel D: $|u_{fit} - u(x,y)|$ after having corrected the singularity position (now at O_{true} in panel A). The fit is now good everywhere, including in the very vicinity of the crack tip.

A PERIDYNAMIC FRAMEWORK FOR SIMULATING DUCTILE FRACTURE

Masoud Behzadinasab*[1], John T. Foster[2], and Yuri Bazilevs[1]
[1]School of Engineering, Brown University, 184 Hope St., Providence, RI 02912, USA
[2]Hildebrand Department of Petroleum & Geosystems Engineering, The University of Texas at Austin, 200 E. Dean Keeton St., Austin, TX 78712, USA

Summary A semi-Lagrangian constitutive correspondence framework has been recently developed for peridynamics as a remedy for shortcomings of the theory in modeling large deformation. In the new formulation, peridynamic material point interactions depend only on the current properties in the deformed configuration. A bond-associated approach is introduced, which enhances stability and enables localization of damage. We show that the new model is more reliable in simulating ductile fracture, through a Sandia Fracture Challenge study. A novel, convenient approach for incorporating natural boundary conditions in peridynamics is also presented. Application of the new framework to other extreme events (e.g. air-blast simulation) is discussed.

PERIDYNAMIC MODELING OF DUCTILE FRACTURE

Prediction of ductile fracture, which is a prevalent failure mode in most engineering structures, is vital to numerous industries. Despite significant advancements in fracture mechanics, ductile fracture modeling has remained a challenging task and a continuing area of research. Peridynamics [1, 2], a nonlocal theory based on integration instead of partial differentiation, has attracted broad interest in recent years, mostly for its natural capabilities in handling material discontinuity (e.g. cracks). While peridynamics has been largely utilized to simulate cracking events in brittle materials, its ability in predicting ductile failure remains unclear.

An investigation into the capabilities of peridynamics in simulating ductile fracture in metallic alloys was recently conducted [3]. The third Sandia Fracture Challenge (SFC3) [4], as a true blind prediction challenge, was employed in the examination, where the state of the art of peridynamic modeling of ductile fracture was implemented to predict deformations and failure of an additively manufactured metal, with a complex geometry, under the dynamic tensile experiments performed by Sandia National Laboratories. While the peridynamic approach led to qualitatively good results, it underpredicted the load-carrying capacity of the structure and simulated an early fracture. Post-experiment analysis identified the main sources of error to be (1) material instabilities associated with the finite deformation peridynamic model [5] and (2) unreliability of a Lagrangian peridynamic framework in solving large distortion problems.

A bond-associated, semi-Lagrangian, constitutive correspondence model

Due to the involvement of a mapping between the deformed and reference configurations, the Lagrangian framework (which is the foundation of most previous developments of peridynamics) can become unsuitable under extremely large deformations, i.e., the Lagrangian kinematic variables (e.g. the peridynamic deformation gradient [2]) become non-physical (e.g. have non-positive determinants). With the motivation of simulating extreme events, a semi-Lagrangian constitutive correspondence framework for peridynamics has been recently developed [6]. In the semi-Lagrangian theory, while the material points are still tracked in motion (the Lagrangian view), an updated kernel is used to determine the degree of interactions between material points (the Eulerian view).

The local balance of linear momentum in the semi-Lagrangian model is given by

$$\rho \frac{\mathrm{D}\dot{\mathbf{x}}}{\mathrm{D}t} = \int_{\mathcal{H}(\mathbf{x})} \left[\underline{\mathbf{t}}(\mathbf{x})\langle \boldsymbol{\eta} \rangle - \underline{\mathbf{t}}(\mathbf{x}+\boldsymbol{\eta})\langle -\boldsymbol{\eta} \rangle\right] \mathrm{d}\boldsymbol{\eta} + \rho \mathbf{b}, \tag{1}$$

in which $\mathbf{x}$ is a material point in the current domain of peridynamic body $\mathcal{B}$ with density ρ. $\mathbf{b}$ is an applied body force density field. $\mathcal{H}(\mathbf{x})$ is the neighbor set of $\mathbf{x}$, defined in the deformed configuration, i.e.,

$$\mathcal{H}(\mathbf{x}) = \{\mathbf{x}+\boldsymbol{\eta} \mid \mathbf{x}+\boldsymbol{\eta} \in \mathcal{B},\, 0 < |\boldsymbol{\eta}| \leq \delta\}\,. \tag{2}$$

$\boldsymbol{\eta}$ denotes a peridynamic *bond* in the current domain, and δ is called the *horizon*. $\underline{\mathbf{t}}$ is the force vector state operating in the deformed frame, analogous to the Cauchy stress. Following an energy balance analysis [6]

$$\dot{\mathrm{u}}(\mathbf{x}) = \int_{\mathcal{H}(\mathbf{x})} \underline{\mathbf{t}}(\mathbf{x})\langle \boldsymbol{\eta} \rangle \cdot \dot{\boldsymbol{\eta}}\, \mathrm{d}\boldsymbol{\eta}, \tag{3}$$

where u is the strain energy density function. The classical (local) theory postulates that the strain power density is the power conjugate of the velocity gradient and Cauchy stress tensors. A bond-associated velocity gradient is given by

$$\underline{\mathbf{L}}(\mathbf{x})\langle \boldsymbol{\eta} \rangle = \frac{\bar{\mathbf{L}}(\mathbf{x}) + \bar{\mathbf{L}}(\mathbf{x}+\boldsymbol{\eta})}{2} + \left(\dot{\boldsymbol{\eta}} - \frac{\bar{\mathbf{L}}(\mathbf{x}) + \bar{\mathbf{L}}(\mathbf{x}+\boldsymbol{\eta})}{2} \cdot \boldsymbol{\eta}\right) \otimes \frac{\boldsymbol{\eta}}{|\boldsymbol{\eta}|^2}, \tag{4}$$

*Corresponding author. E-mail: masoud_behzadinasab@brown.edu.

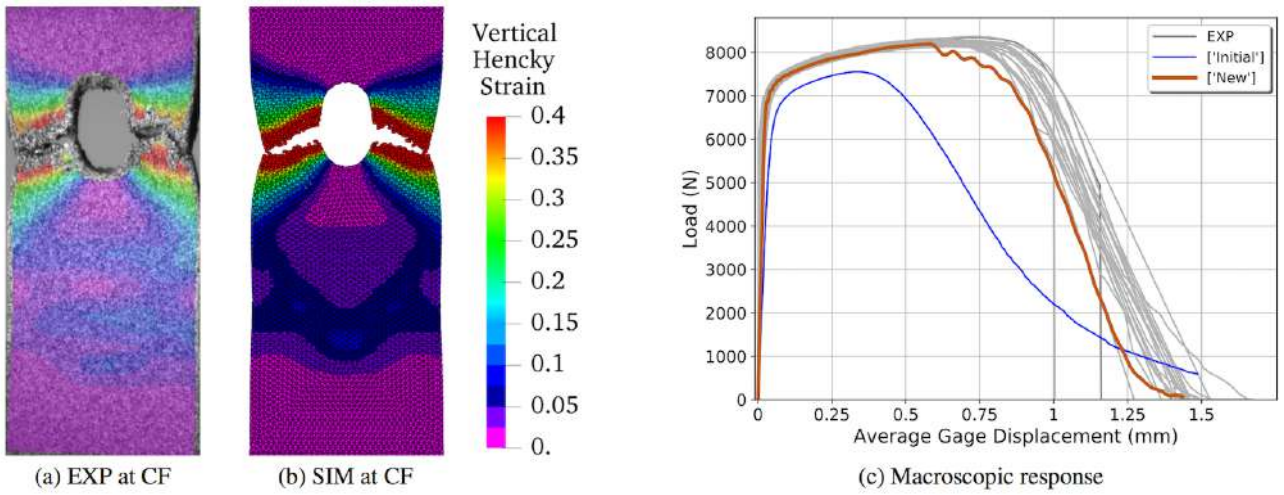
which maps a bond (vector) to a velocity gradient (tensor). $\bar{\mathbf{L}}(\mathbf{x})$ is the nodal velocity gradient at $\mathbf{x}$ that accounts for the collective deformation of the neighborhood, i.e.,

$$\bar{\mathbf{L}}(\mathbf{x}) = \left(\int_{\mathcal{H}(\mathbf{x})} \underline{\omega}\langle \boldsymbol{\eta} \rangle \, \dot{\boldsymbol{\eta}} \otimes \boldsymbol{\eta} \, \mathrm{d}\boldsymbol{\eta} \right) \mathbf{M}^{-1}(\mathbf{x}), \quad \mathbf{M}(\mathbf{x}) = \int_{\mathcal{H}(\mathbf{x})} \underline{\omega}\langle \boldsymbol{\eta} \rangle \, \boldsymbol{\eta} \otimes \boldsymbol{\eta} \, \mathrm{d}\boldsymbol{\eta}. \tag{5}$$

$\underline{\mathbf{L}}$ is used as an intermediate kinematic variable in determining the (bond-associated) Cauchy stress (using local theories) and evaluating the force state [6]. A bond-associated damage correspondence framework is also developed in [6] by incorporating local fracture models using the bond-associated properties (i.e., deformation, stress, strain, etc.), which enables the modeler to localize failure and avoids loss of a finite amount of material in numerical simulations.

REVISITING SANDIA FRACTURE CHALLENGE 2017

The bond-associated, semi-Lagrangian formulation is employed to revisit SFC3. To effectively assess the applicability of the new theory to modeling large deformation and ductile fracture (in the context of SFC3), minimal changes to the initial attempt in solving the challenge problem were made. Therefore, only the material and damage models were adopted using the new framework. To achieve a blind-prediction setting, experimental data from the challenge main objective is masked during the model calibration. Fig. 1 compares the simulation results with the experiments. The correct crack path is resulted from the simulation. The new model significantly improves the load-displacement predictions of the structure, in addition to a better capturing of the crack propagation speed.



(a) EXP at CF (b) SIM at CF (c) Macroscopic response

Figure 1: Vertical Hencky strains compared between the experimental DIC measurements (EXP) and the new simulations (SIM) at complete failure (CF) (a–b). The new approach has significantly improved the bulk response predictions (c).

ADDITIONAL DISCUSSIONS

We introduce a novel approach for incorporating natural boundary conditions within peridynamics (both Lagrangian and semi-Lagrangian models). The proposed method would be helpful in local-nonlocal coupling to conveniently model traction/stress conditions on boundaries/interfaces. We also present applications of the semi-Lagrangian formulation to other extreme events, such as air-blast-structure interactions (ABSI), using an immersed isogeometric-peridynamic framework for ABSI modeling.

A PHASE-FIELD MODEL FOR FATIGUE CRACK GROWTH AND LIFETIME ESTIMATION

Md Mehedi Hasan and Theocharis Baxevanis*
Department of Mechanical Engineering, University of Houston, USA

Summary A phenomenological, phase-field, continuum model for lifetime estimation and fatigue crack formation and growth in brittle materials is proposed. Additionally to the classical elastic stiffness degradation in the phase-field approach to overload fracture, a fracture toughness degradation through a suitably defined fatigue history variable is introduced. The model's ability to estimate the lifetime of smooth specimen under uniaxial constant cycling loading, *i.e.*, to predict Wöhler curves and 1D critical plane models, such as the Smith-Watson-Topper parameter, as well as to reproduce the Paris law with exponents characteristic of brittle fatigue crack growth is demonstrated. The numerical implementation of the model in a staggered scheme is described and its ability to handle complex geometries and loading conditions demonstrated.

INTRODUCTION

In the phase-field approach to fracture, also known as variational approach to fracture, proposed in the pioneering works of Francfort and Marigo [1] and Bourdin et al [2], the solution to the fracture problem is found as the minimizer of a global energy functional that includes a surface term associated with the energy required to create a unit area of fracture surface. The major advantage of the phase-field approach over the complexity of discrete fracture models stems from the regularization of the sharp crack surface topology by a diffusive crack zone governed by a scalar auxiliary variable, a phase field, which interpolates between the unbroken and the broken state of the material. An alternative to the aforementioned formal and mathematically demanding formulation, based on continuum mechanics and thermodynamic arguments, was presented by Miehe et al [3, 4]. The proposed work builds on a growing body of recent phase-field approaches to fatigue of brittle materials that aim at linking regularized overload fracture to fatigue crack growth [5, 6] based on a proposed degradation of the surface term associated with the energy required to create a unit area of fracture surface, *i.e.*, the fracture toughness, through a suitably defined fatigue history variable.

PHASE-FIELD MODEL FOR FATIGUE

The proposed phase-field model for fatigue is derived for isothermal quasistatic proccesses, *i.e.*, neglecting inertia, wave propagation, and thermal effects, under the small-strain assumption. The model formulation is based on postulating a microforce balance. The resulted strong-form, boundary-value problem of the constitutive response reads as

Mechanical Equilibrium. –

$$\nabla \cdot \boldsymbol{\sigma} = 0, \tag{1}$$

Microforce Balance. –

$$\frac{2\mathcal{G}_c^0 \ell}{\rho} \nabla \cdot \nabla c = g'(c)\mathcal{H}\left[1 + a(\tilde{\mathcal{H}} - \mathcal{H})^b\right] + \frac{\mathcal{G}_c^0}{2\ell} c, \tag{2}$$

Constitutive equation. –

$$\boldsymbol{\sigma} = g(c)\left[\lambda\langle \mathrm{tr}\,\boldsymbol{\varepsilon}\rangle \boldsymbol{\delta} + 2\mu\boldsymbol{\varepsilon}^+\right] + \left[\lambda\left(\mathrm{tr}\,\boldsymbol{\varepsilon} - \langle \mathrm{tr}\,\boldsymbol{\varepsilon}\rangle\right)\boldsymbol{\delta} + 2\mu\boldsymbol{\varepsilon}^-\right]. \tag{3}$$

with appropriate boundary conditions that are omitted here due to space limitations.

In the above, $\boldsymbol{\sigma}$ stands for the stress tensor, $\boldsymbol{\varepsilon}$ for the strain tensor, c is the phase field variable, $\ell > 0$ is a model length parameter that controls the width of the smooth approximation of the cracks, $\mathcal{G}_c^0$ stands for the fracture toughness of the material in its reference state, $W^+ = \frac{1}{2}\lambda\langle \mathrm{tr}\,\varepsilon\rangle^2 + \mu \mathrm{tr}\left[(\varepsilon^+)^2\right]$ and $W^- = \frac{1}{2}\lambda\left(\mathrm{tr}\,\varepsilon - \langle \mathrm{tr}\,\varepsilon\rangle\right)^2 + \mu \mathrm{tr}\left[(\varepsilon - \varepsilon^+)^2\right]$ are the strain energies computed from the positive and negative components of the strain tensor defined through its spectral decomposition [3, 4], λ and μ are the Lamé constants, $\mathcal{H}$ satisfies the Kuhn-Tucker conditions for loading and unloading

$$W^+ - \mathcal{H} \leq 0, \quad \dot{\mathcal{H}} \geq 0, \quad \dot{\mathcal{H}}\left(W^+ - \mathcal{H}\right) = 0, \tag{4}$$

$\tilde{\mathcal{H}}$ is an accumulated strain energy history functional, which evolves only for increasing driving force, $\dot{W}^+ > 0$, and for $W^+ > W_e^+$, where W_e^+ is the endurance limit, *i.e.*, the lowest energetic barrier again fatigue damage,

$$\dot{\tilde{\mathcal{H}}} = H\left(W^+ - W_e^+\right)\langle \dot{W}^+ \rangle, \tag{5}$$

$H(x)$ is the Heaviside function, $\boldsymbol{\delta}$ is the Kronecker's delta, $g(c) = (1-c)^2$and a and b are positive material constants that should be calibrated by appropriate experimental data.

RESULTS & DISCUSSION

*Corresponding author. E-mail: tbaxevanis@gmail.com

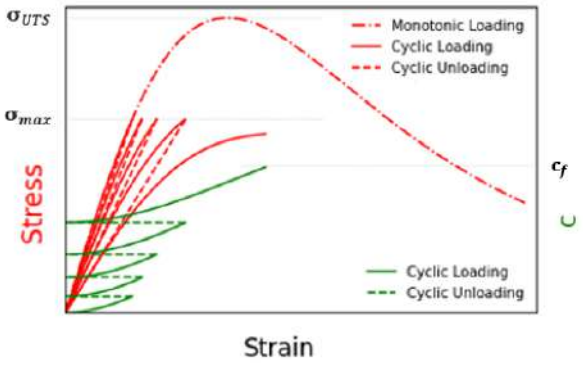

Figure 1: Stress–strain response and phase field evolution (inset) at uniaxial (constant) stress-controlled cyclic loading with maximum applied load σ_{max} and load ratio $R = 0$.

Presuming a homogeneous stress state within test specimens, the numerical model reduces essentially to a single material point and the deformation response may be tracked in closed form or with low numerical effort even for large numbers of cycles. The general response of the model under uniaxial homogeneous (constant) stress-controlled cyclic loading is shown in Figure 1. The maximum attainable traction, σ_{UTS} (ultimate tensile strength) successively reduces until it falls below the external applied load level and final failure occurs.

Experimental S–N or Wöhler curves showing stress amplitude vs. fatigue life N_f have been simulated. In Figure 2, the model estimation of lifetime for an epoxy glass composite subjected to an stress-controlled cycling of a load ratio $R = 0$ is depicted. Ignoring the endurance limit, the model reduces to the following equation

$$\frac{\sigma_{max}^2}{2E} + a(N_f - 1)^b \left(\frac{\sigma_{max}^2}{2E}\right)^{b+1} = -\frac{\mathcal{G}_c^0}{2\ell g'(c_f)} c_f \tag{6}$$

where N_f is the number of cycles at failure, and c_f and σ_{max} (the latter being the experimental maximum applied stress level) correspond to the values of c and the stress, respectively, obtained at $\partial\sigma/\partial\varepsilon = 0$, *i.e.*, σ_{max} equals the maximum attainable traction at N_f and c_f is the corresponding value of the phase field parameter. A least square fit is then performed over the experimental data that allows for the calibration of the model parameters $a = 0.0017$ and $b = 3.545$.

The efficiency of the numerical implementation of the model is verified by crack growth simulations in complex geometries and loading conditions. The fatigue crack growth path in a Compact Tension (CT) specimen with a hole in the vicinity of the initial crack tip subjected to cyclic tensile loading is shown in Figure 3. Isotropy and plane strain conditions are assumed and a sufficiently fine mesh is used to resolve the process zone properly. The model predicts crack turning observed in experiments recently performed in aluminum alloy AL2024-T351 [7].

Moreover, a systematic analysis of the mean load effect and load sequence on the uniaxial fatigue life prediction as well as of the correlation between the model parameters and the global fatigue crack growth characteristics (Paris law) is performed. The model calibration for the latter case is discussed and the physical meaning of the parameter ℓ in both the uniaxial lifetime and crack growth cases is explored.

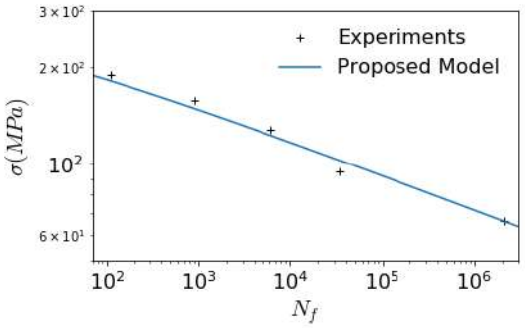

Figure 2: Model predictions vs experimental lifetime for an epoxy glass composite subjected to an $R = 0$ stress-controlled cycling.

Figure 3: Phase field simulations showing the path of fatigue crack growth in a CT specimen with a hole in the vicinity of the initial crack tip subjected to cyclic tensile loading.

FAILURE CRITERIA FOR INTERFACE CRACKS

Leslie Banks-Sills*
Dreszer Fracture Mechanics Laboratory, School of Mechanical Engineering,Tel Aviv University, Ramat Aviv, Israel

Summary A crack along an interface between two dissimilar linear elastic, homogeneous and isotropic materials is considered. Failure criteria for this case have been presented in the literature. Criteria have been based upon the stress intensity factors K_1 and K_2 or the interface energy release rate $\mathcal{G}_i$ together with a mode mixity phase angle ψ. Thus, two parameters are required to predict failure. Several criteria will be presented. The parameter $\mathcal{G}_i$ is an invariant and does not depend on a length scale; the parameter ψ does depend upon a length scale. Recently, a second invariant parameter L_1 has been defined. This investigation will examine use of the the two invariant parameters in a failure criterion.

INTRODUCTION

Interface fracture mechanics is a well established discipline. The failure of an interface is treated here. Results from an interface crack between glass and epoxy were considered. Tests were carried out on this material pair and presented in [1]. The results from the tests were reanalyzed and given in [2]. These results were used here to examine two failure criteria.

Various failure criteria were presented in [3, 4]. The best criterion for this data, as well as for an interface crack between two ceramic clays [5] is given by

$$\mathcal{G}_{ic} = \overline{\mathcal{G}}_{1c}\left(1+\tan^2\hat{\psi}\right) \ . \tag{1}$$

In eq. (1), $\mathcal{G}_{ic}$ and $\overline{\mathcal{G}}_{1c}$ are the critical interface and mode 1 energy release rates, respectively; the phase angle $\hat{\psi}$ is

$$\hat{\psi} = \tan^{-1}\left(\frac{\hat{K}_2}{\hat{K}_1}\right) \tag{2}$$

where

$$\hat{K} = K\hat{L}^{i\varepsilon}. \tag{3}$$

In eq. (3), the complex stress intensity factor

$$K = K_1 + iK_2 \tag{4}$$

where K_1 and K_2 are real and are the modes 1 and 2 stress intensity factors and $i=\sqrt{-1}$; $\hat{L}$ is a length scale which is used to fit the failure data to the failure curve and ε is the oscillatory parameter and related to the mechanical properties of the two materials on either side of the interface. In eq. (1),

$$\overline{\mathcal{G}}_{1c} = \text{avg}\left(\frac{\hat{K}_1^2}{H}\right) \tag{5}$$

where avg is the average of the quantity in parentheses, values of $\hat{K}_1$ are calculated from eq. (3) for each specimen and H is related to the mechanical parameters of the materials. It should be emphasized that choosing $\hat{L}$ properly leads to a good fit between the failure curve in eq. (1) and the failure data. The failure criterion in eq. (1) was also found to fit the data for a carbon/epoxy laminate with an interface between two plies, one with fibers in the $0°$- direction and the other with fibers in the $90°$- direction [6].

In [7], invariant parameters which do not depend on $\hat{L}$ were presented. The interface energy release rate given by

$$\mathcal{G}_i = \frac{1}{H}\left(K_1^2+K_2^2\right) = \frac{1}{H}\left(\hat{K}_1^2+\hat{K}_2^2\right) \tag{6}$$

is known to be an invariant. A second, new invariant is defined as

$$L_1 = \hat{L}\exp\left(-\frac{\hat{\psi}}{\varepsilon}\right) \ . \tag{7}$$

It turns out that the combination of $\hat{L}$ and $\hat{\psi}$ in eq. (7) causes L_1 to be independent of $\hat{L}$.

In the next section, the criterion in eq. (1) and a criterion related to the parameter L_1 will be presented for a crack along the interface between glass and epoxy. Conclusions are made in the last section.

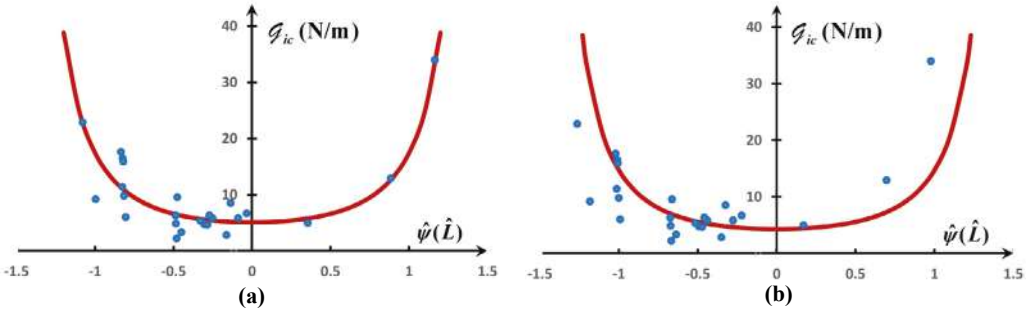

Figure 1: Failure curves for glass/epoxy interface using eq. (1) with (a) $\hat{L} = 1.2$ mm and (b) $\hat{L} = 10$ mm.

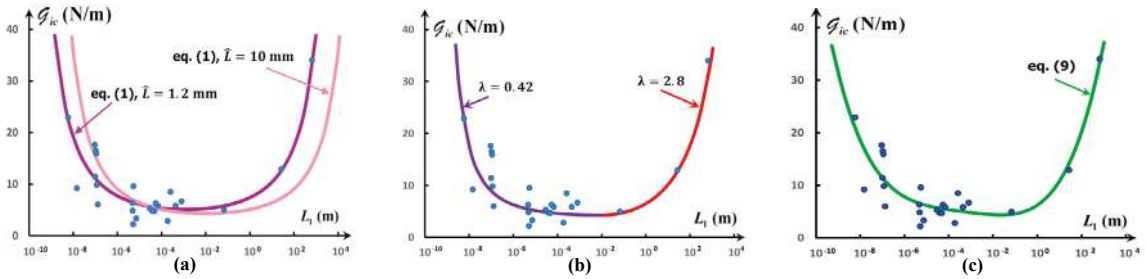

Figure 2: Failure curves for glass/epoxy interface using the invariants in eqs. (6) and (7). The data and failure curves from (a) eqs. (1), (b) (8) and (c) (9).

FAILURE CRITERIA FOR GLASS/EPOXY

Tests on Brazilian disk specimens fabricated from glass and epoxy were presented in [1]. The data presented here was taken from [2] where analyses were improved. For the glass/epoxy pair considered here, the oscillatory parameter is $\varepsilon = -0.0881$ and the modulus $H = 6.56$ GPa. By choosing $\hat{L} = 1.2$ mm, the failure curve in eq. (1) fits the data well as shown in Fig. 1a. Note that $\mathcal{G}_{1c} = 5.09$ N/m. If $\hat{L} = 10$ mm, then the failure curve does not fit the data well, as may be observed in Fig. 1b, where $\mathcal{G}_{1c} = 4.31$ N/m.

Next, the data is plotted in a $(\mathcal{G}_{ic}, L_1)$-plane in Fig. 2a. The failure curve in eq. (1) for $\hat{L} = 1.2$ mm fits the data well. But for $\hat{L} = 10$ mm, the failure curve does not fit the data well. Various failure curves were examined with the data in Fig. 2. One possibility is to write

$$\mathcal{G}_{ic} = \overline{\mathcal{G}}_{1c}\left(1 + \lambda \tan^2 \hat{\psi}\right) \ . \tag{8}$$

To test this curve, $\hat{L} = 10$ mm was chosen, so that $\mathcal{G}_{1c} = 4.31$ N/m. With $\lambda = 0.42$ and 1.28, it is possible to fit that data as seen in Fig. 2b. Another option is to use brute force with curve fitting applied to obtain a quartic equation given by

$$\mathcal{G}_{ic} = 6.27 + 2.84\log(L_1) + 1.44[\log(L_1)]^2 + 0.28[\log(L_1)]^3 + 0.02[\log(L_1)]^4 \tag{9}$$

with the coefficient of determination $R^2 = 0.81$ as shown in Fig. 2c.

CONCLUSIONS

Although the invariants are attractive, the failure curve using these quantities was found here by curve fitting. The failure curve in eq. (1) was determined from first principles [4]. Of course, for this criterion, a proper choice of $\hat{L}$ is required.

Summary Adhesive joints have potential structural application in ships in joining a composite superstructure to the steel hull, but joint reliability is a concern. The purpose of this study is to develop a mechanics model for the adhesive fracture of lap joints under shear loading. An MMA-based adhesive is being considered for use in the ship-building industry. Modified Thick-Adherend-Shear-Test (TAST) joints are designed and fabricated. The cracking response of these joints are measured and monitored by Digital Image Correlation (DIC). A cohesive zone model is able to predict the average shear strain across the adhesive layer both at crack initiation and at peak load. However, the as-calibrated model is less successful at predicting the degree of crack growth as a function of shear strain across the adhesive layer.

INTRODUCTION

Historically, mechanical joints such as bolts and rivets were used in ship building, however, bonded joints offer benefit such as reduced weight, reduced through life maintenance, and reduction of the stress concentrations. A limitation in advancing this technology is the lack of acceptance of adhesive by the qualifying agencies. Although the adhesive joint is subjected to shear loading, mode II fracture of adhesives has received limited attention in the literature [1, 2]. Our aim is to investigate the effect of geometry and material parameters upon the shear strength of an adhesive joint.

EXPERIMENTS

The shear strength of a pre-cracked specimen is measured as a function of adhesive layer thickness, h, and pre-crack length, a_0. The adhesive is the MMA-based Scigrip-300, and the substrates are low carbon steel. The Young's modulus of this adhesive is 322 $\pm$ 33 MPa, its ultimate strength is 14.2 $\pm$ 1.8 MPa, and the tensile failure strain is 0.26 $\pm$ 0.06. In order to evaluate the mechanical properties of adhesive under shear and adhesive/steel interface fracture properties, a modified Thick-Adherend-Shear-Test (TAST) joint is designed and manufactured (see Fig. 1(a)). Pre-cracks of length a_0 are placed at each end of the adhesive layer, as shown in Fig. 1(a). Samples with selected adhesive layer thickness h = 3, 5, 8, 10, 13 mm, and pre-crack length a_0 = 0, 10, 20 mm are manufactured and tested. The aim of the study is to measure the fracture response of the joint including the degree of crack extension versus shear displacement across the adhesive layer.

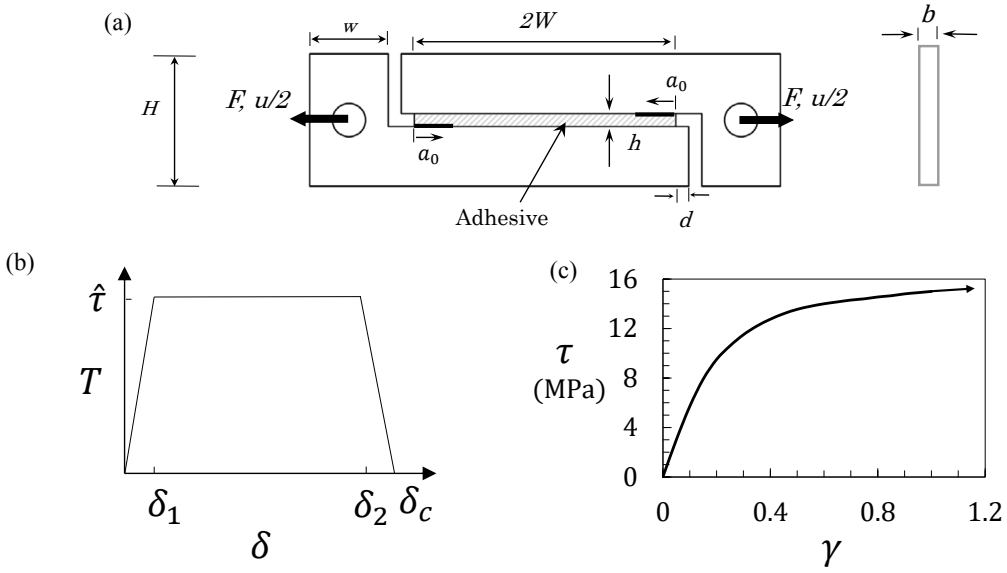

Figure 1: (a) Sketch of modified TAST joint ($2W$ = 100 mm, h = 3, 5, 8, 10, 13 mm, H = 50.4 mm, w = 30 mm, a_0 = 0, 10, 20 mm, d = 5 mm, b = 6.35 mm), (b) Shear cohesive zone law assumed in this study ($\hat{\tau}$ = 13 MPa, δ_1 = 0.05 δ_c, and δ_2 = 0.95 δ_c, δ_c = 1.3 mm), (c) The measured shear stress-strain for the adhesive ($\dot{u}/h = 5 \times 10^{-4}\ s^{-1}$).

*Corresponding author. E-mail: sa898@cam.ac.uk

COHESIVE ZONE MODELLING

Crack advance is predicted by the progressive failure of a shear cohesive zone, placed at the interface between adhesive and substrates (see Fig. 1(b)). The cohesive zone is implemented into the Finite Element (FE) model by means of cohesive elements [3]. A mesh sensitivity study is chosen to ensure that the cohesive zone is resolved. The shear response of the cohesive zone law is given in Fig. 1(b) in the form of a shear traction T versus shear displacement δ. The value of $\hat{\tau}$ is chosen to fit the experimental peak load for the case of $h = 3$ mm ($\hat{\tau}$ = 13 MPa) and DIC is used to measure the displacement jump between the adhesive and the substrate at the crack tip (δ_c = 1.3 mm). The shear stress strain curve of the adhesive is used in the FE simulations.

RESULTS AND DISCUSSIONS

Take representative case of $h = 8$ mm and a_0 = 10 mm. Fig. 2(a) compares the numerical and experimental results for average shear stress ($F/2Wb$) versus shear strain (u/h) across the adhesive layer. Crack extensions of 1 mm, 5 mm and 10 mm are included. The FE simulation has a limited ability to predict the degree of crack extension, see Fig. 2(b), but is able to predict the initiation of crack extension and the displacement jump u across the adhesive layer at peak load, see Fig. 2(c).

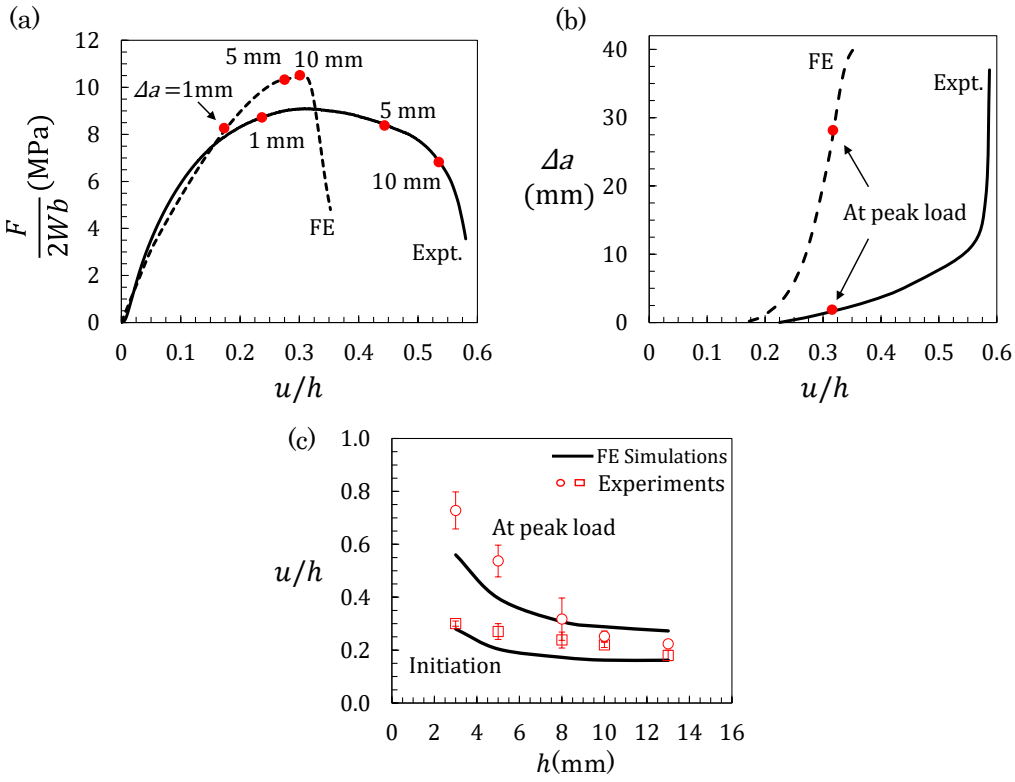

Figure 2: (a) Average shear stress versus shear strain across the adhesive layer in finite element simulation and experiment for the case of $h = 8$ mm and $a_0 = 10$ mm. (b) Interface crack extension as a function of shear strain across the adhesive layer for the case of $h = 8$ mm and $a_0 = 10$ mm. Shear strain across the adhesive layer at crack initiation and peak load as a function of adhesive layer thickness for the case of $a_0 = 10$ mm.

CONCLUSIONS

A numerical and experimental study on Mode II fracture of a ductile adhesive joint is reported. The geometry of TAST setup is considered. The capability of cohesive zone modelling with trapezoidal shear cohesive zone law in predicting failure of these joints is evaluated. The shear cohesive zone model is capable of predicting the fracture strength and average shear strain at crack initiation and peak load.It is less accurate in predicting the details of crack extension.

MODELING FATIGUE EFFECTS IN BRITTLE MATERIALS WITH A VARIATIONAL PHASE-FIELD APPROACH

Roberto Alessi*[1], Jacopo Ciambella[2], and Giovanni Lancioni[3]
[1]Department of Civil and Industrial Engineering, Università di Pisa, Pisa, Italy
[2]Department of Structural and Geotechnical Engineering, Sapienza Università di Roma, Roma, Italy
[3]Department of Construction, Civil Engineering and Architecture, Università Politecnica delle Marche, Ancona, Italy

Summary Fatigue is a key material degradation phenomenon in mechanics, since it is largely responsible for most structural failures. Yet, the prediction of fatigue failures still represents an open challenge for modelling and simulation at the cutting edge of mechanics. Indeed, most existing fatigue theories are based on empirical laws that lack of generality and predictive capabilities. Moreover, a unified framework that links the mechanics of monotonic fracture and the fatigue behavior reproducing, for instance, the Wöhler curve and the Paris law together with the transition between low- and high-cycle fatigue is still missing. The present work aims at discussing some novel ideas for the development of a unified framework to model fatigue effects in brittle materials in both small and large strain regimes, taking advantage of the variational phase-field approach to fracture.

Fatigue degradation phenomena are responsible for most of structural failures. Despite the significance of the problem, most existing fatigue theories are based on empirical lawsthat lack of generality and predictive capabilities. Current available fatigue analysis tools are characterised by some limitations since they are often based on empirical laws and strongly rely on expensive experimental tests. Furthermore, they describe each fatigue failure stage (initiation, stable fatigue crack propagation and abrupt failure) separately. As a consequence, they lack generality and are not sufficiently flexible to describe complicated fatigue crack scenarios. In this work, new ideas for the development of unified framework to model fatigue effects in brittle materials, built on top of the variational phase-field approach to fracture, are presented.

The phase-field approach to fracture [1, 2] has demonstrated to be an effective tool for the description of fracture phenomena and has recently gained a lot of attention, see [3] for a review. Its main advantage is the possibility of capturing complicated crack patterns through the solution of a minimization problem. In the recent years, the phase-field approach to brittle fracture has been extended to simulate also ductile and cohesive fracture phenomena, as well as coupled problems such as thermal- and diffusion-induced cracking, to mention a few. Nevertheless, the majority of these models are restricted to the case of monotonic loading without the capability to capture cyclic effects.

The common underlying theoretical framework for the development of all these phase-field models is the Energetic Formulation for rate-independent systems [4], which has been successfully applied to the modelling of many problems of non-smooth evolution and material instability induced by strain localization. According to this energetic approach and within the theory of Generalised Standard Materials [5], once the state variables, the potential energy, the dissipation potential and the work of external actions have been specified, the entire evolution is governed by solely three energetic requirements, which are a stability condition, an energy balance and a dissipation inequality. Compared to standard theories, the energetic formulation owns the advantage of being completely derivative-free, admitting discontinuities both in space and in time. Such a feature, in addition to evolution governing principles, allows for a natural and straightforward numerical implementation based on incremental energy minimization schemes, which is a valuable alternative to the integration of differential evolution equations. It is worth to remark that in the phase-field approach to brittle fracture, the dissipated work turns out to be a state function and therefore, a total internal energy is introduced instead of the internal potential energy and the dissipation potential.

As first introduced in [6], the basic idea to include fatigue effects within phase-field models is that not only the stiffness degrades due to damage, but also the apparent fracture energy (or fracture toughness) decreases as a suitable history variable increases, describing the material "mileage". Such fracture energy reduction, which promotes the occurrence of a macroscopic crack, may be caused by a multitude of different microscopic degradation mechanisms. In order to model such feature, a state dependent dissipated work energy functional cannot be prescribed anymore and a dissipation potential (dissipated power) must be introduced instead. In summary, the additional ingredients that we include in the phase-field approach to brittle fracture to capture fatigue effects are: A fatigue history variable, as the accumulated elastic energy; A fatigue degradation function, that reduces the fracture toughness as the fatigue history variable increases; An explicit dissipation potential. The two-dimensional numerical analyses performed in [7] have demonstrated that this fatigue model is capable to contemporary describe fatigue crack initiation, according to typical Wöhler curves, and fatigue crack propagation, in agreement with Paris law. Despite such result, the model has limited capabilities in tuning separately the fatigue crack initiation and fatigue crack propagation features, therefore not allowing for a real material parameters identification.

In this work, we further develop such a model under many points of view. First, we provide an analytical model within Griffith's theory of brittle fracture. To the author's knowledge, fatigue effects have been considered in cohesive models [8], by using the accumulated crack opening variable as fatigue history variable, but never within Griffith's brittle fracture

*Corresponding author. E-mail: roberto.alessi@unipi.it

model. Then, the phase-field approach to brittle fracture is again considered and an updated fatigue model considered, based on the analytical estimates, in order to overcome the limits emerged in [7] and to separately describe, with a unique model, independent fatigue crack initiation and fatigue crack propagation behaviours. Finally, the extension to finite strain elasticity is discussed. The capability of the model to describe the three typical fatigue fracture regimes, namely the elastic stage, the stable fatigue crack propagation phase and the final abrupt fracture, is highlighted. In addition, mean strain/stress effects as well as different energy split, are discussed. For both the small and large strain theory, an effective numerical implementation is proposed and the model validated against experimental results taken from the literature.

STATISTICAL FRACTOGRAPHY: A NEW TOOL FOR QUANTIFYING THE DAMAGE MECHANISMS CONTROLLING THE TOUGHNESS OF MATERIALS

Laurent Ponson*[1,2]
[1]Institut Jean le Rond d'Alembert, CNRS – Sorbonne Université, Paris, France
[2]Tortoise, Paris, France

Summary The roughness of fracture surfaces is the fingerprint of the interaction of cracks with the microstructure of materials. During this presentation, I will show how their statistical features can help us to characterize the dissipation processes accompanying failure, and ultimately, reveal the basic mechanisms controlling the toughness of materials. I will also discuss some applications of these findings by illustrating how the statistical analysis of fracture surfaces can now be used to characterize and measure the failure properties of materials at multiple scales, overcoming the characterization achieved by standard mechanical tests.

INTRODUCTION

Crack propagation is the main mechanism leading to material failure. However, the processes controlling the resistance of materials to crack growth are far from being fully understood. The main challenge lies in the multiscale nature of failure problems: The macroscopic behavior of materials (like their toughness) is governed by damage processes localized at the crack tip vicinity at the microstructural scale. These are then extremely difficult to investigate in real time during fracture experiments and they might also not be amenable to a theoretical treatment by standard methods of continuum mechanics. Another challenge lies in the seemingly wide variety of damage mechanisms as one explores different types of material, so that formulating a generic description of the dissipative processes driving crack growth resistance seems nearly impossible. Here, we address this challenge by adopting an original strategy: our approach consists in investigating the fingerprints left by dissipative failure processes on fracture surfaces. We show that it resolves these both difficulties at once: the roughness of fracture surfaces can then be investigated post-mortem at the microscale and it reveals that cracks proceed through nucleation, growth and coalescence of damage, irrespective of the material considered. This crack growth mechanism is characterized by a length scale ξ, specific to each material, that can be extracted from the statistical analysis of the roughness of fracture surfaces. Last but not least, this length scale correlates with the toughness of materials, opening new perspectives in material characterization and structural failure analysis.

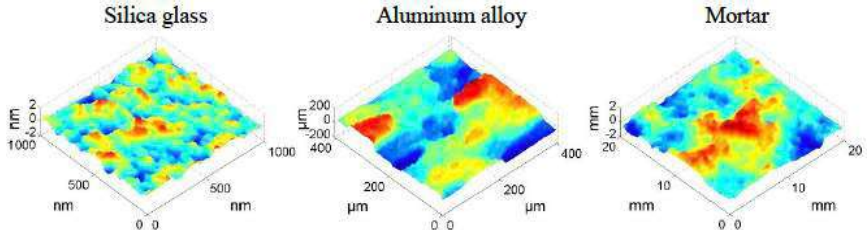

Figure 1. Three fracture surfaces of three very different materials. Despite their apparent diversity, their roughness shares similar fractal statistical properties signature of a common mechanism of crack growth by damage coalescence [1,2].

STATISTICAL FRACTOGRAPHY: FROM ROUGHNESS TO TOUGHNESS

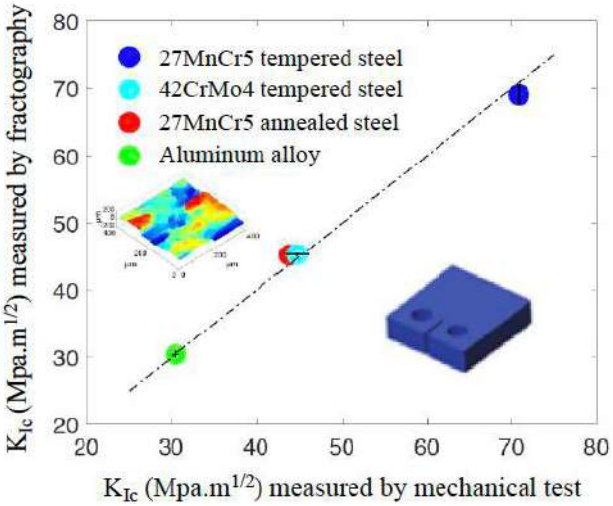

Figure 2. Comparison of the toughness measured by mechanical test and by statistical fractography on four different metallic alloys [6]. Both measurements are carried out independently.

Since the seminal work of B. Mandelbrot et al. [1] in the 80's, the investigation of the statistical features of the roughness of fracture surfaces has drawn a lot of attention (see Ref. [2] for a recent review). Until recently, the main motivation has been to understand the origin of the common properties observed on a large range of materials (Fig. 1), and more specifically the seemingly universal value of the fractal exponent characterizing the scale invariant properties of fracture surfaces [3]. But these last few years, this research field has taken another turn with the measurement of a material dependant length-scale ξ embedded in the statistical properties of the roughness of cracks [4]. In this work, we go one step further, and show on experimental examples that this length scale correlates with the toughness of materials, in line with previous numerical observations [5]. As a result, the toughness of materials can now be measured from the statistical analysis of fracture surfaces (see Fig. 2 for the application of this approach to metallic alloys [6]).

APPLICATION TO MATERIAL CHARACTERIZATION AND STRUCTURAL FAILURE ANALYSIS

In this presentation, I will review these recent findings and discuss their implications for the characterization of materials and the analysis of structural failure [7,8]. As a matter of fact, characterizing the failure properties of materials without resorting to a mechanical test, but from the analysis of a scan of its fracture surface, greatly simplifies the mechanical characterization of materials. But it also enables to reach new information that were not accessible before, beyond the average material toughness obtained by standard mechanical tests. Like a microscope to mechanical properties, statistical fractography also provides the field of toughness of a material within its fracture plane with a resolution of a few hundred of micro-meters (see Fig. 3e). Beyond the detailed characterization of the fracture properties of materials, it also provides new means to analyse a failed part to determine the root causes of failure (initiation region, amplitude and nature of the mechanical loading at failure...), thus enabling the redesign of safer parts (Fig. 3).

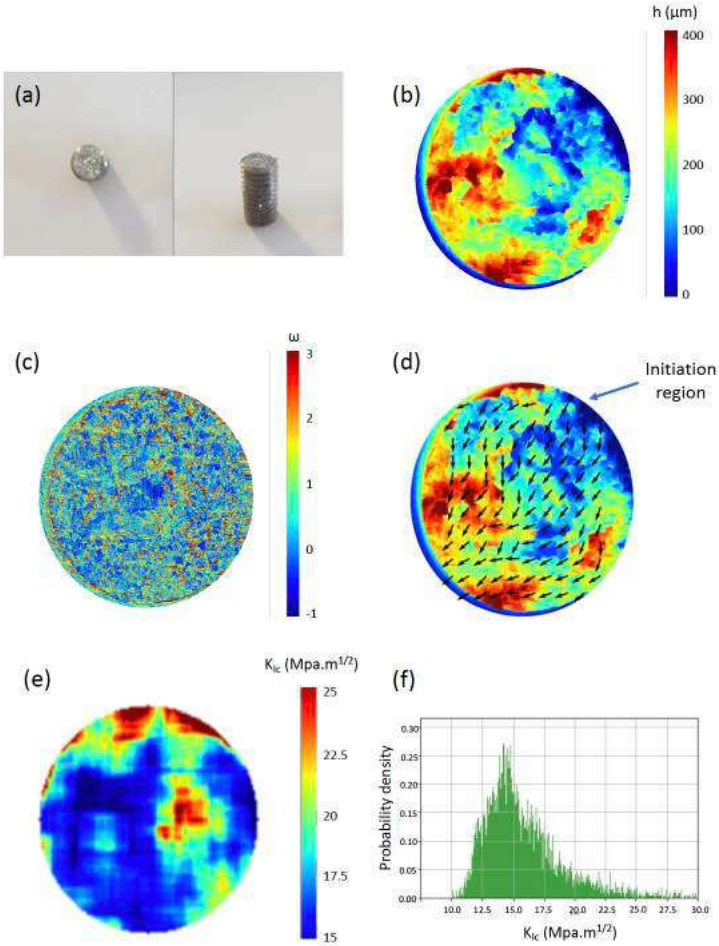

Figure 3. Example of data extracted from a statistical fractographic analysis performed on a broken screw (a). The topographic map (b) of the fracture surface is used as input data. It is first used to compute the field ω of local slopes (c) that is reminiscent of the damage coalescence processes. The anisotropy of ω allows the determination of the crack propagation direction and its sense (d). The cliffs visible on the field ω allow the measurement of the length ξ and ultimately, the toughness field (e) of the specimen within its fracture plane. Figure (f) finally provides the dispersion of the local toughness values, thereby quantifying the degree of homogeneity of the material.

CONCLUSIONS

In summary, the recent advances in the statistical analysis of the topography of fracture surface reinvents classical fractography, by changing it into a quantitative technique. This new tool may assist scientists in the development of predictive multi-scale models of failure that will provide a microscopic understanding of the crack growth resistance of materials. It also opens new perspectives for analysing structural failures to assist the design of safer structures and materials.

FRACTURE PROPAGATION AS A STANDARD DISSIPATIVE PROCESS: APPLICATION TO HYDRAULIC FRACTURES

Alberto Salvadori*[1] and Francesca Fantoni[2]
[1]DIMI, University of Brescia, Brescia, 25123, Italy 2DICATAM, University of Brescia, Brescia, 25123, Italy

Summary We propose a novel set of differential equations to model hydraulic fracture processes. Current formulations are affected by an inherent difficulty brought by the moving boundary nature of the problem, since the fronts velocitiesdo not appear explicitly in the governing equations, which makes recourse to standard computational methods for front tracking (as level sets) not possible. The formulation here proposed is capable to model the evolution of the lag and of the crack advancing in a straightforward way and can be easily extended to account for fractures pressurized by gas or other substances.

BACKGROUND AND MOTIVATIONS

Recent publications framed the problem of three-dimensional quasi-static crack propagation in brittle materials into the theory of standard dissipative processes [1]. Variational formulations, stated therein, characterize the three dimensional crack front quasi-static velocity as the minimizer of constrained quadratic functionals. An implicit in time crack tracking algorithm, that computationally handles the constraint via the penalty method algorithm, was developed and implemented in [2].

Although the theoretical setting is sound, the derived crack tracking methods suffered from a major drawback that limited the interest in the method to its theoretical content. Specifically, the need of still currently unavailable accurate approximations for weight functions made the approach of minor interest from the numerical standpoint. Such a drawback was overcome in [3], where a viscous regularization of the fracture propagation in brittle materials as a standard dissipative process was formulated. Rate-dependency provided a simple and accurate approximation of the crack front velocity, thus allowing to formulate effective crack tracking algorithms, as depicted in Fig. 1.

NUMERICAL SIMULATIONS

As well known, three-dimensional crack propagation in brittle materials still presents unresolved issues, pertaining to *when* and *how* crack elongates. For this sake, we focus in this paper on pressurized cracks that propagate in their own plane in a state of pure mode I at every point of $\mathscr{F}(t)$. Hence, at any location of $\mathscr{F}(t)$ the evolution in time of the crack path generates a smooth curve in the normal plane, at least of class C^1.

Figure 1, reprinted from [3] , depicts an example that falls out of these assumptions with the mere aim to show the potential of the algorithm devised in [3] in generic configurations when dealing with real-life, three-dimensional applications.

Consider a penny-shape crack with radius $r(t) \geq r(0) > 0$ embedded in an unbounded continuum body, loaded by two point-loads $\vec{P} = -\kappa(t)\left[\vec{n} + 0.2\vec{t}\right]$ acting on the upper and lower crack surfaces, which are directed away from the crack faces, thus opening the crack.

To cause non-planar crack growth, a shear component was added to normal point forces. The magnitude of the shear component was 20% of the normal, and the forces were applied at a location 10% of the distance from the center to the radius of the initial crack.

Because the normal and shear loads were increased proportionally, as the crack extends it shall asymptotically approach a state of planar crack growth, where resultant direction of the applied normal and shear forces is perpendicular to the growth plane.

Figure 1 shows three different views of the predicted final crack shape and the interim converged crack fronts. Six load steps are depicted: the magnitude of the applied forces were increased by 20% for each crack step (both normal and shear proportionally). It is clearly seen that the crack front rapidly approaches the plane normal to the applied load.

HYDRAULIC FRACTURES

That idea is further developed here to model hydraulic fracture processes. Current formulations are affected by an inherent difficulty brought by the moving boundary nature of the problem, since the fronts velocitiesdo not appear explicitly in the governing equations, which makes recourse to standard computational methods for front tracking (as level sets) not possible. The main novelty of the formulation stands in its ability to explicitly account for the evolution of the lag and of the crack advancing in the differential governing equations.

The problem under investigation is the penny-shaped hydraulic fracture in impermeable rock described in [4], subjected to a point-wise injection at its center of magnitude $Q(t)$. The infinite domain in which the crack is defined shows a

(a) (b) (c)

Figure 1: Penny shaped crack of radius equal to $10\,\mu$m in an unbounded linear elastic medium, subject to two point-loads $\vec{P} = -\kappa(t)\left[\vec{n}+0.2\vec{t}\right]$ at a distance $1\,\mu$m from the center. $\vec{n}$ stands for the outer normal, whereas $\vec{t}$ is a unit vector that spans the radial direction. Top view (a), side view (b), perspective view (c).

linear elastic behavior with no limitation in stress and strain magnitudes. The problem is formulated in the realm of small strains, as usual for linear elastic fracture mechanics.

We can idealize a process in this form. At time $t = 0$ a crack of radius $a(0)$ is given, without any fluid in it. A (sufficiently smooth in time) injection of magnitude $Q(t)$ takes place. It develops a fluid flow, and the zone occupied by the fluid is also axis-symmetric of radius $\ell(t) \leq a(t)$. The fluid lag is denoted with $\lambda(t) = a(t) - \ell(t)$.

The fluid in the crack experiences a pressure $p(r,t)$ that opens the crack of the amount $w(r,t)$. Both p and w are assumed to be smooth in time.

The set of governing equations stem from the viscous regularized formulation described in [3] for capturing the crack advancing, on the mass balance to describe the fluid front advancing, to linear elasticity theory to account for the response of the rock, and on the so-called lubrication equation (Reynold's form of the fluid transport equation) to model the fluid response, connecting the crack opening to the fluid pressure.

CONCLUSIONS

Although limited to a penny shaped crack benchmark, the novel set of differential equations that are here proposed are capable to model the evolution of the lag and of the crack advancing in a straightforward way. The formulation can be easily extended to account for fractures pressurized by gas or other substances.

I-INTEGRAL METHOD FOR FRACTURE OF MULTI-INTERFACE MATERIALS

Hongjun Yu*[1]
[1]Department of Astronautic Science and Mechanics, Harbin Institute of Technology, Harbin 150001, China

Summary The interaction integral (I-integral) has been widely used to extract the stress intensity factors of homogeneous and nonhomogeneous materials. The I-integral is the cross terms of the J-integral through superimposing an auxiliary field on the actual field. Due to the designability of the auxiliary field, the I-integral was developed to solve the SIFs and the T-stress of nonhomogeneous materials with continuous and discontinuous properties. This paper introduces a new I-integral which is independent of integration domain size, regardless of the existence of thermo-mechanical interfaces. The new I-integral is thus effective for the materials with complex interfaces.

INTRODUCTION

Most of composite materials, such as particulate and granular composites, contain complex interfaces which usually act as the source of cracks and holes, due to deformation mismatch during the manufacturing process. These composite materials are prone to fracture than homogeneous materials and the residual thermal stresses often act as the driving forces of crack growth. In order to decouple mixed-mode SIFs, Stern et al. [1] proposed the I-integral method through substituting a composition of an auxiliary field and the actual field into the J-integral. Subsequently, the I-integral method was developed to solve the T-stress [2]. In the early 2000s, the I-integral was expanded to extract the SIFs of a crack in functionally graded materials which possess continuously differentiable material properties [3]. For isotropic and orthotropic FGMs, Kim and Paulino [4] proposed three alternative auxiliary fields and gave a summary on how to extract the SIFs and the T-stress. The domain-independent I-integral (DII-integral) developed by Yu et al. [5, 6] is independent of the size of the integral domain, regardless of the existence of material interfaces. The DII-integral shows its superiority in dealing with the materials with complex interfaces. As thermal loading is applied, the I-integral becomes domain-dependence for the interfaces across which the coefficients of thermal expansion jump [7]. To overcome this difficult, a new auxiliary field was proposed and the new DII-integral was established [8, 9]. This paper will discuss the influences of the auxiliary fields on the DII-integral.

DOMAIN-INDEPENDENT I-INTEGRAL

As shown in Figure 1, the standard J-integral for thermo-elasticity is given by

$$J=\lim_{\Gamma_\varepsilon\to 0}\int_{\Gamma_\varepsilon}\left(\frac{1}{2}\sigma_{jk}\varepsilon^m_{jk}\delta_{1i}-\sigma_{ij}u_{j,1}\right)n_i d\Gamma \tag{1}$$

where σ_{jk} is the stress tensor, $\varepsilon^m_{ij}=\varepsilon_{ij}-\varepsilon^T_{ij}$ is the mechanical strain tensor, $u_{j,1}$ is the derivative of the displacement u_j with respect to the coordinate x_1, n_i is the unit outward normal vector to the contour Γ_ε and Γ_ε is the integral path from the lower surface to the upper surface of the crack. The thermal strain is given by $\varepsilon^T_{ij}=\alpha(T-T_0)\delta_{ij}$, where α is the coefficient of thermal expansion, T and T_0 are the current and initial temperatures, respectively, and δ_{ij} is the Kronecker delta. Extracting the interaction terms from the J-integral for the superposition of the actual field and an auxiliary field, one can obtain the I-integral as

$$I=\lim_{\Gamma_\varepsilon\to 0}\int_{\Gamma_\varepsilon}\left(\frac{1}{2}(\sigma^{aux}_{jk}\varepsilon^m_{jk}+\sigma_{ij}\varepsilon^{aux}_{jk})\delta_{1i}-\sigma^{aux}_{ij}u_{j,1}-\sigma_{ij}u^{aux}_{j,1}\right)n_i d\Gamma \tag{2}$$

The auxiliary fields marked by the superscript "*aux*" are given by

$$u^{aux}_i=\frac{K^{aux}_I f^I_i(\theta)+K^{aux}_{II}f^{II}_i(\theta)}{\mu_{tip}}\sqrt{\frac{r}{2\pi}},\quad \sigma^{aux}_{ij}=\frac{K^{aux}_I g^I_{ij}(\theta)+K^{aux}_{II}g^{II}_{ij}(\theta)}{\sqrt{2\pi r}},\quad \varepsilon^{aux}_{ij}=S^{(\mathbf{x})}_{ijkl}\sigma^{aux}_{kl} \tag{3}$$

where K^{aux}_I and K^{aux}_{II} are the mode-I and mode-II auxiliary SIFs, respectively, and $S_{ijkl}(\mathbf{x})$ is compliance tensor. In numerical calculations, the I-integral is generally converted into a domain form. As shown in Fig. 1, if the angular functions $f^I_i(\theta)$, $f^{II}_i(\theta)$, $g^I_{ij}(\theta)$ and $g^{II}_{ij}(\theta)$ are taken to be those of the asymptotic solutions of the crack-tip fields [4], the I-integral can be simplified as [8]

$$I=\int_A(\sigma_{ij}u^{aux}_{j,1}+\sigma^{aux}_{ij}u_{j,1}-\sigma^{aux}_{jk}\varepsilon^m_{jk}\delta_{1i})q_{,i}d\Gamma-\int_A\sigma_{ij}(S^{(\mathbf{x})}_{ijkl}-S^{(0)}_{ijkl})\sigma^{aux}_{kl,1}qd\Gamma+\int_{A_1+A_2}\sigma^{aux}_{ii}[\alpha(T-T_0)]_{,1}qdA+I_{\Gamma_I} \tag{4}$$

The last term is a non-zero line integral along the interface Γ_I. If the zero-mean-stress auxiliary field [8] is adopted, i.e., $-f^I_1=f^{II}_2=\cos\frac{\theta}{2}$, $f^{II}_1=f^I_2=\sin\frac{\theta}{2}$, $-g^I_{11}=g^I_{22}=g^{II}_{12}=\cos\frac{\theta}{2}$ and $-g^{II}_{11}=g^{II}_{22}=-g^I_{12}=\sin\frac{\theta}{2}$, the interface integral vanishes and the I-integral can be simplified as

$$I=\int_A(\sigma_{ij}u^{aux}_{j,1}+\sigma^{aux}_{ij}u_{j,1}-\sigma^{aux}_{jk}\varepsilon^m_{jk}\delta_{1i})q_{,i}d\Gamma-\int_A\sigma_{ij}(S^{(\mathbf{x})}_{ijkl}-S^{(0)}_{ijkl})\sigma^{aux}_{kl,1}qd\Gamma+\int_{C^+ +C^-}\sigma^{aux}_{2j}u_{j,1}qd\Gamma \tag{5}$$

*Corresponding author. E-mail: **yuhongjun@hit.edu.cn**. This study was supported by the NSFC (No. 11772105).

Compared with the I-integral in Eq. (4), Eq. (5) eliminates the area integral with respect to the thermal property gradient, including the gradient of the thermal expansion coefficient and the gradient of temperature. Moreover, Eq. (5) does not contain any terms related to the thermal properties. These features facilitate the practical implementation of the I-integral in dealing with the materials with complex thermo-mechanical interfaces.

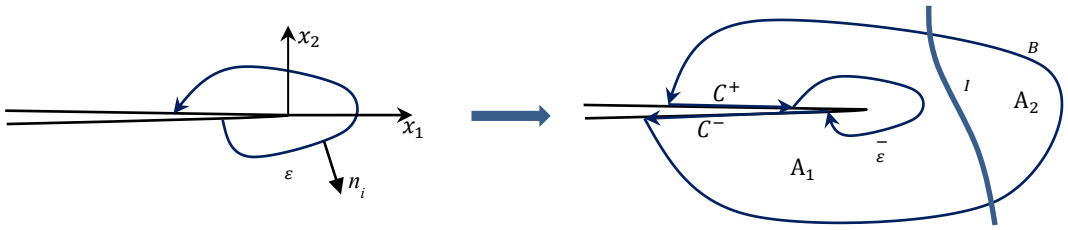

Figure 1. Integral contours around a crack tip

A REPRESENTATIVE EXAMPLE

As shown in Figure 2, a square plate of length $2W = 100$ contains a central crack of length $2a = 40$ and a particle of radius $R = 16$. The top and bottom edges are fixed and adiabatic. The left and right edges are traction-free, and the temperatures on the edges are prescribed to be $T_1 = 0$ °C and $T_2 = -20$ °C, respectively, with initial temperature $T_0 = 0$ °C. The relations between material constants of the particle and those of the matrix are as follows: $E_p = 4E_m$, $\nu_p = \nu_m$, $\alpha_p = 4\alpha_m$. Numerical results show that the interface affects the DII-integral in Eq. (4) greatly as the integration domains contain interfaces but has no influence to the new DII-integral in Eq. (5). It implies that the new I-integral in Eq. (5) can facilitate the calculation of the SIFs of multi-interface materials.

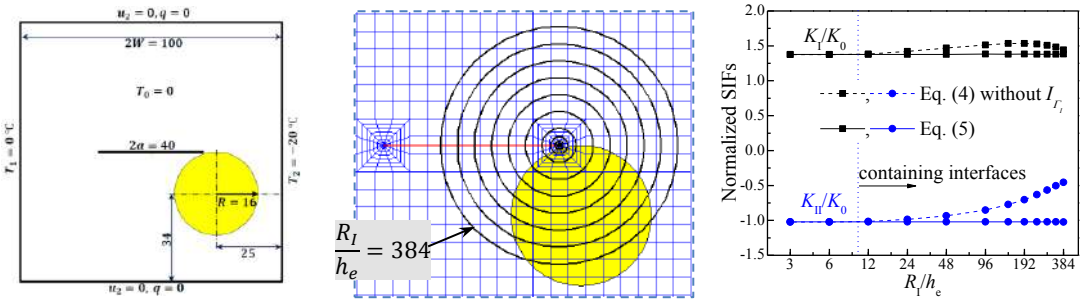

Figure 2. A particle-reinforced plate: model, integration areas of radius R_I, and normalized SIFs (h_e: edge length of the tip element).

CONCLUSIONS

In comparison with the I-integral using the classical solutions of the crack-tip fields, the I-integral applying a zero-mean-stress auxiliary field is domain-independent for the interfaces across which the coefficient of thermal expansion is discontinuous. The new I-integral is devoid of the calculation of the interface integrals and the gradient of the thermal expansion coefficient, which facilitates the practical implementation on the extraction of the SIFs for the materials with complex interfaces.

REVIEW ON FINITE ELEMENT ANALYSIS AND FRACTURE MECHANICS FOR COMPUTING INTENSITY FACTORS FOR NOTCHES CRACKS

José Airton Neiva Alves da Silva Brasil, Jorge Luiz de Almeida Ferreira *1
[1]Department Mechanical Engineering, Universidade de Brasília, Brasília, Brazil

Summary This paper presents the theory of the finite element analysis for fracture mechanics and a method for calculating the stress intensity factor for cracks emanating from notches. The results of the finite element analysis results will be compared with data from literature to demonstrate the accuracy of the method.

INTRODUCTION

For a fracture mechanics analysis, it is important to observe the interplay between the initial state of the component (no crack was present), the initial crack and its growing, especially in situations where notches are present, which occurs in most of real engineering situations. The difficult behind this analysis is that for every geometry, crack size and load condition the stress intensity assumes a different formulation, but can be expressed in general for by:

$$K = \sqrt{JE'} = F\sigma\sqrt{\pi a} \quad (1)$$

For actual engineering analysis the finite element method has become common to use as procedure to fracture problems. The use of finite elements in fracture predictions requires considerations: the crack tip singularity modelling and the displacement and stress fields throughout the cracked solid.

The objective of this work is to review the theory for the determination of the stress intensity factor K, apply it together with a finite element code, and compare the results with the results of different geometries with the results of others authors.

REVIEW OF J-INTEGRAL

Moran and Shih [n1], developed a formulation for the calculation of the J-integral by applying the integral method over the energy domain. Fakkoussi Et al [1], discretized this formulation, in the formula presented in Equation (2).

$$J = \sum_{A*}^{n} \sum_{p=1} \left\{ \left[\left(\sigma_{ij} \frac{\partial u_j}{\partial x} - w\delta_{1i} \right) \frac{\partial q}{\partial x_i} \right] \det \left(\frac{\partial x_j}{\partial x_{\xi_k}} \right) \right\} w_p \quad (2)$$

Where A^* is the area of the surface between the contours, q is parameter of the smoothed function, n_p is the number of Gauss points, w_p the integration weight and ξ_k the coordinates of elements in local landmarks.

The J-integral is equivalent to the rate of the energy restitution under a single mode. The integral J is used to calculate the stress intensity factor for mechanical case with linear elastic rupture.

REVIEW OF FINITE ELEMENT IN LINEAR ELASTIC FRACTURE MECHANICS

For a line integral path with multiple integral contours, which will enclose the crack tip and the initial and end points lies on the crack faces, this is show in Figure 1. The integral quantity is path independent when taken along any path which satisfies the condition represented by Equation (2).

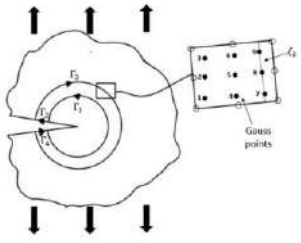

Figure 1. Closed contour path for J-integral evaluation

The J-integral estimates from different contours may vary because of nature of the finite element solution. Strong variation in the estimates indicates an error of contour dependence. Gradual variation indicates that finer mesh is needed.

*Corresponding author. E-mail: airton.bra@gmail.com.

The first contour integral is defined specifying the nodes at the crack tip, the first few contours tends to be inaccurate, so the study is made increasing the number of contours until the results converges.

FRACTURE ANALYSIS

To test the accuracy of the finite element analysis, some different of notched specimen will be compared using data of obtained from Tada, Paris and Irwin [6] compilation, and the results of the simulations. The geometric configuration, mesh, boundary conditions and results for 5 mm crack can be seen in Figure 2.

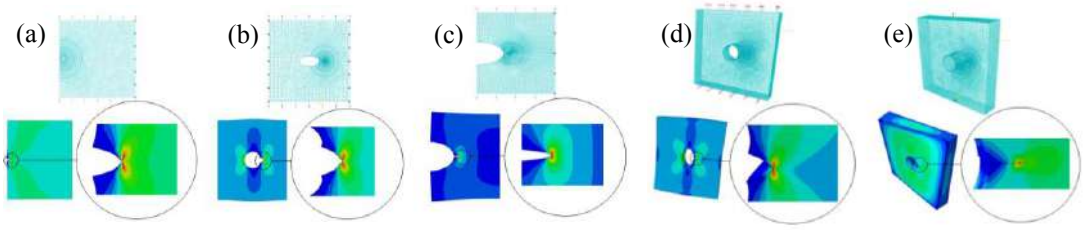

Figure 2. Simulation conditions and results. (a) 2D model of specimen without notch subjected to normal stresses, (b) 2D model of specimen with central ellipse hole subjected to normal stresses, (c) 2D model of specimen with lateral ellipse hole subjected to normal stresses, (d) 3D model of specimen with circular hole subjected to normal stresses, (e) 3D model of specimen with circular hole subjected to shear stresses

The results and the comparison between the data and the simulation for the tested notches, will be presented relating the generalized crack size and the correlation function, to avoid the characterization of the crack size and remote stress, applying the found correlation function in Eq. 1 the stress intensity factor could be calculated. The results could be seen in Figure 3.

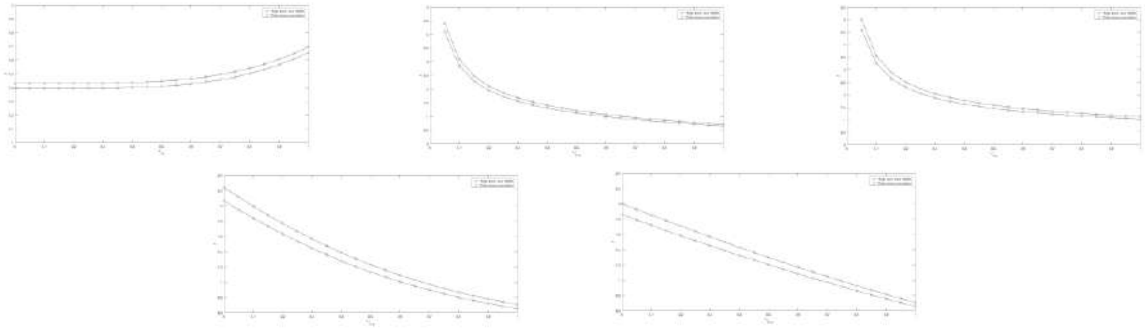

Figure 3. Comparation between the data of Tada and Irwin (2000), and the data from finite element simulation. (a) 2D model of specimen without notch subjected to normal stresses, (b) 2D model of specimen with central ellipse hole subjected to normal stresses, (c) 2D model of specimen with lateral ellipse hole subjected to normal stresses, (d) 3D model of specimen with circular hole subjected to normal stresses, (e) 3D model of specimen with circular hole subjected to shear stresses

The simulation without notch had a mean error of 2,20% and the simulations with notches had a mean error of 7,73 % between they and the data.

CONCLUSION

To test the accuracy of the finite element analysis, some different geometries were compared with already established data, proving that the FEA method can be used having relatively low error, so this model can be used for complex geometries, especially in real component cases where testing has a high cost and has technical difficulties.

DISLOCATION INTERACTING WITH A CRACK IN A SEMI-INFINITE PLANE

Xiaodong He[1], Wenjiao Dan *[1], and Weigang Zhang[1]
[1]School of Naval Architecture, Ocean and Civil Engineering,Shanghai Jiao Tong University, Shanghai, China

Summary The pre-existing edge dislocation interacting with a sharp crack under Mode I loading is examined by atomistic simulations using a semi-infinite crack model. The simulation results show that, an edge dislocation generates more shielding when approaching the crack tip along the crack propagation direction. When placed orienting at an angle in respect of crack plane, the effect produced by an edge dislocation on crack tip, shielding or anti-shielding, depends on both the angle and distance of its location defined in the polar coordinate located at crack tip. The results presented here also broaden the application of semi-infinite crack model in fracture mechanics.

INTRODUCTION

It has been recognized that discrete dislocations near crack-tip field generate shielding or anti-shielding effect on crack-tip behaviors which are associated with materials' brittle-ductile transition[2]. In the present letter, we perform direct "K-test" simulations[3] to exhibit the effect produced by discrete edge dislocations on crack tip.

SIMULATION METHOD

We perform molecular statics simulations using LAMMPS[4], in which a semi-infinite crack with a discrete edge dislocation existed under plane strain condition is introduced. The whole dimensions of the system are approximately $30\times30\times1$ nm. The dislocation is constructed by displacing the atoms according to the anisotropic displacements[1](as shown in Fig. 1a). The crack is loaded incrementally by anisotropic displacements based on linear elastic fracture mechanics[5] and after each increment of displacement, atoms within boundary (blue atoms in Fig. 1a) are held fixed during energy minimization process.

We first investigate the effect of a discrete edge dislocation located at the plane with θ=0, then dislocations placed at the same distance away from crack tip with different angles are considered. Finally, we simulate the dislocations with the same angle but at different distances from crack tip. The simulation is terminated when crack-tip cleavage occurs(see Fig. 1b and Fig. 1c).

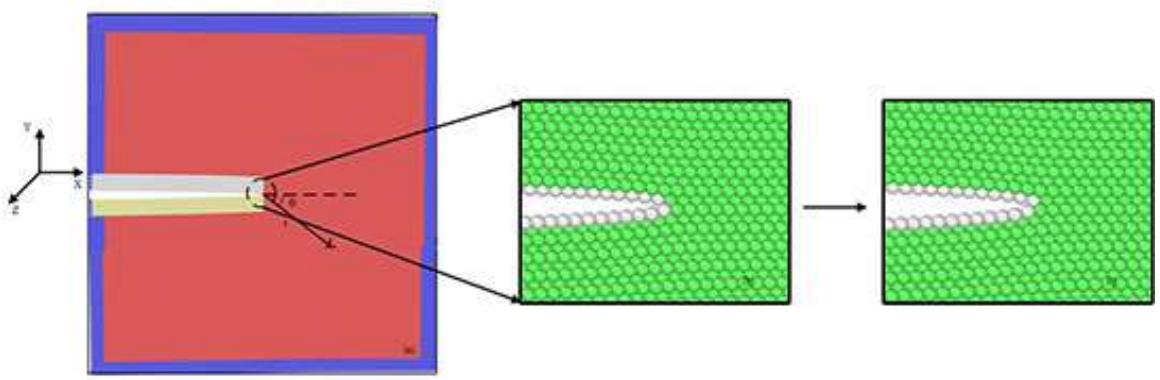

Figure 1: Illustration of atomistic simulation model:(a) a semi-infinite crack model with an edge dislocation; (b) crack tip geometry before cleavage; (c) crack tip geometry at cleavage (FCC atoms are shown in green colour and white coloured atoms represent surface atoms).

RESULTS

Fig. 2 exhibits the results of critical stress intensity factor K_{Ic} for crack-tip cleavage accompanied by the dislocation-induced shielding effect at crack tip. With the distance between crack tip and a discrete edge dislocation increasing, the shielding effect on crack tip is decreasing.

It is shown in Fig. 3a that when an edge dislocation is inserted at a distance 9 nm from crack tip, it anti-shields the crack tip first, and then shileds it with the increment of the value of θ.

Fig. 3b presents the results of K_{Ic} with dislocations at $\theta = -35.26°$ but at differnet distances away from crack tip. At this given angle, anti-shielding effect is apparent to find while minor difference is detected.

*Corresponding author. E-mail: wjdan@sjtu.edu.cn.

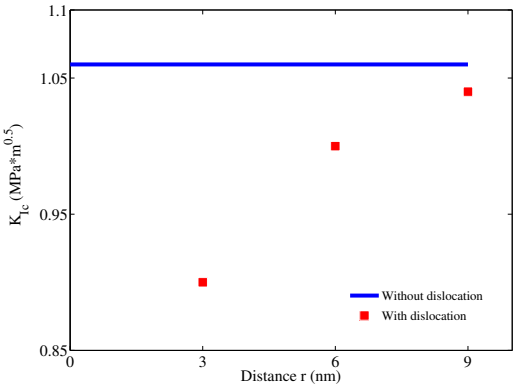

Figure 2: Critical stress intensity factor K_{Ic} for crack tip cleavage with an edge dislocation placed at different distances away from crack tip along the crack propagation direction. Blue line: K_{Ic} acquired without dislocation, Red squares: K_{Ic} obtained with dislocation.

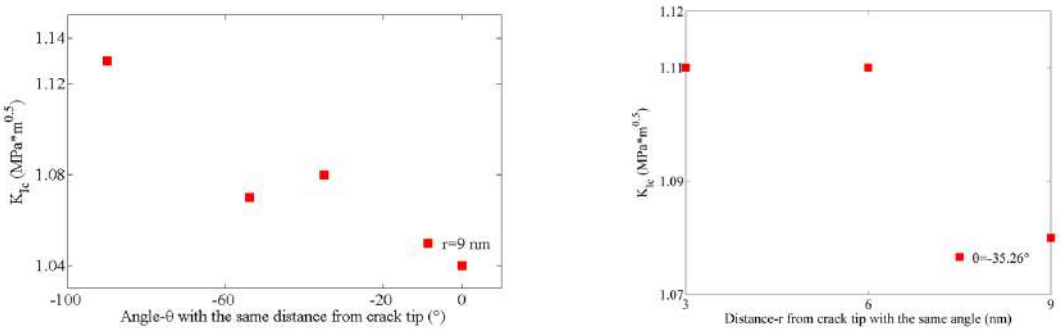

Figure 3: Results of K_{Ic} with dislocations inserted at $\theta < 0$. Fig. 3a shows the variation of K_{Ic} with dislocations at the same distance with different angles from crack tip; Fig. 3b presents the results of K_{Ic} with dislocations at different distances with the same angle.

CONCLUSIONS

The dislocation-induced effect on crack tip, whether shielding or anti-shielding, decreases with the increment of the distacne between the edge dislocation and crack tip. When the crack propagation direction is coincidence with pre-existing dislocations' Burgers vector direction, the shielding effect becomes predominant. The interaction between crack tip and an edge dislocation is mainly through changing crack tip local stress state which can be measured and viewed directly in atomistic simulations.

EFFECT OF STRAIN RATE ON FRACTURE IN ROUNDED V-NOTCHED SPECIMENS UNDER COMPRESSION

Elżbieta Bura*[1] and Andrzej Seweryn[1]
[1]Faculty of Mechanical Engineering, Bialystok University of Technology, Bialystok, Poland

Summary The paper presents the results of experimental compression tests (with unloading) of Poly(methyl methacrylate) (PMMA) notched specimens. Elements with V-notches with root radius equal to 1 mm were used. Three measurement base shortening levels u_{max} were implemented. The effect of strain rate on the fracture process was investigated, by asking three different velocities of the measurement base shortening v. The occurring deformation and fracture processes were recorded with the PHANTOM high-speed camera – different locations of crack initiation were indicated. Two types of cracks were observed and the causes and moments of their formation were diagnosed.

INTRODUCTION

Fracture is a complex process, which depends on many factors. Material, operating and environmental parameters have a strong influence on this phenomenon. It becomes particularly dangerous in the presence of notches. This makes all structural materials subject to fracture tests. Nowadays, polymers such as PMMA have become particularly popular. The interest in Plexiglas is mainly due to its good optical and impact properties, but its big disadvantage is its susceptibility to brittle or quasi-brittle fracture. Both in the case of PMMA and other materials, it is particularly important to build tools for predicting fracture processes, i.e. determining the points and moments of crack initiation. The basis for formulating fracture criteria is experimental testing. Components made of PMMA were analyzed during experimental tests of tensile [1], compressive [2], three-point bending [3], torsion [4] and complex states [5]. A large group of works concerns the fracture tests during uniaxial compression of specimens in the form of Brazilian discs weakened by rhombus-shaped notch [6], key-hole [7] and many others. It has been observed that thin elements, weakened by sharp notches or with small root radius, were subjected to fracture during compression. These actions made it possible to obtain linear characteristics and thus to predict processes using the brittle fracture criteria. There were no studies on fracture during compression with unloading stage. The influence of strain rate on the fracture process was not analyzed in most of the studies.

SPECIMENS AND TESTING STAND

The subject of the study was Poly(methyl methacrylate). Flat elements (9.7 mm thick) were weakened with double-sided V-notches with the root radius $R \sim 1$ mm and opening angle equal to 90°. Monotonic compression tests (with unloading) were carried out on a MTS 809.10 biaxial testing machine. The tests were carried out under displacement control using an INSTRON 2620.601 axial extensometer with a measuring base of 25 ± 5 mm. In order to investigate the influence of the strain rate on the fracture process, three velocities of the measurement base shortening v were used: (a) 0.02 mm/s – 0.2 mm/s, (b) 0.1 mm/s – 1 mm/s and (c) 0.5 mm/s – 5 mm/s. Unloading stage was realized respectively 10 times faster than loading. In addition, three levels of the maximum base shortening u_{max} were used. Fracture processes were observed in real time, thanks to the PHANTOM v1610 monochromatic camera.

RESULTS

As a result of experimental research, load curves as a function of measurement base shortening were obtained (Fig. 1). With the increase in the base shortening, a gentle increase in the maximum compressive force is observed. The increase of base shortening velocity v causes the increase of the maximum compressive force value. For the shortening of $u_{max} = 3$ mm, the maximum compressive force at $v = 0.02$ mm/s was about 24.75 kN. With a five-fold increase in the base shortening velocity to $v = 0.1$ mm/s, an increase in the maximum compressive force of approximately 17.5% was recorded. Another increase to $v = 0.5$ mm/s was associated with an increase in the maximum compressive force by about 10.3%. Similar trends were noted for the remaining u_{max} values. The load curve is characterized by a visible step, which regardless of the base shortening velocity v, always occurs for a shortening at $u \approx 3.25$ mm. The analysis of recordings from the PHANTOM camera, allows to conclude that the visible offset of the graph is related to the start of notch closing process. It should be noted that regardless of the preset shortening speed v, after unloading, a similar level of base shortening was obtained.

Two types of cracks were observed. The first one is formed in the result of contact stress during the notch closure (crack type A – Fig. 1). The crack initiates from the edge of the contact surface and takes the form of a butterfly wing. For the base shortening velocity $v = 0.02$ mm/s and 0.1 mm/s, the first crack initiation was recorded for $u \approx 5.85$ mm. It was only the increase in velocity v to 0.5 mm/s that accelerated the destruction process. The first crack initiation was recorded for $u \approx 4.38$ mm. The second crack type is initiated during the unloading stage (crack type B – Fig. 1). As the

*Corresponding author. E-mail: e.bura@doktoranci.pb.edu.pl

level of maximum base shortening u_{max} increases when loading the specimen, the critical force responsible for the crack initiation decreases. An increase in the base shortening velocity v accelerates the destruction process. The higher the rate of deformation, the higher the compressive force at which the crack initiation was recorded. It was found that for u_{max} = 3 mm, the crack initiates at 29%, 31% and 33% of the maximum compressive force value – respectively for base displacement velocity (unloading) 0.2, 1 and 5 mm/s. And for u_{max} = 7 mm, the crack initiation corresponds to a load of 6.7%, 6.9% and 7.7% of the maximum compressive force for the base shortening velocity (unloading) 0.2, 1 and 5 mm/s respectively. The higher the level of base shortening the differences resulting from different velocities v become less visible.

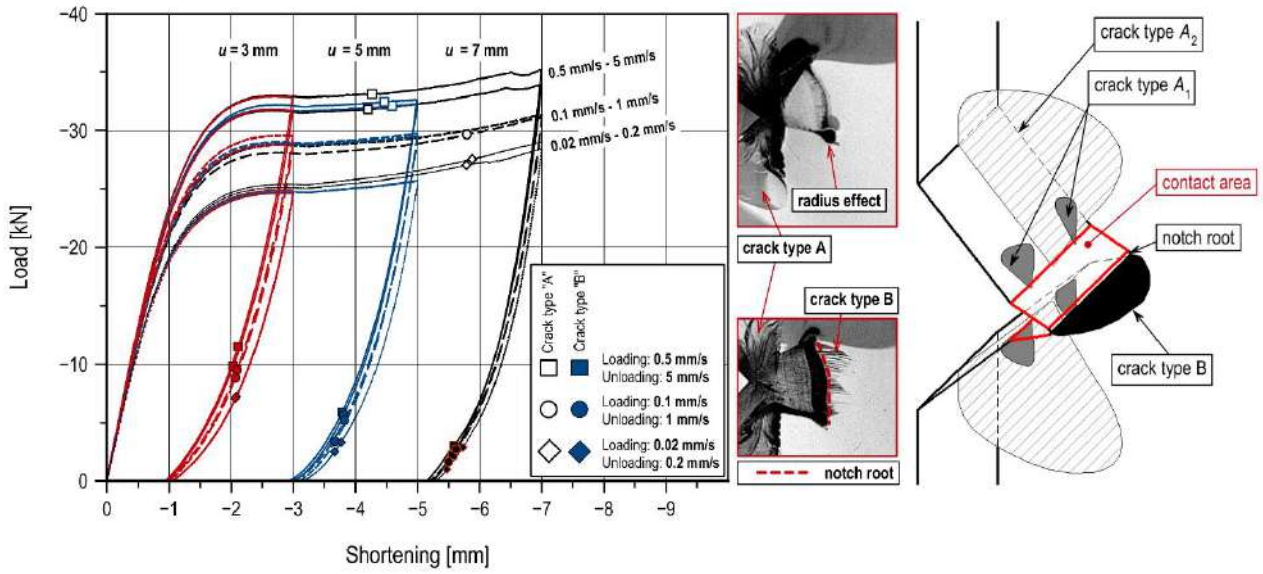

Figure 1. Compression curves with fracture initiation points for specimens with rounded V-notches.

CONCLUSIONS

The paper presents the results of experimental fracture tests of PMMA flat specimens, weakened by rounded V-notches. The phenomenon was analyzed during the loading and unloading stages, taking into account such parameters as: maximum shortening of the measurement base u_{max} and the velocity of base shortening v. Two types of cracks were observed. The first of them was formed during the loading stage as a result of contact stress. The second one was initiated at the notch root, during the unloading. The influence of the base shortening velocity on the moment of crack initiation was observed. The contact cracks initiated for a similar value of base shortening u, with base shortening velocity v = 0.02 and v = 0.1 mm/s. Significant acceleration of the destruction process was observed only at a velocity equal to v = 0.5 mm/s. An increase in the deformation velocity led to an earlier (at a lower value of the base shortening) initiation of the crack from the contact surface. In the case of cracks created by residual stresses, the influence of the strain rate on the moment of crack initiation was also found. For a given maximum level of base shortening u_{max}, it can be stated that the higher the strain rate, the fracture process occurs at higher force values. Thus, the greater the base shortening u_{max}, the differences resulting from the change in base shortening velocity v become less significant.

A UNIFIED MICROSTRUCTURE-BASED APPROACH FOR DUCTILE AND BRITTLE FRACTURE OF A MORPHOUS GLASSY POLYMERS

Osman Gültekin*[1], Fabian Welschinger[2], and Hüsnü Dal[3]
[1,3]Department of Mechanical Engineering, Middle East Technical University, Ankara, Turkey
[2]Corporate Sector Research and Advance Engineering, Applied Material and Manufacturing Technologies for Metals and Polymers, Robert Bosch GmbH, Renningen, Germany

Summary Amorphous glassy polymers exhibit *shear yielding* and *crazing* associated with *ductile* and *brittle* fracture responses, respectively, under certain internal and external conditions. This study presents a microstructure-based approach to model both responses by incorporating the local evolution equations and failure criteria into staggered solution of mechanical problem that involves the total, plastic and crazing strains and the phase–field problem governing the non-local evolution of the crack phase–field. Finally, the numerical performance of the model is demonstrated through a benchmark boundary value problem in regard to the onset and growth of plastic and crazing strains inducing the ultimate rupture in the material.

INTRODUCTION

Amorphous glassy polymers, such as polymethylmethacrylate (PMMA) and polystyrene (PS), have broad end-use applications in automobile, construction and aerospace industry. They exhibit *shear yielding* under *low strain-rate*, relatively *high temperature* (around glass transition temperature θ_g) levels and *high entanglement density*, see Berger & Kramer [4], accompanied by volume-preserving inelastic deformations leading to *ductile* response. The well-accepted double-kink theory proposed by Argon [2] explains the ductile response of the glassy polymers. Constitutive models accounting for the finite viscoplastic behavior of glassy polymers can be found among others in [1, 8]. The development of *crazes* the amorphous polymers is favored by *high strain-rate*, relatively *low temperature* levels, and *low entanglement density* under tension dominated straining due the existence of flaws or grooves in the material leading to *brittle* response, see Berger & Kramer [4]. Craze development can be investigated in three stages, namely, the nucleation, growth, and failure. The growth is well explained by the interface convolution mechanism, i.e. the meniscus instability, see Argon [3]. The most widely used failure criteria for the breakdown of craze are the critical craze tip opening displacement, e.g., [10], the critical inelastic strain criterion, e.g., [6]. Although such properties of thermoplastics are separately treated in the literature, a unique research which treats thermal, mechanical and failure aspects concurrently is lacking.

THEORY

Let $\mathcal{B}$ and $\mathcal{S} \subset \mathcal{R}^3$ be the reference and the spatial configuration of the body of interest at time t_0 and $t \in \mathcal{T} \subset \mathcal{R}_+$, respectively. Then, we introduce the nonlinear *deformation map*, the covariant *Lagrangian inelastic metrics* for the shear-yielding and crazing processes, and the *crack phase–field* based on Miehe et al. [9] as follows,

$$\boldsymbol{\varphi} : \left\{ \begin{array}{ccc} \mathcal{B}\times\mathcal{T} & \rightarrow & \mathcal{S}\in\mathcal{R}^3 \\ (\boldsymbol{X},t) & \mapsto & \boldsymbol{x}=\boldsymbol{\varphi}(\boldsymbol{X},t) \end{array} \right. \qquad \boldsymbol{G}^{p,c} : \left\{ \begin{array}{ccc} \mathcal{B}\times\mathcal{T} & \rightarrow & \mathcal{R}^6 \\ (\boldsymbol{X},t) & \mapsto & \boldsymbol{G}^{p,c}(\boldsymbol{X},t) \end{array} \right. \qquad d : \left\{ \begin{array}{l} \mathcal{B}\times\mathcal{T}\rightarrow[0,1] \\ (\boldsymbol{X},t)\mapsto d(\boldsymbol{X},t) \end{array} \right. \tag{1}$$

Focusing on the kinematics, one can define the Hencky-type total, plastic and crazing strains in the sense of Miehe et al. [7], i.e.

$$\boldsymbol{\varepsilon} := \frac{1}{2}\ln \boldsymbol{C}\,, \qquad \boldsymbol{\varepsilon}^p := \frac{1}{2}\ln \boldsymbol{G}^p \qquad \text{and} \qquad \boldsymbol{\varepsilon}^c := \frac{1}{2}\ln \boldsymbol{G}^c \tag{2}$$

in the logarithmic strain space, which enables the use of additive decomposition of the strain measures, i.e. $\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}^e + \boldsymbol{\varepsilon}^p + \boldsymbol{\varepsilon}^c$, akin to the small strain context. Next, postulating stronger conditions on the reduced form of the Clausius–Planck inequality, the inelastic processes read

$$\boldsymbol{\pi}^p : \dot{\boldsymbol{\varepsilon}}^p \geq 0\,, \qquad \boldsymbol{\pi}^c : \dot{\boldsymbol{\varepsilon}}^c \geq 0 \qquad \text{and} \qquad \pi^d : \dot{d} \geq 0 \tag{3}$$

where $\boldsymbol{\pi}^p$, $\boldsymbol{\pi}^c$, and π^d are driving thermodynamic logarithmic stress tensors and scalar associated with shear yielding, crazing and phase-field of damage, respectively. An isotropic, volume-preserving viscoplastic flow in the direction of the deviatoric stress $\mathrm{dev}(\boldsymbol{\pi}^p)$ and another flow in the direction of the maximum effective stress $\boldsymbol{\pi}_0$ drive the shear yielding and crazing, i.e.

$$\dot{\boldsymbol{\varepsilon}}^p := \dot{\gamma}^p \frac{\mathrm{dev}(\boldsymbol{\pi}^p)}{||\,\mathrm{dev}(\boldsymbol{\pi}^p)||} \qquad \text{and} \qquad \dot{\boldsymbol{\varepsilon}}^c := \dot{\gamma}^c \boldsymbol{e}_{max}\otimes\boldsymbol{e}_{max} \tag{4}$$

*Corresponding author. E-mail: osmang@metu.edu.tr

in terms of the scalar flow functions $\dot{\gamma}^p$ and $\dot{\gamma}^c$ in the sense of Boyce et al. [5] and Gearing & Anand [6], respectively. In the sequel, we postulate two serial viscoplastic dashpots along with a one-way switch function for craze initiation

$$\mathcal{F}_c(\boldsymbol{\pi}) : \begin{cases} f_c(\boldsymbol{\pi}) \leq 0 & \vee \quad \pi_{max} \leq 0 \quad \vee \quad \pi_{vol} \leq 0 \quad \longrightarrow \quad \text{shear yielding} \\ f_c(\boldsymbol{\pi}) > 0 & \wedge \quad \pi_{max} > 0 \quad \wedge \quad \pi_{vol} > 0 \quad \longrightarrow \quad \text{crazing} \end{cases} \tag{5}$$

where the mean normal stress reads $\pi_{vol} = \mathrm{tr}(\boldsymbol{\pi})/3$ in the logarithmic strain space. A slightly modified version of that stated in Gearing & Anand [6] is adopted for the craze nucleation criterion $f_c(\boldsymbol{\pi})$. Considering the quasi-static conditions, the fundamental balance laws that serve as the basic axioms of the thermomechanics are the balance of linear and angular momentum, i.e.

$$J\,\mathrm{div}(\boldsymbol{\tau}/J) + \rho_0 \boldsymbol{\gamma} = \boldsymbol{0} \quad \text{and} \quad \boldsymbol{\tau} = \boldsymbol{\tau}^T\,, \tag{6}$$

where $\boldsymbol{\tau}$, ρ_0 and $\boldsymbol{\gamma}$ represent the Kirchhoff stress, the material density and the prescribed body force, respectively. Next, we write down the balance equation for the fracture process

$$\frac{1}{l}(d - l^2\Delta d) = 2(1-d)\mathcal{H}\,, \tag{7}$$

that governs the non-local evolution of the crack phase-field. l indicates the length-scale parameter inherent in the phase-field theory, while a monotonically increasing specific crack driving source term $\mathcal{H}$ drives the phase-field from intact to ruptured state, i.e. $d \to 1$, of the solid. On the spatial side, a canonical Galerkin-type finite element procedure, together with a standard discretization, yields the algebraic counterparts of the weighted residual expressions and the symmetric tangent matrices from (6) and (7). Subsequently, the partition of the monolithic solution scheme on the temporal side successively updates the history fields, the deformation and the crack phase-field . During the non-local update of the deformation field, the local updates associated with the shear yielding and crazing are also performed.

RESULTS

We perform a tension test on a micro-structure plate with a hole in the center made of PMMA. The lower edge is fixed in horizontal and vertical directions, while the upper edge is only fixed in the horizontal direction. The specimen is loaded monotonically in the vertical direction. The simulation results are shown in terms of the maximum principal stress π_{max}, the amount of plastic strain $||\boldsymbol{\varepsilon}^p||$ due to the shear yielding, and the amount of plastic strain ϵ^c due to crazing. When the applied stresses reach the yield stress, plastic deformations due to shear yielding occurs. Until the onset of crazing, a full-fledged shear band is evident whose development is later terminated by the initiation of the craze, see Fig. 1(i). Plastic strains due to crazing continue to accumulate and as soon as ϵ^c exceeds the threshold $\overline{\epsilon^c}$, the crack phase-field develops. The crack phase-field fully grows at the intersection of the circular hole with the mid-plane leading to the first visible crack. Figure 1(ii) shows stresses, plastic strains due to shear yielding and plastic strains due to crazing at the onset of crack, respectively. Figure 1(iii) depicts the stress concentration at the crack front, plastic strains due to shear yielding and crazing as the crack advances in the horizontal direction. Finally, in Fig. 1(iv), the fully ruptured specimen is visualized. Due to excessive plastic deformations, the specimen cannot recover its initial unloaded shape.

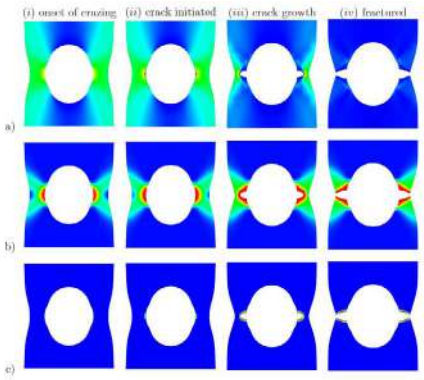

Figure 1: Contour plots of a) actual driving stress π_{max}, b) amount of plastic shear yielding strain $||\boldsymbol{\varepsilon}^p||$ and c) crazing strain ϵ^c at the (i) onset of crazing, (ii) the initiation of the crack, (ii) while the crack grows, and (iv) when the fracture occurs.

PHASE FIELD MODELLING OF ENVIRONMENTALLY ASSISTED FATIGUE

Alireza Golahmar*[1], Emilio Martínez-Pañeda [2], Christian F. Niordson[1]
[1]Department of Civil and Environmental Engineering, Imperial College London, London SW7 2AZ, UK
[2]Department of Mechanical Engineering, Technical University of Denmark, Kgs. Lyngby DK-2800, Denmark

Summary A novel variational approach to assess environmentally assisted fatigue in structural steels is presented. A coupled deformation-diffusion-phase field scheme has been developed in the framework of the finite element method. The model builds upon a hydrogen-dependent surface energy degradation law based on Density Functional Theory that adequately characterizes the sensitivity of the fracture energy to atomic hydrogen concentration. The results demonstrate the capability of the model to appropriately capture the main trends observed in laboratory experiments; namely, the sensitivity of fatigue crack growth rates to (i) the hydrogen content and (ii) the loading frequency.

INTRODUCTION

The phase field fracture model has recently emerged as a promising computational method for addressing crack initiation and propagation in solids. The model builds upon Griffith's thermodynamics framework and enables predicting complex cracking features such as crack nucleation, branching, kinking or merging in arbitrary geometries and dimensions, on the original finite element mesh, and without convergence problems [1]. The method has very recently been extended to fatigue damage [2, 3], showing that features such as fatigue crack growth rate curves or S-N curves can be predicted without any prior assumption. However, most failures often occur due to the combination of environmental effects and mechanical fatigue loading. One of the most relevant environmental effects is the role of what is generally referred to as hydrogen embrittlement. Hydrogen has been known, for over a hundred years, to cause catastrophic failure in many engineering alloys such as high strength steels [4]. Hydrogen atoms enter the material, migrate through the crystal lattice and degrade the mechanical properties of the material, reducing (by up to 90%) the fracture toughness and augmenting fatigue crack growth rates.

In this work, the phase field formulation is extended to predict environmentally assisted fatigue. The modelling framework builds upon the success of recent phase field fracture formulations for environmentally assisted cracking under static loads [5, 6]. Of interest are hydrogenous environments and capturing the synergy between corrosion fatigue and hydrogen embrittlement. The model is first used to gain fundamental insight and provide a mechanistic rationale for the trends observed in the experiments; namely, the sensitivity of fatigue crack growth rates to the hydrogen content and the loading frequency. Secondly, the model is employed to predict the impact of the environment on fatigue crack growth rate curves, in several 2D and 3D case studies of technological interest, enabling optimising design and maintenance through *Virtual Testing*, as well as planning efficient and targeted experimental campaigns.

STRESS-ASSISTED HYDROGEN DIFFUSION COUPLED WITH PHASE FIELD FATIGUE

Hydrogen transport towards the fracture process zone and subsequent cracking are studied through a coupled mechanical-diffusion-phase field finite element (FE) formulation. The model builds upon: (i) a phase field formulation of fatigue cracking, (ii) a coupled mechanical-diffusion response, driven by chemical potential gradients, as an extension of Fick's law for mass diffusion, and (iii) a hydrogen-dependent surface energy degradation law grounded on Density Functional Theory (DFT). The response of a material point, in terms of displacements $\boldsymbol{u}$, phase field order parameter ϕ and hydrogen concentration C, is governed by a set of three equilibrium equations on a bulk domain Ω along with the corresponding set of boundary conditions on its external surface $\partial\Omega$ of outward normal $\boldsymbol{n}$,

$$\begin{aligned} &\nabla\cdot\boldsymbol{\sigma}=\boldsymbol{0} \\ &\nabla\cdot\boldsymbol{\zeta}-\omega=0 \\ &\frac{\mathrm{d}C}{\mathrm{d}t}+\nabla\cdot\boldsymbol{J}=0 \end{aligned} \quad \text{on } \Omega \qquad \begin{aligned} &\boldsymbol{h}=\boldsymbol{\sigma}\cdot\boldsymbol{n} \\ &p=\boldsymbol{\zeta}\cdot\boldsymbol{n} \\ &q=\boldsymbol{J}\cdot\boldsymbol{n} \end{aligned} \quad \text{on } \partial\Omega \tag{1}$$

where $\boldsymbol{\sigma}$ is the symmetric Cauchy stress tensor, ω and $\boldsymbol{\zeta}$ the microstress quantities work conjugates to the phase field ϕ and its gradient $\nabla\phi$, respectively, $\boldsymbol{J}$ the hydrogen flux, $\boldsymbol{h}$ the prescribed boundary traction, p the phase field fracture microtraction and q the concentration flux entering the body across its external surface. The deformation, diffusion and phase field fracture problems are weakly coupled. First, mechanical deformation affects hydrogen diffusion through the stress field by governing the hydrostatic stress dependence of the bulk chemical potential. Secondly, mass transport impacts the fracture resistance via hydrogen accumulation at the fracture process zone, lowering the critical energy release rate. Thirdly, the hydrogen-sensitive phase field variable degrades the strain energy density of the solid.

NUMERICAL RESULTS: PROPAGATING CRACKS IN THE PRESENCE OF HYDROGEN

The modelling framework is implemented in the commercial finite element (FE) package Abaqus using user-defined subroutines. The coupled deformation-diffusion-phase field FE equations are solved in an implicit time integration scheme by means of a residual control-based staggered algorithm [7]. A remote mode I K-field is prescribed and both crack initiation and crack growth are considered. Dimensional analysis shows that the hydrogen concentration ahead of a stationary crack can be quantified by the interplay between loading frequency f and hydrogen diffusion coefficient D via $\bar{f} = fR_0^2/D$ where R_0 is a measure of the gradients close to the crack tip: $R_0 = K_{\text{mean}}^2/E^2$. Fig. 1(a) demonstrates, in agreement with experimental observations, that the sensitivity of a material to hydrogen embrittlement is bounded between two limiting cases: (a) slow tests, where the test time significantly exceeds the characteristic diffusion time of hydrogen throughout the specimen – very low value of $\bar{f}$, and (b) fast tests, where the test time is much less than the characteristic hydrogen diffusion time – very high value of $\bar{f}$. Subsequently, the effect of hydrogen embrittlement on the stable crack growth behaviour (Paris law regime) is demonstrated in Fig1(b). By applying the well-known Paris equation $\mathrm{d}a/\mathrm{d}N = C\Delta K^m$, one can readily observe that C increases with the hydrogen content, in agreement with the experimental trends. On the other hand, results yield a Paris' exponent that demonstrates less sensitivity to the hydrogen content ($m3 \approx 3.2$), lying in all the cases in the experimentally reported range of 2 to 4 for metals in inert environments. For higher values of ΔK, the red curve (1 wt ppm) starts deviating from the linear behaviour, demonstrating a transition phase between the stable (Paris' regime) and unstable crack propagation regions. A reference stress intensity factor is defined as $K_0 = \sqrt{G_c(C)E/(1-\nu^2)}$ for $C = 13\text{wt}3\text{ppm}$. Other problem parameters are $f = 1\text{Hz}, R = 0.1, D = 0.0127\text{mm}^2/\text{s}, E = 210\text{GPa}, \nu = 0.3, \text{and}3G_c = 2.73\text{kJ/m}^2$.

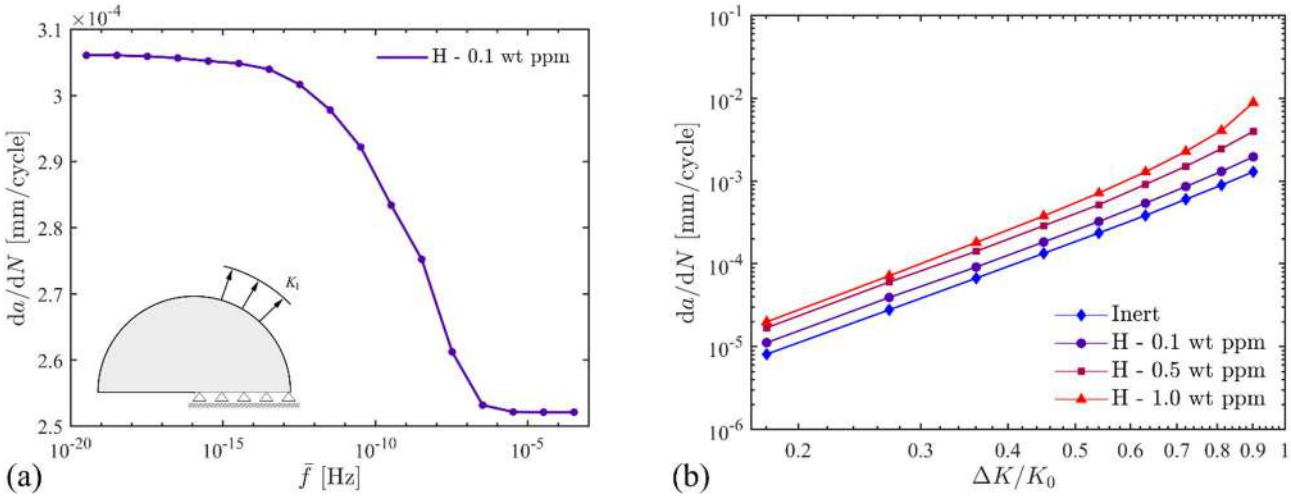

Figure 1. Hydrogen embrittlement effects on propagating cracks: (a) Sensitivity of crack growth rate to the loading frequency (relative to the diffusion coefficient) for $\Delta K/K_0 = 0.543$(b) Impact of environment on Paris curves.

CONCLUSIONS

We have presented a phase field formulation for the long-standing problem of environmentally assisted fatigue. A coupled mechanical-diffusion-phase field scheme has been developed in the context of finite element method using Abaqus user-defined subroutines. We show that the model can appropriately capture the main experimental observations: (i) the impact of environment on fatigue crack growth rates, (ii) the effect of loading frequency/testing time on the crack growth rate of a fracturing solid undergoing hydrogen embrittlement.

CRACK FRONT SHAPE EFFECT ON LIFETIME PREDICTIONS

Louis David*[1,2] and Véronique Lazarus[1]
[1]IMSIA, CNRS, EDF, CEA, ENSTA Paris, Institut Polytechnique de Paris, 828bd des Maréchaux, 91762 Palaise au cedex, France

Summary Accurate fatigue lifetime prediction is a central element in many industries. Often, a damage tolerant approach is used to ensure that some given imperfection are safe. However, these lifetime predictions are frequently made using simplified crack geometries (circular or straight cracks), leading to costly conservatism. Using an iterative perturbation method, we simulate the fatigue growth of many complexly shaped cracks, and find a metric of crack size whose evolution with the number of loading cycles does not depend on the actual shape of the crack, namely the cracked surface.

INTRODUCTION

Damage tolerant design of mechanical part assumes the presence of a known defect in the media and ensures that the crack propagation caused by this defect will not lead to catastrophic consequences before the next inspection or reparation. Such defects can have complex shapes as shown by initial observation or postmortem fractography, however, their lifetimes are often predicted using massively simplified geometries : circular or straight cracks, for example. This simplification leads to costly conservatism since the simple cracks used for lifetime assessment are bigger (for example totally enclose the original crack) than the original crack to prevent overly optimistic predictions. The aim here is to focus on the influence of the shape on lifetime predictions, and to find a way to use less conservative circular cracks to assess the lifetime of defects in damage tolerant design. Hence, we consider a planar crack embedded in an infinite, linear elastic isotropic material, loaded by a uniform and constant cyclic tensile mode I stress. We assume the crack advances following a simple Paris's law. In this way, the sole complexity comes from a possible distorted crack front, avoiding any additional effect such as free boundary conditions, mode mixity, material anisotropy or non-linearity, complex loading condition and history, or sophisticated advance law.

ITERATIVE PERTURBATION METHOD USED TO STUDY THE CRACK EVOLUTION

The perturbative method based on the weight-function theory initially developed by Bueckner-Rice [1, 2, 3], allows the computation of the variation of the stress intensity factor (SIF) along a given plane crack caused by some small perturbation of the crack front, knowing the SIF K along the original front and an influence function W derived from the weight function. Using it iteratively, we can simulate any propagation of a crack front if we know the initial K and W. Moreover, we can compute K and W for any crack front by perturbing a circle, for which they are known ($W = 1$, and $K = 2\sqrt{r/\pi}$, r being the radius). Therefore, the iterative perturbation method can be used to simulate the propagation and predict the lifetime of a crack of any shape subject to uniform remote tensile stress in an infinite media in two steps: (i) Starting from a circle and perturb it in order to get the desired shape (initialisation step, fig 1b); (ii) Apply perturbations that correspond to the advance of the crack given by a Paris's law or any fatigue propagation law (propagation step, fig 1c). Details of the method and its implementation can be found in [4].

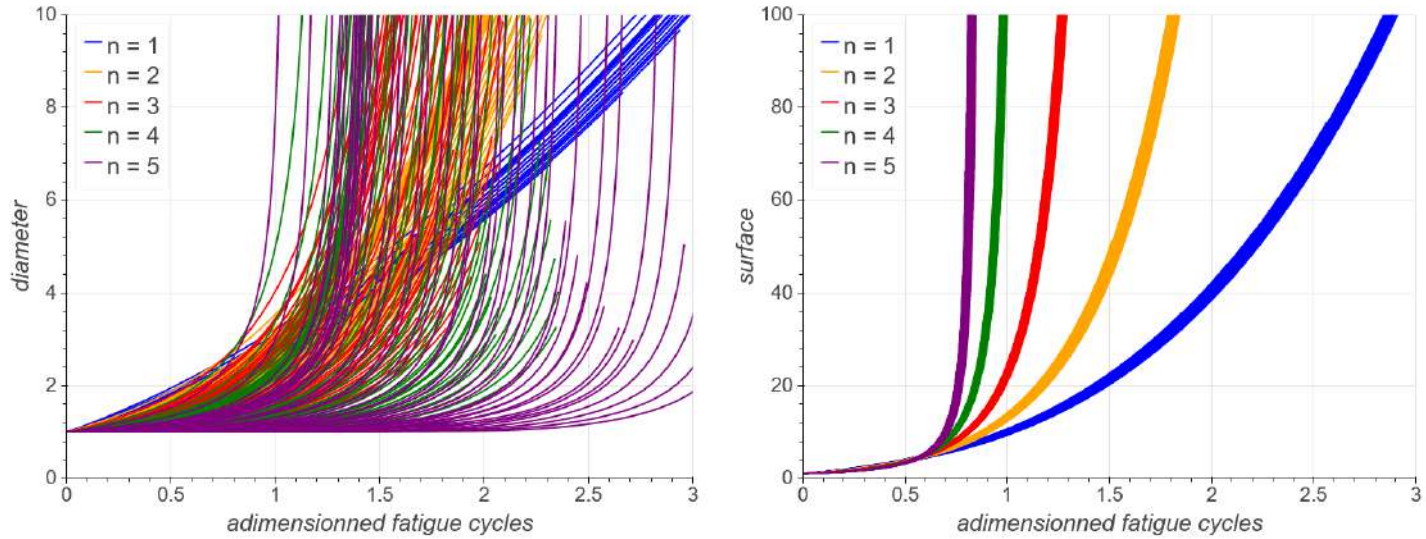
Figure 1: Example of flower shaped crack with five petals used in this study

For a given planar crack front (see figure 1), several metrics can be chosen to describe its size a: diameter, width, area, and perimeter. For each of them, the iterative perturbation method can be used to get the dimensionless crack size a/a_0 as a function of the

*Corresponding author. E-mail: louis.david@ensta-paris.fr.

dimensionless number of loading cycles $NC\,(\Delta\sigma)^n\,a_0^{n/2-1}$, $\Delta\sigma$ being the amplitude of the applied stress, C, n Paris parameters, a_0 the initial crack size.

Here, two metrics are chosen as representative cases: the external diameter and the surface area. The figure 2 shows for both metrics, the evolution of the crack size with the number of loading cycle for 450 cracks different crack growth simulations. Each curve represents a single crack growth simulation and a given value of n ($n = 1$ being the slowest growing bundle and $n = 5$ the fastest). We observe that, while the curves are dispersed for choice 1, they are grouped in five bundles corresponding to the five values of n when the surface area is chosen as metric. It shows that this evolution does not depend on the crack shape provided that the crack area is chosen. This is the main result that can be directly implemented in damage tolerant methodologies : given an arbitrarily shaped crack, its lifetime can be predicted with acceptable precision as if it was a circular crack of the same initial area (under the hypotheses listed earlier). The precision of this approximation is quite good since the bundles are rather tight.



(a) adimensionned cracked diameter

(b) Adimensionned cracked surface

Figure 2: Evolution two different crack size metrics versus the dimensionless number of loading cycles for large bunch of different crack shapes and values of the parameter n of the Paris's law

CONCLUSIONS

Using an iterative perturbative method whose main advantage is to restrict the meshing operations to that of the initial crack front, we show that under the hypotheses of a plane crack uniformly loaded in mode I only in an infinite media :

1. The evolution of a cracks' surface area due to its propagation in fatigue is not dependent on the shape of the crack.
2. Using the fact that cracks of equal area have therefore similar lifetimes in fatigue, it is possible to avoid some conservatism in damage tolerant design by using simpler cracks (in our case circular) with an area equal to that of the original crack, instead of cracks enclosing the original crack, for example.
3. It is possible to keep using analytical tools requiring simple crack shapes to assess the lifetime of a crack while taking into account the real shape of defect more accurately: only the choice of equivalent circular crack is changed.

IS THERE A UNIFIED RULE FOR POLYGONAL CRACKING IN COOLED LAVA SURFACE?

Yuri Akiba, Aika Takashima, and Hiroyuki Shima*[1]
Department of Environmental Sciences, University of Yamanashi, Yamanashi, Japan

Summary An orderly polygonal crack pattern is often found on the exposed surface of columnar joints, which are geological structures engendered from cooled lava flow. In the present work, field measurements of columnar joints at four sites with different lithologies in Japan were performed to explore the unified law that regulates the statistical fluctuation in the geometry of polygonal cracks. Drone shooting and digital image analysis were fully utilized to examine the geometric attributes of constituent polygons and their statistics with high accuracy. The investigation established that the geometric fluctuation is regulated by the Gumbel distribution, a special class of distribution curve that is widely used when analyzing deterioration phenomena over time and accidental fracture phenomena. A possible relevance of the present result to the desiccation-based crack network is also discussed.

INTRODUCTION

Polygonal cracking is a typical quasi-regular pattern that occurs spontaneously in nature. It includes cracks on dried soil surface and those in old paintings; a further example is found on the planetary surface [1]. In polygonal crack systems, the entire surface of the fractured medium is divided into numerous polygonal cells in which hexagons, pentagons, and heptagons dominate with irregularity in terms of edge lengths and cell domain area. The most important observation is that the geometry of the polygonal patterns is preserved over many systems despite considerable differences in chemical composition and spatial length scale. This strongly suggests the existence of a common rule for polygonal crack networks, although it has not yet been clarified which mechanism governs this spontaneous formation.

To elucidate the unified rule, the statistical fluctuations in the crack pattern geometry observed at the exposed surface of the columnar joint were investigated in this study. A columnar joint is a spectacular geological structure composed of an array of well-ordered prismatic columns with polygonal sections. The quasi-regularity in the column's cross section is a consequence of inward penetration of cracks driven by thermal contraction of the original hot lava flow. In principle, the typical column diameter depends on the cooling rate of lava, whereby slower cooling rates produce large-diameter columns and vice-versa. In addition, a previous argument based on the least-work principle led to a conjecture [2] that each polygon tends to be a cyclic polygon, that is, a polygon with vertices upon which a circle can be circumscribed. However, it should be noted that the cracking process is intrinsically stochastic; thus, in real columnar joints, the section geometry should deviate from cyclic polygons in both size and shape. The two competing effects, preference to and deviation from cyclic polygons, will regulate the degree of geometric fluctuation in the columnar section. If it is true, then a unified rule regarding the fluctuation in polygonal cracking at the surface can be established. In order to test this hypothesis, field surveys of several columnar joints in Japan were conducted in this study. At each locality, the columnar joint exposed surface was photographed from above by a drone, followed by image analysis to study the geometric fluctuation in polygonal cracking.

METHODS

Japan is one of the world's most volcanically active countries, with many volcanoes distributed along the subduction zones of four tectonic plates. When flowing lavas cool and contract, this may result in formation of fractures and jointing called columnar jointing. Consequently, various columnar joints with diverse lithological characters and columnar cross-section sizes are distributed at more than 60 locations in Japan. Among the choices, four specific sites were investigated as presented in Figure 1. Three sites (O, Sm, and Sz) are positioned along the seacoast and the remaining site (Y) is situated inland. It was necessary to choose field survey sites that did not have significant obstructions, such as buildings or overgrown tree branches, to obtain sufficiently clear image analysis photographs.

Aerial images of the localities were taken using a drone. From a height of 10 m above, it was directed to take an elevated view of the site using the hovering mode. Next, the drone was sequentially moved slightly parallel to the ground such that additional overlapping photos could be acquired. An example of the aerial photos taken from O-site is shown in Figure 2. Several hundred photos that were taken at each site were merged into a single large-scale image, which was then converted into polygonal patterns using an analytic software called ArcGIS. The resulting data set contains geometric information about the coordinates of the polygon vertices and the topology of the line segments between the vertices. The total number of polygons acquired was 1069 from O-site, 894 from Y-site, 1012 from Sm-site, and 3987 from Sz-site.

Once the numeric data were processed, the geometric deviation of constituent polygons from a cyclic counterpart was quantified. Given an n-sided polygon, any three vertices that make up the polygon were selected to form a triangle connecting each vertex. Then the coordinates of the center of the circle that passes through these three points were calculated; see Figure 3. This procedure was repeated for all ${}_nC_3$ triangles in order to obtain a point set of ${}_nC_3$ circumcenters, designated by $\boldsymbol{R}_i$ $(1 \leq i \leq {}_nC_3)$. Then the geometric center of the point set, designated by $\boldsymbol{G}$, and distances given by $r_i = |\boldsymbol{R}_i - \boldsymbol{G}|$ were evaluated. Finally, μ was defined by the standard deviation of r_i divided by the

*Corresponding author. E-mail: hshima@yamanashi.ac.jp.

average of r_i; $\mu = 1$ if the *n*-gon inscribed a circle, while $\mu \gg 1$ if the *n*-gon was considerably distorted compared with a cyclic polygon.

RESULTS & DISCUSSION

Figure 4 shows the probability distribution of the μ value for each of the four investigation sites. All the distributions are upward convex with asymmetry, which are slightly slanted to the left. After the fitting procedure, it was found that all the data are well collapsed onto a special class of distribution curve called the Gumbel distribution, independent of the size, shape, or investigation sites. The Gumbel distribution is a probability distribution that is widely used to statistically describe the strength of brittle materials and is also used to analyze deterioration phenomena over time and accidental fracture phenomena. The study's finding implies that the geometric fluctuation in polygonal cracking at columnar joints is regulated by the Gumbel distribution.

An interesting problem related to the present finding is whether the Gumbel distribution is universal over other types of polygonal cracking. For instance, the polygonal prismatic shape of columnar joints can be reproduced by numerous table-top analog experiments as have been successfully demonstrated earlier. Most of these experiments were based on desiccation cracks of starch–water mixtures [3] and calcium carbonate–water mixtures [4]. These mixtures consist of solid grains and pore spaces filled with either liquid or air bubbles. Upon drying, the liquid content evaporates, causing volumetric shrinkage of the mixture. Subsequently, cracks occur at the surface and develop toward the interior of the mixture. As a result, these materials exhibit a regular array of tiny polygonal prisms reminiscent of columnar joints. Considering the similarity in the cracking mechanism, it is expected that the Gumbel distribution also governs analog-experiment systems. Regarding the issue, we have not yet obtained a conclusion at the time of writing this Abstract. The experimental results will be presented at the conference venue.

CONSTITUTIVE MODELLING: UP- AND DOWN-SCALING (MICRO TO MACRO AND BETWEEN)

Stefan Luding[1]
[1]Multiscale Mechanics, Engineering Technology, University of Twente, Enschede, Netherlands

Summary The behavior of particles is of interest in a wide range of industries and nature. These materials are dissipative and disordered with a wide distribution of particle sizes and materials or mixtures, and can behave both solid- or fluid-like. The related mechanisms and processes are active at multiple scales (from nanometers to meters) and understanding them is an essential challenge for both science and application, as well as the theoretical description of all the transitions between the different states. The step from micro-mechanics(particle simulations) to large-scale flow applications, due to their enormous particle numbers, has to be addressed by so-called micro-macro transition methods that translate particle positions, velocities and forces into density-, stress-, and strain-fields, compatible with the conservation equations for mass, momentum and energy of continuum mechanics.

OVERVIEW

The behavior of particles such as powders and granular matter is of considerable interest in a wide range of industries and nature. These materials are intrinsically dissipative and disordered; often they come with a wide distribution of particle sizes and materials or mixtures, and can behave both solid- or fluid-like. The related mechanisms and processes in particle systems are active at multiple scales (from nanometers to meters) and understanding them is an essential challenge for both science and application, as well as the theoretical description of all the transitions between the different states.

In order to understand the fundamental micro-mechanics one can use particle simulation methods [1-6]. However, large-scale flow applications (due to their enormous particle numbers) have to be addressed by coarse-grained models [1,3,6] or by rheology and continuum theory [1,5,6]. In order to bridge the gap between the scales, so-called micro-macro transition methods are necessary, which translate particle positions, velocities and forces [2,3,4] into density-, stress-, and strain-fields, which all must be compatible with the conservation equations for mass, momentum and energy of continuum mechanics.

THERMO-HYDRO-MECHANICAL BEHAVIOUR OF FROZEN SOILS: TESTING AND MODELLING

Francesca Casini[1]
[1]Department of Civil Engineering and Computer Science Engineering, Universit degli Studi di Roma Tor Vergata, Roma, Italy

Summary Artificial Ground Freezing (AGF) is often used as temporary supporting technique for excavation in granular materials below the water table . The ability to predict the effects induced by AGF on granular materials is therefore crucial to assessing construction time and cost and to optimising the method. In this keynote, the thermo-hydro-mechanical behaviour of frozen soil is presented and discussed. Then, the experimental results obtained using an advanced triaxial apparatus (FROZEN) working under temperature and stress path controlled shown.
Finally, the experimental results are interpreted using a constitutive model that encompasses frozen and unfrozen behaviour within a unified effective-stress-based framework. It makes use of a combination of ice pressure, liquid water pressure and total stress as state variables.

INTRODUCTION

The control of displacements is crucial to the viability of urban tunnelling in soft ground as ground movements transmit to adjacent structures as settlements, rotations and distortions of their foundations, which can, in turn, induce damage affecting or function, and, in the most severe cases, stability of the structure. Therefore, is necessary to adopt controllable method as support of excavation to mitigate damage on the building surrounding.

The thermo-hydro-mechanical (THM) processes induced by freezing and thawing of pore fluid within soils are complex and can have significant mutual interaction [1]. As the temperature decreases, the ice content of the soil increases; the ice becomes a bonding agent between soil particles or blocks of rock, increasing the strength of the soil/rock mass and modifying the pore water pressures and the effective stress on the soil skeleton, which, in turn, induces mechanical deformation. At the same time, any changes in the hydraulic and mechanical boundary conditions can affect the thermal processes by advection and changes of ice and water contents [1].

The experimental behaviour of frozen soils are first summarized based on the available literature data. Then, some recent advances in the development of new apparatus are presented and a set of experimental results discussed. Finally, the ability of new fully coupled THM framework developed to describe the behaviour of frozen soils is validated against experimental data ([2], [3]).

SIMULATION OF UNDRAINED BEHAVIOR OF SAND-SILT MIXTURES USING GENERALIZED PLASTICITY MODEL WITH STATE PARAMETER

Fu-Hsuan Yeh*[1], Min-Chien Chu[1], Louis Ge[1], and Chi-Chin Tsai[2]
[1]Department of Civil Engineering, National Taiwan University, Taipei, Taiwan
[2]Department of Civil Engineering, National Chung Hsing University, Taichung, Taiwan

Summary Recent findings have shown that sands with a high amount of fines, non-plastic and/or low plastic silt exhibit a complex stress-strain-volume change behavior. From past research, one of the factors affecting the behavior of granular material is effective mean stresses. The effect of fines content (FC) on critical state, including effective mean stresses (p') and void ratio, is considered to simplify a constitutive model in order to present the complexity of geomaterial. From a series of triaxial test results, the void ratio was found to be presented in terms of FC and p'. Therefore, the aim of the research is to numerically perform monotonic undrained triaxial tests within the framework of a generalized plasticity model, where a state parameter was incorporated. In summary, the proposed model is capable of mimicking the stress-strain-volume change behavior of sand-silt mixtures.

INTRODUCTION

The concept of generalized plasticity theory was first introduced by Pastor and Zienkiewicz in 1985 [1]. Unlike conventional elastoplastic hardening models, the developed model with an explicit form provides an analytical geometrical interpretation to formulate stress-strain behavior through the plastic flow rule, loading direction, and plastic modulus. The theory of generalized plasticity incorporating the state parameter is adopted herein to describe the constitutive behavior of the sand-silt mixtures. Within this framework, the fines content (FC) in the state parameter has to be considered to improve the accuracy of the model.

GENERALIZED PLASTICITY MODEL

Generalized plasticity theory incorporating a state parameter

The model incorporates the deformation characteristics of sand and sand-silt mixtures into generalized plasticity by subsequently defining nonlinear elasticity, dilatancy, and plastic modulus. In recent years, a number of models based on this theory have been developed to simulate the specific soil materials ([2]-[7]). This model has the advantage that the yield and potential surfaces are not directly defined, but only the scalar functions for plastic modulus $H_{L/U}$, direction tensors $\mathbf{n}$, and $\mathbf{n}_g$, are required.

For conventional elastoplastic behavior of any materials. The total strain increment can be divided into elastic and plastic components as follows:

$$d\boldsymbol{\varepsilon} = d\boldsymbol{\varepsilon}^e + d\boldsymbol{\varepsilon}^p \tag{1}$$

where $d\boldsymbol{\varepsilon}$, $d\boldsymbol{\varepsilon}^e$, and $d\boldsymbol{\varepsilon}^p$ are the increments of total, elastic, and plastic strain tensors, respectively.

The increments of elastic and plastic strain can be calculated as below:

$$d\boldsymbol{\varepsilon}^e = \mathbf{C}^e : d\boldsymbol{\sigma} \tag{2}$$

, and

$$d\boldsymbol{\varepsilon}^p = d\lambda \mathbf{n}_g = \frac{1}{H_{L/U}} \left(\mathbf{n}_{gL/U} \otimes \mathbf{n} \right) : d\boldsymbol{\sigma} \tag{3}$$

where $\mathbf{C}^e$ is the elastic constitutive tensor, $d\boldsymbol{\sigma}$ is the increment of the stress tensor, $\mathbf{n}_g$ is the unit tensor defining the plastic flow direction, $\mathbf{n}$ represents the loading-direction tensor, $d\lambda$ is a plastic scalar, and $H_{L/U}$ is the plastic modulus, which can be assumed directly without introducing a hardening rule. Subscripts L and U indicate loading and unloading, respectively.

In this study, the definition of the elastic matrix, flow rule, plastic modulus is based on Manzanal et al. [6], whereas the state parameter is extended in following chapter.

STATE PARAMETER AND CRITICAL STATE

In a series of monotonic tests, the results show that the void ratios are affected by the fines content and effective mean stresses. The correlations, including the 3D curved surface and projected fitting curves at a critical state, are shown in Figure 1. The void ratio e_{cs} at the critical state is the function of fines content and effective mean stress, which is defined as

$$e_{cs} = f(\mathrm{FC}, p') = a + b \times \mathrm{FC} + c \times \mathrm{FC}^2 + d / p' \tag{4}$$

where a, b, c, and d are model constants, FC is fines contents, and p' is effective mean stress. These model constants are determined by fitting the laboratory test data.

Moreover, in the proposed model, the state parameter ψ is followed by Been and Jefferies [8] as:

$$\psi = e - e_{cs} \tag{5}$$

where e is the void ratio varying at the loading stage.

*Corresponding author. E-mail: d06521001@ntu.edu.tw

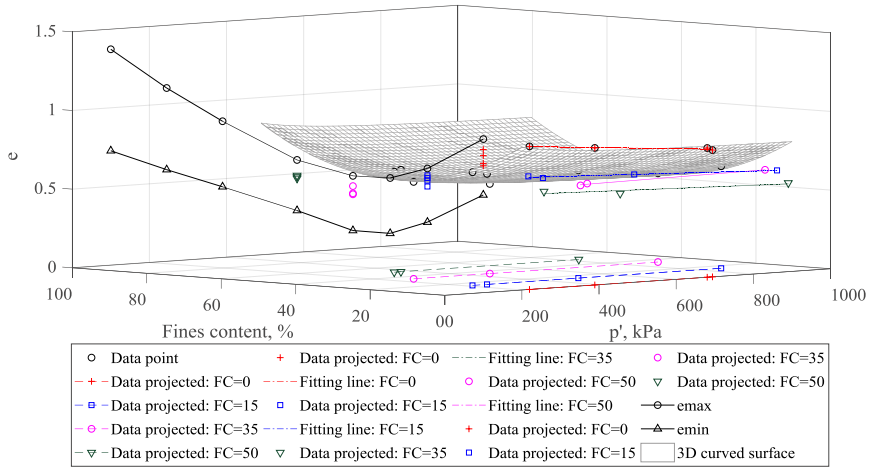

Figure 1. Illustration of critical state surface in effective mean stress (p') and fines content (FC)

MODEL VALIDATION AND SIMULATION

In order to consider the different percentages of fines content under varies effective mean stresses, the state parameter incorporating fines content is involved so that these parameters can be determined meaningfully. Figure 2 displays the simulation results of the stress paths, the deviatoric stress versus axial strain response, and pore pressure verse axial strain behavior under different fine aggregates, and shows that the model can fit the laboratory test data.

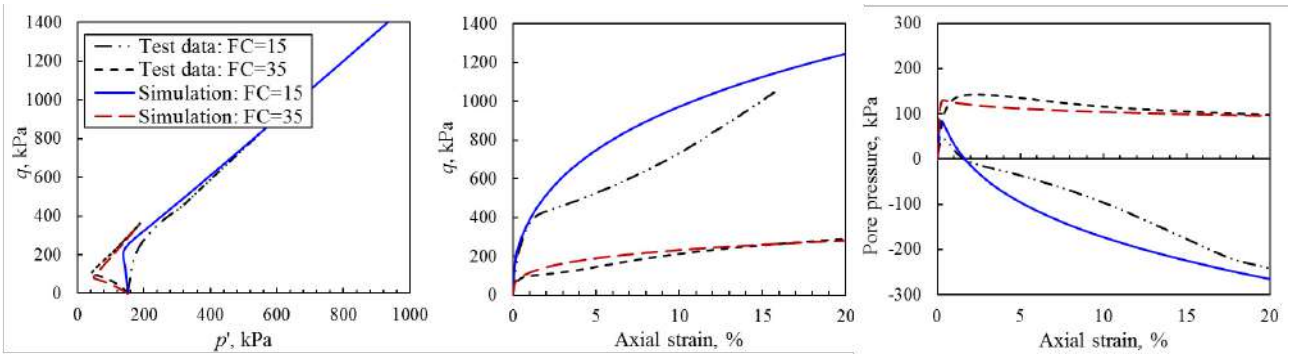

Figure 2. Undrained triaxial compression tests on sand-silt mixtures

CONCLUSIONS

The proposed model with a state parameter incorporating fines content has been shown to predict the undrained behavior of sand-silt mixtures. Also, the generalized plasticity model has been recognized as an effective framework to describe soil behavior. Through the study, a series of monotonic triaxial tests were successfully simulated by the proposed model. The results show that the stress-strain response of sand-silt mixtures can be captured by this model.

ON THE BEHAVIOUR OF FINE-GRAINED SOILS IN LABORATORY TESTS AND CONSTITUTIVE MODELING

Merita Tafili*[1] and Theodoros Triantafyllidis[1]
[1]Institute of Soil Mechanics and Rock Mechanics, Karlsruhe Institute of Technology, Karlsruhe, Germany

Summary The complex behaviour of clays is described with a new constitutive model and by experimental observations. Hereby, a new experimental study performed on Lower Rhine Clay (LRC) is presented. Based on the dilatancy rule presented by Taylor (1984), a state dependent dilatancy relation for clays is proposed. A new model neither afflicted with the intergranular strain nor with the fabric-dilatancy tensor is proposed. This model introduces an evolving and rotating historiotropic flow surface, which accounts i.a. for the induced anisotropy and for the degradation of shear modulus. Simulations of LRC are shown to be in good agreement with experimental results, whereby also the 8-shaped hysteresis in the stress space under undrained cyclic loading has been described well. The validation of the model is performed simulating some boundary value problems with ABAQUS.

PROBLEM DEFINITION

Worldwide, more and more areas with soils of low bearing capacity and low stiffness, as in the case of cohesive soils, have to be accessed. Reasons for this include, for example urban expansion or infrastructure projects. Investigations of the ultimate limit state and in particular the serviceability of geotechnical structures on soft soils by means of numerical methods require the use of sophisticated material models which accurately reproduce the specific material behaviour of these soils. Different types of loading have to be considered. A static (or monotonic) loading results from the construction of buildings or a groundwater drawdown, while a cyclic loading is caused by traffic due to cars, trucks and trains. A well documented example is the Metro Line No. 4 in Shanghai [1] where up to 16 cm cumulative settlement within the first four years of operation has been recorded (Fig. 1a). These settlements were mainly caused by the cyclic loading due to the passing trains in the tunnel and resulted in soil subsidence of the surface where buildings suffered cracks and damage. Due to the plasticity of the subsoil, time-dependent settlements have been observed as well.

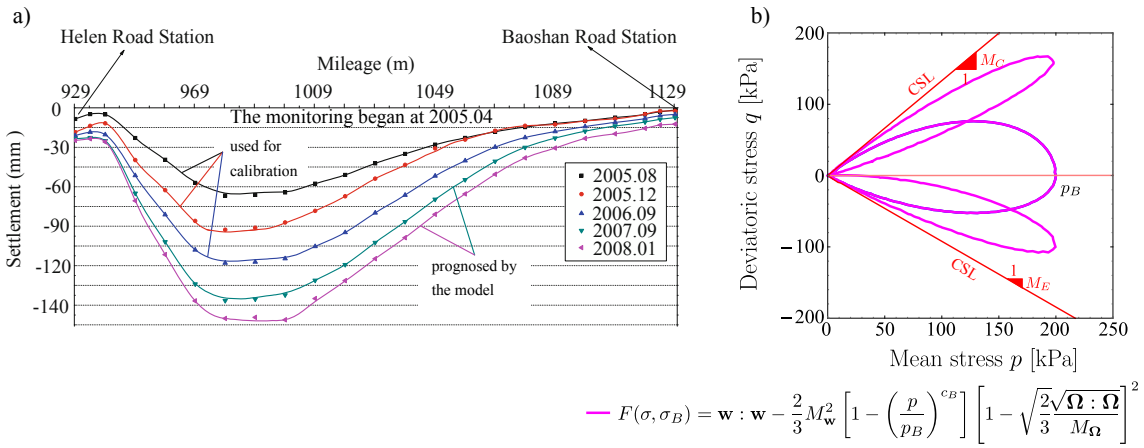

Figure 1: a) Monitoring data (symbols) and prediction with the model (solid lines) of tunnel settlement of Metro Line 4. b) Historiotropic surface for different values of the deviatoric structural tensor $\mathbf{\Omega}$.

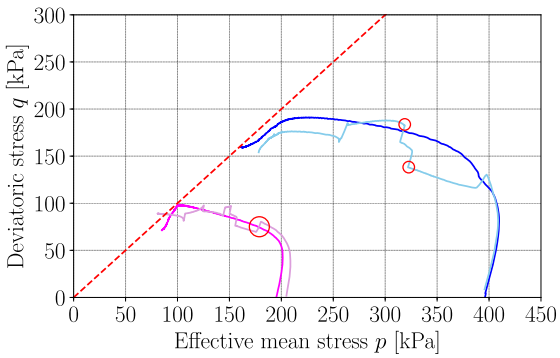
To enable the development of constitutive models for the purpose of improving the forecast capabilities of the practical problems addressed above, a new experimental series on the highly plastic LRC ($I_P = 34\,\%$) has been performed at the Institute of Soil Mechanics and Rock Mechanics (IBF) at KIT. Due to the high plasticity of LRC, the realisation of these experiments takes a comparatively very long time. The study comprises tests on normally as well as overconsolidated samples under monotonic and cyclic loading. The loading velocity has been varied in order to evaluate the strain rate dependency of the LRC behaviour. Based on these laboratory tests a new constitutive model with anamnesis function is developed. This model is neither afflicted with the intergranular strain nor with the fabric-dilatancy tensor. It introduces an evolving (in magnitude) and rotating (anisotropic) historiotropic flow surface (Fig. 1b), which accounts i.a. for the induced anisotropy (preloading history of the soil) and for the degradation of shear modulus. The validation of the model was accomplished with the forecast of the accumulated deformations due to cyclic loading of Metro Line No. 4.

RESULTS AND CONCLUSIONS

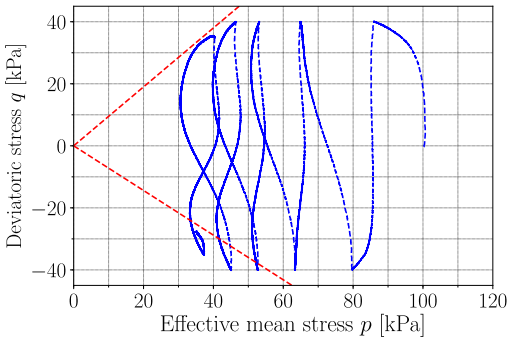
The experimental study on LRC comprises oedometric tests as well as triaxial tests on normally and overconsolidated samples under monotonic and cyclic loading with variation of initial mean pressure, displacement rate, initial overconsolidation ratio OCR_0 and deviatoric stress amplitude. The effective stress paths of initially normally consolidated samples

*Corresponding author. E-mail: merita.tafili@outlook.de.

reflect a contractant behaviour after an initial isobaric increase of the deviatoric stress. The shear strength increases with increasing initial mean pressure. For initially overconsolidated samples $OCR_0 > 2$ the material behaviour is rendered dilatant and the undrained shear strength increases with OCR_0. The well-known decrease of the undrained shear strength with decreasing displacement rate has also been confirmed with these experiments, see Fig. 2a. Isotropic consolidation with variation of cyclic deviatoric stress amplitude lead to a failure due to large strain accumulation with eight-shaped effective stress paths in the final phase of the tests, Fig. 2b. The inherent anisotropy has been additionally evaluated using samples cut out in either the vertical or the horizontal direction.



(a) Monotonic undrained triaxial tests with variation of displacement rate $\dot{s}$ on initially normally consolidated samples.



(b) Cyclic undrained triaxial test with $q^{ampl} = 40$ kPa and $\dot{s} = 0.02$ mm/min.

Figure 2: Results of some laboratory tests on LRC.

The new constitutive model with anamnesis function has been used to simulate the experiments. Besides the introduction of inherent and induced anisotropy through the historiotropic surface shown in Fig. 1b, a state-dependent dilatancy rule for clays (depending also on the straining direction) has been proposed:

$$\tan\psi = \beta \left(\overrightarrow{\boldsymbol{\sigma}}^{*} : \overrightarrow{\dot{\boldsymbol{\varepsilon}}}^{*} \tan\varphi_m - \tan\varphi_c \left(\frac{e}{e_c} \right)^{n_{PTL}} \right). \tag{1}$$

Three strain rate components consisting of: total $\dot{\boldsymbol{\varepsilon}}$, hypoplastic $\dot{\boldsymbol{\varepsilon}}^{hp}$ and viscous $\dot{\boldsymbol{\varepsilon}}^{vis}$ strain rates are introduced into the model. Therefore, also rate- and time-dependent phenomena can be described. Even the eight-shaped stress hysteresis at cyclic mobility is reproduced well with this model, see Fig. 3.
In addition the model has been used to predict the monitored settlements of Metro Line No. 4 (symbols in Fig. 1a). Thereby, the three monitoring data sets from August 2005, December 2005 and September 2006 have been used to calibrate the material parameters of the constitutive anamnesis model (solid lines in Fig. 1a). These parameters are used to calculate the subsequent settlements in September 2007 and January 2008 showing a perfect agreement between the model and the monitored data (solid lines in Fig. 1a).

Summary In this paper, a novel hybrid FEM and Peridynamic modelling approach is used to predict the forerunning fracture behavior in dry and saturated porous solids. Fracturing in a rectangular structure with a central initial crack is simulated both under mechanical loading and fluid-driven conditions. In the mechanical loading fracture case, fixed concentrated forces are applied on the upper and lower surfaces of the initial crack at the central position to force its opening. In the fluid-driven fracture case, a fixed fluid injection rate is adopted. Under the action of the applied concentrated force and fluid injection, forerunning of the fracture is observed.

INTRODUCTION

According to some experimental and numerical evidences [1-2], the dynamic fracture propagation in dry and fully saturated porous solids is not always smooth and continuous. The stepwise fracture tip advancement has duly been documented with experiments and geophysical observations [3]. A special type of stepwise tip advancement is forerunning observed in dynamics [4-6]. In particular Tvergaard and Needleman [4] observe in case of a dynamic crack growth in a ductile porous medium that "sometimes a secondary crack develops ahead of the main crack and subsequently links up with it. This leads to a situation where the crack appears to be stationary for a relatively long time and then grows rather abruptly". Inspired by [6], which evidences that the action of high-amplitude incident sinusoidal waves could lead to forerunning mode of fracture, Peridynamic-based numerical approach is used to investigate the possibility of forerunning fracture behavior in a rectangular structure with a central initial crack under different loading conditions. A novel hybrid FEM and Peridynamic modelling approach, based on Hybrid Mixture Theory [7] and proposed in [8], is adopted to simulate the hydro-mechanical coupled fracturing process in saturated porous media. Under the action of the applied concentrated force and fluid injection, forerunning fracture behavior is observed in the structure.

MATERIALS AND METHODS

Governing equations

In the whole domain Ω of the porous medium, the solid phase is governed by the ordinary state-based peridyanmic equation:

$$\rho\ddot{\boldsymbol{u}}\left(\boldsymbol{x},t\right)=\int_{\mathcal{H}_x}\left\{\underline{\mathbf{T}}\left[\boldsymbol{x},p,t\right]\left\langle\boldsymbol{\xi}\right\rangle-\underline{\mathbf{T}}\left[\boldsymbol{x}',p',t\right]\left\langle-\boldsymbol{\xi}\right\rangle\right\}dV_{x'}+\boldsymbol{b}\left(\boldsymbol{x},t\right)\tag{1}$$

and the flow field in the saturated porous medium is described by Darcy's law, resulting in a mass conservation equation of the fluid as:

$$\rho s\frac{\partial p}{\partial t}+\rho\alpha\frac{\partial\varepsilon_v}{\partial t}+\rho\nabla\cdot\left[\frac{k}{\mu^w}\left(\nabla p+\rho g\right)\right]=q\tag{2}$$

Discretization and numerical algorithm

In a plane discretization, the solid portion is discretized by PD nodes and the fluid portion is discretized by 4-node FE elements. PD nodes and FE nodes share the same node coordinates. A 'staggered approach' is used to solve the coupled system. The peridynamic and FEM equations are solved sequentially, and the previously solved results of $\boldsymbol{u}$ and $\boldsymbol{p}$ are used to evaluate the fluid volumetric source terms or nodal forces for the next solving sequence.

NUMERICAL RESULTS

The geometry and constraints of the considered rectangular structure are shown in Figure 1. The mechanical and fluid parameters used in the calculation are, Young's modulus: $E=10GPa$, Poisson's ratio: $\upsilon=0.2$, critical energy release rate: $G_c=1J/m^2$, porosity: $n_r=0.002$, mass density: $\rho_r=\rho_f=1000kg/m^3$, Biot constant: $\alpha=1$, bulk modulus and viscosity coefficient of the fluid: $K_w=2.2GPa$ and $\mu_w=10^{-3}Pa\cdot s$, permeability coefficient of the reservoir domain: $k_r=10^{-12}m^2$.

Two different loading conditions, mechanical loading and fluid injection, are adopted. In the mechanical loading case, concentrated forces, $25000N$, are applied on the upper and lower surfaces of the initial crack at the central position to force its opening, and both dry and saturated condition are considered. In the fluid injection case, the injection rate is adopted as $Q=5\times10^{-2}m^2/s$. In the simulation, the forerunning of the fracture, see Figures 2a to 2c, is observed. As shown in Figures 3a-3d, the wave propagation of pore pressure is also observed in the saturated structures both under the action of mechanical loading and fluid injection conditions.

CONCLUSIONS

The hybrid FEM and Peridynamic modelling approach is applied in the simulation of dynamic fracture propagation in dry and fully saturated porous media. In the simulations, forerunning fracture events, a phenomenon that has been observed experimentally in geomaterials [5], occur in the studied structures. Besides of the mechanical wave, the pressure waves have also been numerically confirmed to exist in saturated structures. The interaction between mechanical waves and pressure waves makes dynamic fracturing in saturated media more complicated, influencing also the forerunning episodes.

3D DEM INVESTIGATION OF THE MECHANICAL PROCESSES OCCURING IN DRY GRANULAR MASSES DURING IMPACTS

Irene Redaelli*[1], Claudio di Prisco[1], and Francesco Calvetti [2]
[1]Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy
[2]Department of Architecture, Built Environment and Construction Engineering Politecnico di Milano, Milano, Italy

Summary In this work, the authors will investigate the physical and mechanical processes occurring during impacts between rigid bodies and coarse granular materials. Two different configurations will be considered: (i) impact between a granular flowing mass and a rigid body at rest, (ii) impact between a boulder and a granular material at rest. The impact process will be numerically simulated by employing the Discrete Element Method (DEM) since this is capable of automatically take into account the discrete nature of the granular material and allows to correlate the macroscopic quantities, such as the impact force, with local information.

INTRODUCTION

Dry granular materials can be involved in impacts phenomena either when a flow like landslide interacts with structures or during rockfall events, when a boulder impacts against the coarse granular stratum placed along a slope. In the first case, the granular mass is characterized by an initial geometry, velocity and porosity and impacts against a fixed rigid body; in the second case, the collision involves a rigid boulder, characterized by an initial velocity and mass, and the granular material, which is at rest.
In both cases, due to the dynamicity of the impact process, different phenomena occur in the granular materials, such as shock wave propagation, wave reflections, bouncing, force chains buckling effects and phase transition. These processes are strongly influenced by either the energy content of the impact, the granular mass packing, and particle size distribution. The purpose of this work is to investigate the physical mechanisms governing the dynamic interaction of a dry granular mass and a rigid body. The Discrete Element Method is employed and the dry granular mass involved in the impact process is represented as an assembly of polydisperse spherical particles. The contact force among grains is computed by employing a linear model along the normal direction and a linear model in series with a slider obeying the Coulomb failure criterion, along the tangential direction. The parameter employed in [1, 2, 3] have been imposed and damage or fragmentation of soil particles is not considered. In order to reproduce the response of a real granular material with non-spherical particles, particles rotation is not allowed [1]. The DEM allows to correlate the macroscopic quantities, such as time evolution of the impact force, with local information (contact forces, particle velocities, coordination number, energy propagation) and to highlight the physical and mechanical processes responsible for the macroscopic behavior [1,2].

NUMERICAL MODELS AND RESULTS

Dry granular masses impacting against a rigid obstacle

The impacting granular mass has been generated just in front of a vertical wall with a prescribed geometry and initial conditions (Fig 1a) [1, 2, 3]. The geometry of the impacting mass is characterized by the length L and height h. The front of the sliding mass is assumed to be planar and inclined of an angle a. Plain strain conditions are imposed by confining the flow between two smooth lateral walls. The flow width is chosen in order to avoid boundary effects [3]. The mass flows on a frictional horizontal wall, wheras the obstacle is modelled as a frictional vertical rigid and massless wall.
After the impact, different concurring and competiting processes are observed within the granular media [2, 4]: the increase in the contact area between the mass and the obstacle, the propagation of compression and no-tension waves and internal buckling. The last two mechanisms cause a continuous fluidification and resolidification of the granular material, due to the disruption and regeneration of force chains. All these processes are governed by the geometry of the sliding mass (length, width and flow height, inclination of the front) by the initial mass velocity and porosity. Basing on the correlation between physical observations and the shape of the force-time curve, a formula to be used as an input for the dynamic design of sheltering structures has been proposed.

Rigid boulder impacting against dry granular masses

The soil cushion is modelled as an assembly of polydisperse spherical particles [5, 6]. This cushion is generated by employing the pluviation method and is confined by four lateral walls and one wall at the bottom (Fig 1b). The size of the domain has been chosen in order to eliminate lateral boundaries disturbances. Inclined layers are generated by quasi-statically rotating the model of a prescribed angle. The spherical impacting block is generated on the top of the granular layer with an initial incident translational velocity (vertical or inclined). After the impact, an energy exchange between the block and the granular mass is observed. This results in the propagation of a shock wave in the mass and the the

*Corresponding author. E-mail: irene.redaelli@polimi.it

subsequent fluidification and resolidification of the material arount the impacting point. All these processes are governed by the energy content of the impact, by the ratio between impacting bolder radius and mean radius of the particles of the soil layer, by the soil properties (porosity, granular size distribution), by the geometrical and kinematic properties of the impacting boulder (velocity modulus and direction) and by the distance of the bottom wall (representing the bedrock below the scree).

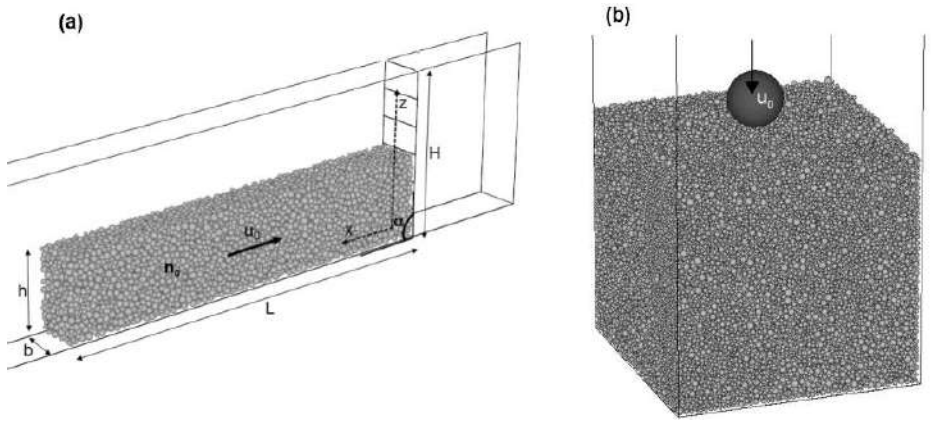

Figure 1. Numerical DEM models: (a) impact of a landslide against a rigid wall (b) impact of a boulder against a granular stratum.

CONCLUSIONS

The impact process between a rigid body and a deformable granular mass is very complex since the dynamicity of the process may induce waves propagation, damage of particles and fluidification within the granular media.
In this study the DEM has been employed to put in evidence all these processes either when a dry granular mass impact a rigid wall or when a spherical boulder impacts against a granular layer. The DEM can in fact automatically take into account local variation of porosity and internal microstructure, the dependence of the material response on strain rate and packing as well as all the dissipation mechanisms characterizing the granular materials such as inelastic collisions and frictional processes occurring between contacting grains. The results have been employed to interpret the macroscopic observation, such as time evolution of interaction force between soil and rigid body (Fig.2). This represent an important information which can be employed for the dynamic design of sheltering structures.

CONSTITUTIVE MODELLING OF SATURATED GRANULAR MATERIALS UNDER STEADY CONDITIONS

Pietro Marveggio[1*], Dalila Vescovi[1], Irene Redaelli [1]and Claudio di Prisco [1]
[1]Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy

Summary The authors introduce a new constitutive model capable of capturing the transition from solid-to-fluid like conditions of dry and saturated granular materials on the base of the mixture theory, according to which granular and liquid phases are considered separately. As far as the granular contribution is concerned, the authors employ an already conceived constitutive model where the critical state concept and the kinetic theory of granular gases are merged, and in which the granular temperature plays the role of state variable for the material. Under saturated conditions, the new model accounts for granular-liquid coupling effects. In fact, the liquid viscosity results to be a function of granular concentration, whereas the evolution of granular temperature is influenced by the liquid molecular viscosity. The model is validated against numerical results and critically discussed.

INTRODUCTION

Flow-slides are commonly numerically simulated tackling separately the inception and the propagation of gravitational movements, since a constitutive model capable of simulating the transition of the material behaviour from solid- to fluid-like conditions and vice versa is still an open challenge. Such a transition takes place when force chains disappear and the energy is mainly dissipated by collisions among grains. From an energetic point of view, under solid conditions the elastic contribution is dominant, whereas under fluid-like conditions the kinetic term (associated with grain agitation) prevails.
Recently, the authors have proposed a constitutive approach to describe the mechanical behaviour of dry granular materials in both regimes (quasi-static and collisional) [6,7]. To extend the proposed framework to saturated conditions, additional dissipation mechanisms associated with the liquid phase have been accounted for.

CONSTITUTIVE APPROACH

The theoretical approach conceived by the authors to describe the mechanical behavior of both dry and saturated granular materials under steady conditions is based on the description of the physics of the grain-grain and grain-water interaction, assuming that: (i) the granular material can be either dry or saturated by water (unsaturated conditions are not taken into account), (ii) solid fraction is made of an assembly of ideal, monodisperse, frictional, deformable and uncrushable spheres.
As far as the granular solid fraction is concerned, the authors employ an already conceived constitutive approach capable of describing, at the same time, the mechanical behaviour of agitated granular flows (fluid-like regime) and solid-like granular systems. The approach followed by the authors is based on the introduction of an additional state variable, the granular temperature [2], describing the system agitation, and on the assumption that the critical state [8,11,12] for highly concentrated granular materials is the limit of steady state conditions for shear strain rates going to zero. Under dry conditions, the energy dissipation may be due either to frictional contacts belonging to force chains, or to instantaneous collisions, these latter dominating in case of small values of concentration and large values of shear rates.
Under saturated conditions, additional dissipation contributions arise in the liquid phase. These are associated with the following effects: (i) deviation of the liquid streamlines due to the presence of particles, behaving as obstacles; (ii) lubrication; (iii) liquid velocity fluctuations due to grain agitation.
These dissipation contributions involve the liquid phase. According to the approach proposed by the authors, the liquid viscosity depends on the concentration according to a suitably calibrated function [10]. On the other hand, the presence of water plays a damping role in reducing the fluctuating energy of the granular phase. This damping effect is associated with an increase in the liquid pressure (dynamic contributions).
The energy balance is used by the authors to describe the coupling between the two phases. In fact, the granular temperature results to be influenced by the liquid phase molecular viscosity and governs the fluid- to solid-like transition and vice versa in the material response.

VALIDATION AND DISCUSSION

The new constitutive approach is validated against DEM numerical simulations for steady conditions and discussed in the framework of the μ-e-I [3,4] and μ-e-K [1,9] rheology for dry and saturated conditions, respectively. For dry materials, DEM simulations by Redaelli et al. [7] are considered, while numerical data by Ness and Sun [5] are simulated by saturated conditions. These simulations have been performed by replacing the liquid phase with some long-range lubrication forces acting at the contact among particles. Concerning saturated conditions the proposed framework is capable of correctly reproducing the reality by capturing: (i) for sufficiently small values of concentration, the transition from Newtonian to Bagnoldian regimes, when the shear rate is increased; (ii) the independence of the shear mechanical behaviour of the mixture when the concentration is sufficiently high and the material behaves like a solid.

*Corresponding author. E-mail: pietro.marveggio@polimi.it.

CONCLUSIONS

The authors presented an innovative approach capable of capturing the transition from solid-to-fluid like conditions, in dry or saturated granular materials, validated under steady conditions against DEM numerical results and the well-known μ rheology for both dry (μ-e-I) and saturated conditions (μ-e-K). The formulation proposed by the authors has been shown to be capable of satisfactorily simulate the mechanical behavior of granular materials (under dry and saturated conditions), in both fluid and solid regimes and to put clearly in evidence the limitations of the commonly employed constitutive approaches not considering separately solid and liquid phases.

CHANGE IN CURVATURE OF PORE WATER IN PARTIALLY SATURATED SAND AND ITS INFLUENCE ON DEVIATOR STRESS UNDER TRIAXIAL COMPRESSION

Ryunosuke Kido*[1] and Yosuke Higo [2]
[1]Department of Civil and Earth Resources Engineering, Kyoto University, Kyoto, Japan
[2]Department of Urban Management, Kyoto University, Kyoto, Japan

Summary Two triaxial compression tests on partially saturated silica sand specimens are conducted under drained and undrained conditions for water. In these tests, microscopic deformation of the specimens focusing on shear bands are visualized using x-ray micro tomography and the change in the curvature of pore water, i.e., suction, is investigated using image analyses. It is found that the curvature of pore water under drained condition for water is higher than that under undrained condition for water, and hence the deviator stress of the specimen under drained condition for water is higher than that under undrained condition for water.

INTRODUCTION

Partially saturated soil comprises soil particle, pore water and pore air. Mechanical behaviors of the partially saturated soil strongly depend on suction at capillary bridges. The suction works as inter-particle force, resulting in higher stiffness of partially saturated soil than fully saturated soil. On the other hand, partially saturated soil exhibits more brittle modes of failure with clearer shear band than fully saturated soil [1]. This is related to the loss of suction due to variations in bulk density and degree of saturation caused by water infiltration and shearing, causing a reduction in the stiffness and the strength of partially saturated soil. It is important, therefore, to measure the variation in suction during deformation of partially saturated soil with shear bands in order to reveal the failure mechanism of partially saturated soil.

In the present study, x-ray micro tomography focusing on shear bands is applied at different stages of deformation during triaxial compression tests on partially saturated sand specimens under two conditions: drained conditions for air and water, and a drained condition for air and an undrained condition for water. Deviator stress-axial strain relationships of the specimens are observed and then the development of shear bands is visualized. A segmentation technique for the soil particle, the pore water and the pore air, i.e., trinarization, is applied to the tomographic volumes obtained in the tests. Principal curvatures of pore water in the trinarized volumes are measured using an image processing technique. It is found that the curvature of pore water under drained condition for water is higher than that under undrained condition for water, and hence the residual stress of the specimen under drained condition for water is higher than that under undrained condition for water.

EXPERIMENTAL METHODS

The material used in the present study was silica sand #5. The physical properties of the silica sand include a soil density of 2.64 g/cm^3, a maximum void ratio of 1.013, a minimum void ratio of 0.694, a D_{50} of 456 μm, a uniformity coefficient of 1.3 and a fines content of 0.1 %. The silica sand is advantageous for visualizing individual soil particles and distributions of pore water and pore air with high spatial resolution because of the large grain size. On the other hand, the water retention capability of the silica sand is relatively low; the level of suction lower than 10 kPa gives the residual degree of saturation of about 20%. Two triaxial specimens were prepared by a water pluviation technique. Once the water-saturated specimens had been prepared, they were desaturated by a water head difference.

The x-ray micro tomography facility used in the present study is KYOTOGEO-μXCT (TOSCANER-32250μhdk, TOSHIBA IT and Control Systems Corporation) [2]. At the different loading stages of the triaxial compression, the local region of interest focusing on shear bands in the specimens was visualized. Axial loading was suspended during x-ray tomography for around two hours, after which it was resumed.

Triaxial tests were performed under two conditions, namely, drained conditions for both air and water, and a drained condition for air and an undrained condition for water. The former condition assumes that partially saturated soil deforms without any excess pore water pressure due to slow shearing or the high permeability of the soil, while the latter condition assumes that partially saturated soil deforms with excess pore water pressure due to relatively fast shearing or low permeability, respectively. Namely, the level of suction in the former condition is kept constant, while that in the latter condition is varied.

IMAGE PROCESSING TECHNIQUES

A minimum unit of CT images is called as voxel. Each voxel in CT images shows a certain CT value depending on the material density. CT images scanning partially saturated sand include voxels for the soil particle phase, the pore water phase and the pore air phase. In the present study, a segmentation technique of the three phases, i.e., trinarization [3], is applied to the CT volumes obtained during the triaxial compression tests. The 3D image analysis software VGstudioMax3.1 (Volume Graphics GmbH) is used for the trinarization. Voxels in the trinarized volumes show three kinds of CT value corresponding to the soil particle phase, the pore water phase and the pore air phase. Therefore, local void ratios and local degrees of saturation in the trinarized volumes can be calculated by counting the number of voxels

*Corresponding author. E-mail: kido.ryunosuke.2m@kyoto-u.ac.jp

for the three phases. The trinarization technique was validated by confirming that the void ratio and the degree of saturation of a specimen and those calculated by the trinarization technique were quite similar to each other.

Interfaces between the pore water phase and the pore air phase were extracted from the trinarized volumes as shown in Figure 1. Maximum principal curvatures whose inverted values are closer to the radius of a sphere locally fitting the interface are calculated as the principal curvatures of pore water. Suction can be estimated by a surface tension of water and principal curvature of water $1/r_1$ as shown in Figure 1.

RESULTS

Two triaxial specimens show the peak deviator stress followed by the strain softening and finally the residual stress is observed. It is found from the CT images that the specimens exhibit shear bands. Trinarization reveals that the void ratio is increased and then the degree of saturation is decreased due to the development of shear bands. The residual stress under drained condition for water is higher than that under undrained condition for water, and then the curvature of pore water, i.e., suction, under drained condition for water is higher than that under undrained condition for water as shown in Figure 2.

CONCLUSIONS

A Principal curvature of pore water in partially saturated sand is lower during the triaxial compression under an undrained condition for water than under a drained condition for water at the residual state, resulting in the lower deviator stress under an undrained condition for water than under a drained condition for water.

Summary Drying granular materials transition between forms of water that are classified as capillary, funicular and pendant bridges. These transitions are controlled either by a slow evaporation induced displacement of the liquid/gas interface, or an unstable reconfigurations of the interface, called correspondingly *isons*, and *rheons*. Some of the above phenomena have been known for long time, but their understanding and quantitative descriptions are lacking. We present results of experiments and their interpretation at three different geometrical scales: a micro-scale of assemblies of several grains, a meso-scale of large assemblies of hundreds of grains, and at a macro-scale of a continuum. At each scale the fluid (water) plays the role of a cohesive medium that transmits forces between the grains, with different characteristics and different repercussion for the other scale.

INTRODUCTION

Transition between various forms of capillary water that are classified as capillary bridges, funicular and pendant bridges are primary events in granular materials undergoing drying. The transitions are due to either a slow evaporation induced displacement of the liquid/gas interface, or an ultra-fast and unstable reconfigurations of the interface, called correspondingly *isons*, and *rheons*. Dynamic manifestations of rheons have been known as Haines jumps. Although some of the characteristics of the above phenomena have been known for long time, their understanding and quantitative descriptions are lacking.

In the paper we present the experiments and their interpretation at three different geometrical scales: a micro-scale of assemblies of several grains, a meso-scale of large assemblies of hundreds to thousands of grains, and finally at a macro-scale of a continuum of grains. At each scale the fluid (water) plays the role of a cohesive medium that transmits forces between the grains, with different characteristics and different consequences for the other scale.

The variables characterizing the evolution during evaporation of capillary bridge between the grains are analyzed. The grains investigated are spheres of different materials, such as glass, Teflon and clay clusters, and are of the same kind and size.

MICRO-SCALE PHYSICAL MODELING

Experimental results for drying micro-scale granular assemblies

The variables at the micro-scale include: average Laplace pressure, forces resulting from pressure, surface tension forces and the resultant total capillary force calculated based on the previously reported geometrical variables using Young-Laplace law. This is the first time to our knowledge that Laplace pressure is calculated from the measured curvatures of the interface between liquid and gas phase, along the process of evaporation and compared to experimental measurement data. A comparison with the experimental data from analogous capillary bridge extension tests is also shown and discussed. The measurements are possible through the image processing for pendular bridges, which constitute the last phase of the evaporation process, prior to loss of cohesion of the medium.

The behavior of evaporating liquid bridges is seen as strongly dependent on the grain separation. Initial negative Laplace pressure at small separations in pendular bridges is seen to significantly augment during an advanced stage of evaporation, but to invert the tendency and become positive pressure, after an instability toward the end of the process, and prior to rupture. At larger separations the pressure is positive all the time, changing a little, but rupturing early. Rupture in all cases occurs at positive pressure. However, because of the evolution of the surface area of contact, the resultant total capillary forces are always tensile, and decreasing toward zero in all cases. Comparison between measured total resultant capillary forces and those calculated from the Young-Laplace law is very good, except for some discrepancies at very small separations (below 50 μm). Up to four consecutive instabilities of capillary bridge are seen developing at some sphere separations. They are: re-pinning-induced suction (pressure) instability; Rayleigh nodoid/catenoid/unduloid unstable transition, associated with zero-pressure; Rayleigh unduloid/cylinder unstable transition, associated with the formation of a liquid-wire; and lastly, a pinching instability of the liquid-wire, associated with the bridge rupture. Rupture of the bridges is seen at large separations to occur quite early, at only 1/4–1/3 of the initial water volume evaporated. At smallest separations, rupture occurs in a seemingly unstable way when water evaporates from the bridge thinnest section of the neck.

At a sub-microscopic scale of a single bridge capillary bridges between two glass spheres show that the bridge gorge radius decreases much faster than the contact radius, distorting the original constant mean curvature bridge shape. In addition, the Laplace pressure calculated from local principal curvatures exhibits high gradients along the bridge moving

external surface, most commonly with a high suction near the triple phase contact and positive pressure near the gorge. The high suction results from a negative external curvature at contact. Numerical dynamic simulations with a moving evaporating interface do not currently allow for reproducing a negative external curvature at contact. A series of static approximation simulations are shown based on a representation of an experimentally observed interface, which does include the negative curvature at contact. The resulting Laplace pressure distribution is close to the experimental ones. Most importantly, the pressure gradients induce a consistent flow of liquid from the central area of the bridge, axially toward the solid contact, and then along the solid interface toward the contact area. The flow is believed to contribute to contact pinning. Pinning is viewed as one of the precursors of capillary bridge rupture.

For larger assemblies of 3, 5 and 8 grains the unstable transition between different water configurations takes the form of air entry episode that correspond to Haines jumps observed at meso-scale. The adhesion-force of a cluster initially grows at most to three times the original value before decreasing to zero by the end of evaporation. The adhesion-force is composed of capillary pressure force acting over the liquid/solid contact surface area, and surface tension forces acting over the three-phase contact perimeter length. This is in contrast with most macro-scale phenomenological models, in which the only desaturation process variables affecting strength are suction and saturation. Both the contact surface area and contact perimeter length are reduced to zero upon complete liquid evaporation. The morphology of an evaporating water body evolves through slow flow controlled by evaporation rate, interrupted by various modes of fast air entry, which are non-equilibrium jumps of liquid/gas interfaces. The instabilities involve large adhesion force discontinuities and substantial water mass reconfiguration with water flow in an extremely short time, which makes the process transient. The reconfigurations can reduce the original multi-grain water clusters to four-, three- and two-grain clusters by way of three different instability modes: of thin-sheet instability, or meniscus snap-through instability, depending on the sign of the Gauss curvature of the liquid surface, or finally, for two-grain bridges only, a liquid wire pinch-off. For larger meso-scale assemblies, however, the global adhesion force evolution is little affected by the jumps. The air entries are potential sites for drying cracks. The (approximately) calculated capillary pressure for two- and three-grain clusters, in no cases is seen to reach high values, predicted from water retention curves.

MACRO-SCALE CONSIDERATIONS

At the macro-scale of a granular continuum modeling of desiccation cracking via macroscopic approach suffers from a major handicap. Consideration of a 1D drying of a constrained saturated granular body easily shows that a modest total stress is generated in reaction to the constraints and that it is tensile, whereas the values of suction induced by the evaporation flux are significant. Consequently, the resulting effective stress appears to be compressive. This is counterintuitive, as drying failure evidently occurs through tensile cracking.

To address this paradox Scherer (1992) postulated a scenario suggesting that desiccation cracking is necessarily triggered through crack propagation from a tip of a pre-existing structural flaw, at which a substantial total stress concentration occurs. As a result, the remote total stress is substantially magnified through the stress concentration and becomes larger in absolute terms than the elevated suction. In turn, the local effective stress becomes tensile, and hence prone to reach the tensile strength of the material. Based on the presented results we postulate that a non-symmetric finger of an air entry, as described above, constitutes a sufficient imperfection (flaw) in the drying granular body to produce a concentration of total stress induced by the kinematic restraints to the drying shrinkage around the tip of the flaw, to generate crack propagation. In this spirit we consider an air finger (flaw) with the given depth and curvature radius at the finger tip at the soil surface, which is surrounded by the micro-tubes pore system. Using the principles of linear fracture mechanics, the stress at the external boundary of the tubes which are placed near the flaw tip can be calculated. Following the methodology by Scherer (1992), the far-field (macro-scale) stress at crack initiation can be found as tensile, easily becoming larger than macroscopic tensile strength of soil.

CONCLUSIONS

The presented data indicate that the abrupt phenomena of air entry inducing adhesion force discontinuities are not seen as discontinuous at a macro-scale. However, they trigger instabilities at a macro-scale that may lead to macro-scale drying crack formation and propagation.

BI-DISPERSE MIXTURES: STUDY OF DENSITY, COMPRESSIBILITY AND CRUSHING

Giulia Guida*[1], Gianluca Salvatori[2], and Francesca Casini[2]
[1]Department of Civil and Environmental Engineering, Politecnico di Milano, Milan, Italy
[2]Department of Civil and Computer Engineering,Università degli Studi di Roma Tor Vergata,Rome,Italy

Summary This work aims to investigate different type of bi-disperse grain size distributions in terms of minimum/maximum density, compressibility and crushing. The material adopted is the Light Expanded Clay Aggregate (LECA), an artificial granular material characterized by light, porous and crushable grains. The bi-disperse grading are firstly analysed in terms of packing efficiency, measuring experimentally the minimum and the maximum void ratios for different combination of fractions and proportions. Then, some selected mixtures are subjected to one-dimensional compression tests up to high pressures. Evolution of grain size due to grain crushing phenomena and compressibility are therefore measured and interpreted. Finally a theoretical model is adopted in order to predict the mechanical material behaviour accounting grain crushing and granular microstructure. The comparison is satisfactory.

PACKING EFFICIENCY

Bi-disperse distributions are composed by two distinct sizes, namely d_1 and d_2 where $d_1 > d_2$. The quantitative proportion of the two volume fraction is expressed by the coefficient $V = V_1/V_{tot}$, where $V_{tot} = V_1 + V_2$ and V_1, V_2 are the percentage by volume of fractions d_1 and d_2 respectively. The choice to express the fraction proportion by volume is due to the material adopted, the light expanded clay aggregate (LECA), which has a unit weight that increases with decreasing particle diameter [1] due to the presence fo intra-porosity [2]. Figure 1 shows experimental measurements of maximum and minimum void ratio for different type of bi-disperse grading, characterised by a ratio between diameters $R = d_1/d_2$ and fractions proportions V. The experimental evidences coming from Figure 1 highlight how, especially for grater R, the material reaches a more efficient packing, both for the maximum and minimum densities, in correspondence of $V \sim 70\%$ in accordance to several theoretical and experimental studies [2, 3, 10]. Note that in the case of mono-disperse distribution, when $V = 0$ or $V = 1$, the void ratios limits assume different values based on the size, higher for smaller grains and *vice versa*. A morphological analysis of grains proved that the shape of the smaller fractions is more irregular than the bigger, and a greater morphology irregularity lead to an increase of maximum and minimum void ratios in accordance with [7, 6].

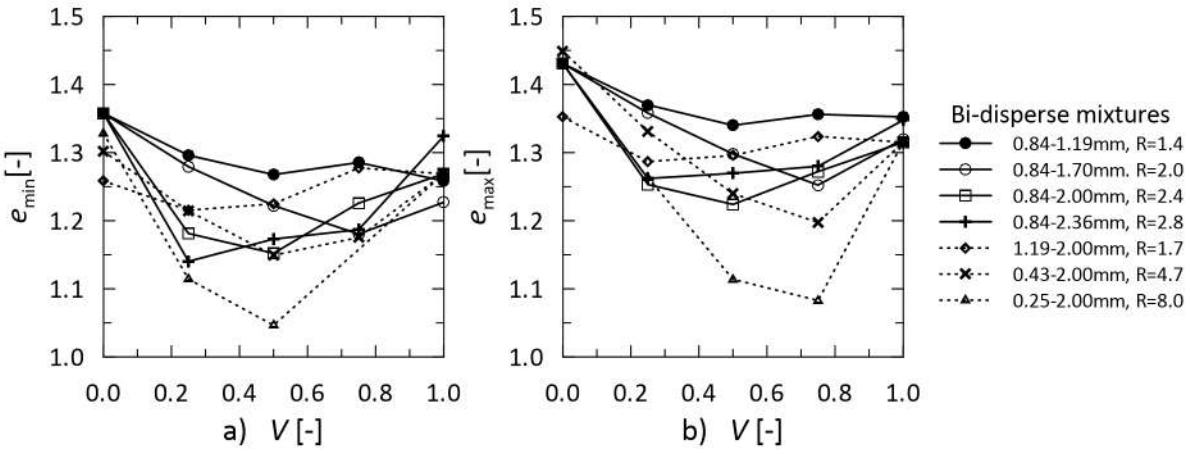

Figure 1: Measures of (a) minimum and (b) maximum void ratios for bi-disperse mixtures with different R and V.

ONE-DIMENSIONAL COMPRESSION TEST

Some selected bi-disperse grain size distributions (*e.g.* in Figure 2 characterised by $d_1 = 2.00$ mm, $d_2 = 0.43$ mm, $R = 4.7$ and $V = 0.6$) are subjected to one-dimensional compression tests up to the maximum vertical pressure of 54 MPa. The results are compared to the mono-disperse gradings relative to the single two constitutive fractions , MONO_{d1} and MONO_{d2}. Samples are prepared by dry pluviation, getting the minimum density configuration state. Figure 2 shows the experimental results in terms of (a) evolution of cumulative grain size distributions (CGSD) obtained by sieving and (b) the compressibility curves. Note that the bi-disperse CGSD at the final maximum vertical stress evolves due to crushing similarly to MONO_{d1} for $d \geq 0.43$mm, and similarly to MONO_{d2} for $d < 0.43$mm. Overall the constitutive fractions start to crush at low pressures applied, with the tendency to assume a fractal configuration [11]. The compressibility

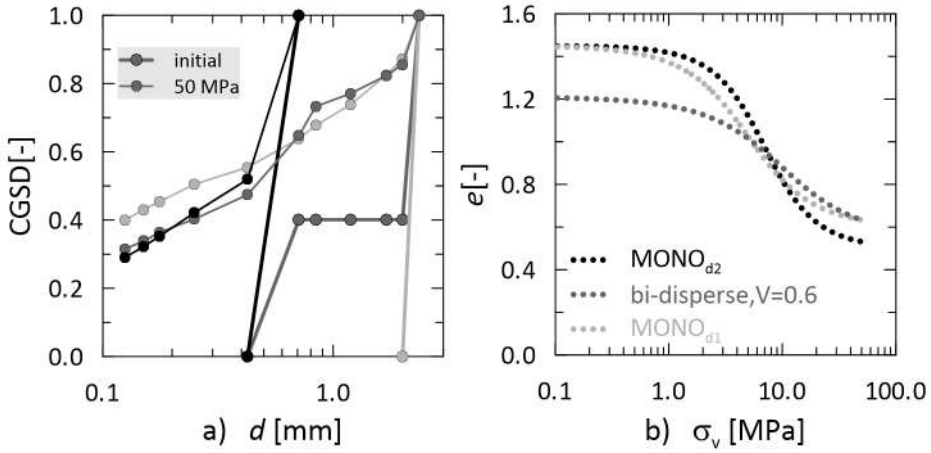

Figure 2: (a) Evolution of cumulative grain size distributions for a bi-disperse grading compared to its relative monodisperse ones; (b) Compressibility curves.

curve of the bi-disperse GSD (Figure 2) has initial stiffness close to that of MONO$_{d1}$, while after yielding it behaves such MONO$_{d2}$. The initial void ratio of the bi-disperse grading, as seen in Figure 1, assumes lower values than monodisperse.

The model developed by [5] is used to predict the compressibility of the mixture. In particular the model links the variation of porosity $\dot{n}$ to the variation of the maximum and the minimum void ratio:

$$\dot{n} = \tau_n \dot{n}_{max} + (1 - \tau_n)\dot{n}_{min}, \tag{1}$$

where τ_n is the auxiliary porosity index such that when $\tau_n = 1$, $n = n_{min}$ and when $\tau_n = 0$, $n = n_{max}$ [8, 9]. The intrinsic values of $n_{max/min}$ are defined as function of GSD polydispersity quantified by the index of grading I_{Gr}:

$$n_{max/min} = n^{MONO}_{max/min} I_{Gr}^{-\alpha}, \tag{2}$$

where $n^{MONO}_{max/min}$ are the minimum and maximum porosity at zero stress of a mono-disperse grading and α is a dimensionless model parameter. The index of grading I_{Gr} is defined as the geometric standard deviation of the particle size distribution of normalized sizes, it is dimensionless and describes the spread of GSD about its geometric mean.

CONCLUSIONS

The experimental results show that bi-disperse mixtures explicate a greater packing efficiency than mono-disperse grading, an evolution of cumulative grain size distribution and a compressibility behaviour in between those of the two mono-disperse constitutive fractions. Finally, those interesting experimental evidences are used to validate a compressibility model for granular material with crushable grains recently developed.

INSTABILITY IN ELASTIC-VISCOPLASTIC MEDIA: FROM MICRO TO MACRO

Luca Flessati*[1] and Claudio di Prisco [1]
[1]Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy

Summary In landslide risk assessment, the justification of unexpected collapses involving creeping landslides is considered to be very crucial. In this paper, the authors consider the case of an infinite long slope constituted of an elastic-viscoplastic material and, by employing the controllability theory, directly applied on the representative elementary volume and here tailored to interpret the global system response, observe that increments in slope acceleration are anticipated by a local increase in strain rate along the shear band. This implies that the observation of inclinometer data may in principle allow to foresee the slope collapse.

INTRODUCTION

In the scientific literature, many authors reported the occurrence of unexpected collapses in creeping landslides. This transition is, in many cases, associated with a phenomenon called "progressive failure", which mainly takes place in geomaterials characterized by a high level of fragility, such as cemented geomaterials. In these materials, at the microscopic scale, the cracks present in both grains and intergranular bonds propagate with time ("subcritical crack growth" [1]). This crack propagation induces a spatial rearrangement of the microstructure which is associated with both an accumulation with time of irreversible strains and a reduction in the material strength. At the global (landslide) scale, this local behaviour causes a spatial propagation of the damaged zone, which, in some cases, may be associated with a rapid increase in the displacement rate in the unstable soil/rock mass.
By taking into consideration an infinite slope resting on a rigid bedrock, the authors intend to illustrate that, by following a suitably defined upscaling procedure, the controllability theory ([2]) employed to analyse the (local) onset of instability at the representative elementary volume scale may also be extended to analyse boundary value problems. Moreover, the employment of controllability theory at both local and global scales allows to put in evidence that the local instability is a precursor of the slope collapse.

LOCAL ONSET OF INSTABILITY

In the case of an infinite long slope (Fig. 1a), if both the hydro-mechanical coupling and dynamic effects are disregarded, the response of every layer is analogous to the one of a representative elementary volume under simple shear conditions. The controlled stress ($\dot{\boldsymbol{\sigma}}'_\alpha$)/strain ($\dot{\boldsymbol{\varepsilon}}_\beta$) variables are:

$$\dot{\boldsymbol{\sigma}}'_\alpha = [\dot{\sigma}'_n \quad \dot{\tau}_{tn}]^T \qquad \dot{\boldsymbol{\varepsilon}}_\beta = [\dot{\varepsilon}_t \quad \dot{\varepsilon}_y]^T, \tag{1}$$

whereas the corresponding response strain ($\dot{\boldsymbol{\varepsilon}}_\alpha$)/stress ($\dot{\boldsymbol{\sigma}}'_\beta$) variables are:

$$\dot{\boldsymbol{\sigma}}'_\beta = [\dot{\varepsilon}_n \quad \dot{\gamma}_{tn}]^T \qquad \dot{\boldsymbol{\varepsilon}}_\alpha = [\dot{\sigma}'_t \quad \dot{\sigma}'_y]^T, \tag{2}$$

where the coordinates *t* and *n* are defined in Fig.1a, while the coordinate *y* represents the out of plane direction.
In case of an elastic-viscoplastic material ([3]) the total, the elastic ($\dot{\boldsymbol{\varepsilon}}^{el}$) and the viscoplastic ($\dot{\boldsymbol{\varepsilon}}^{vp}$) strain rate vectors may be suitably partitioned to put in evidence the controlled and the response variables:

$$\begin{bmatrix}\dot{\boldsymbol{\varepsilon}}_\alpha \\ \dot{\boldsymbol{\varepsilon}}_\beta\end{bmatrix} = \begin{bmatrix}\dot{\boldsymbol{\varepsilon}}^{el}_\alpha \\ \dot{\boldsymbol{\varepsilon}}^{el}_\beta\end{bmatrix} + \begin{bmatrix}\dot{\boldsymbol{\varepsilon}}^{vp}_\alpha \\ \dot{\boldsymbol{\varepsilon}}^{vp}_\beta\end{bmatrix} = \begin{bmatrix}\boldsymbol{C}^{el}_{\alpha\alpha} & \boldsymbol{C}^{el}_{\alpha\beta} \\ \boldsymbol{C}^{el}_{\beta\alpha} & \boldsymbol{C}^{el}_{\beta\beta}\end{bmatrix}\begin{bmatrix}\dot{\boldsymbol{\sigma}}'_\alpha \\ \dot{\boldsymbol{\sigma}}'_\beta\end{bmatrix} + \Phi\begin{bmatrix}\frac{\partial g}{\partial \boldsymbol{\sigma}'_\alpha} \\ \frac{\partial g}{\partial \boldsymbol{\sigma}'_\beta}\end{bmatrix}, \tag{3}$$

being $\boldsymbol{C}^{el}$ the elastic compliance matrix, Φ the viscous nucleus and g the plastic potential. According to [4], Equation 3 may be derived with respect to time and rearranged to put in evidence the relationship between the response variables $\boldsymbol{X} = \left[\dot{\boldsymbol{\varepsilon}}_\alpha \quad \dot{\boldsymbol{\sigma}}'_\beta\right]^T$ and their time derivative $\dot{\boldsymbol{X}} = \left[\ddot{\boldsymbol{\varepsilon}}_\alpha \quad \ddot{\boldsymbol{\sigma}}'_\beta\right]^T$. This relationship is linear and may be expressed as it follows:

$$\dot{\boldsymbol{X}} = \boldsymbol{A}\boldsymbol{X} + \boldsymbol{F}, \tag{4}$$

being **F** a "forcing" term related to the controlled variables, whereas the matrix **A** depends on both the constitutive relationship and the controlled variables. In case of "generalized creep tests" ($\dot{\boldsymbol{\sigma}}'_\alpha = \ddot{\boldsymbol{\sigma}}'_\alpha = \dot{\boldsymbol{\varepsilon}}_\beta = \ddot{\boldsymbol{\varepsilon}}_\beta = \boldsymbol{0}$), **F=0** and **A** only depends on the constitutive relationship. Under simple shear conditions ([5]), the non-nil terms of the constitutive matrix **A** may be expressed as

$$A_{11} = A_{22} = -\frac{\partial \Phi}{\partial f}(H - H_\chi),\ A_{33} = A_{44} = -\frac{\partial \Phi}{\partial f}(H - H_\chi) - \Phi\frac{E}{1-\nu^2}\frac{\partial^2 g}{\partial \sigma'^2_t},\ A_{13} = \Phi\left(\frac{\partial^2 g}{\partial \sigma'_n \partial \sigma'_t} - \frac{\nu}{1-\nu}\frac{\partial^2 g}{\partial \sigma'^2_t}\right) \text{ and } A_{23} = \Phi\frac{\partial^2 g}{\partial \tau_{tn} \partial \sigma'_t}, \tag{5}$$

being f the yield function, E the Young modulus, ν the Poisson's ratio, H the hardening modulus and H_χ the controllability modulus:

$$H_\chi = -\frac{\partial f}{\partial \sigma'_t}\frac{E}{1-\nu^2}\frac{\partial g}{\partial \sigma'_t} \tag{6}$$

According to [6], for **F=0**, a stable response is obtained in case all the eigenvalues of **A** are negative. In other words, instability takes place when at least one eigenvalue of **A** becomes non-negative. Eigenvalues λ_i (with i=1,4) can be expressed as:

*Corresponding author. E-mail: luca.flessati@polimi.it

$$\lambda_1 = \lambda_2 = A_{11} = A_{22} \qquad \lambda_3 = \lambda_4 = A_{33} = A_{44} = A_{11} - \Phi \frac{E}{1-\nu^2} \frac{\partial^2 g}{\partial \sigma_t'^2}. \tag{7}$$

Since E, Φ and $\partial\Phi/\partial f$ are positive, in case g is convex in the stress space, $\lambda_1 \geq \lambda_3$. The instability condition is obtained when $\lambda_1 \geq 0$, i.e. when $H - H_\chi \leq 0$.

GLOBAL ONSET OF INSTABILITY

When the global response of the slope is taken into account, it is convenient the introduction of the following global response variables:

$$\boldsymbol{X} = \left[\dot{u}_n \quad \dot{u}_t \quad \dot{\Sigma}_t \quad \dot{\Sigma}_y\right]^T = \left[\int_0^h \dot{\varepsilon}_n\, dz \quad \int_0^h \dot{\gamma}_{tn}\, dz \quad \int_0^h \dot{\sigma}'_t\, dz \quad \int_0^h \dot{\sigma}'_t\, dz\right]^T \tag{9a}$$

$$\dot{\boldsymbol{X}} = \left[\ddot{u}_n \quad \ddot{u}_t \quad \ddot{\Sigma}_t \quad \dot{\Sigma}_y\right]^T = \left[\int_0^h \ddot{\varepsilon}_n\, dz \quad \int_0^h \ddot{\gamma}_{tn}\, dz \quad \int_0^h \ddot{\sigma}'_t\, dz \quad \int_0^h \ddot{\sigma}'_t\, dz\right]^T \tag{9b}$$

In case of generalized creep tests, by combining Equations 4, 9a and 9b the relationship between $\boldsymbol{X}$ and $\dot{\boldsymbol{X}}$ may be obtained:

$$\dot{\boldsymbol{X}} = \boldsymbol{A}^g \boldsymbol{X} = (\boldsymbol{A}^{max} - \boldsymbol{\Omega})\boldsymbol{X}, \tag{10}$$

where $A_{ij}^{max} = \max\{A_{ij}\}$ in the spatial domain, while the non-nil terms of $\boldsymbol{\Omega}$ are:

$$\Omega_{11} = \frac{\int_0^h (A_{11}^{max} - A_{11})\dot{\varepsilon}_n dz}{\int_0^h \dot{\varepsilon}_n dz}, \quad \Omega_{13} = \frac{\int_0^h (A_{13}^{max} - A_{13})\dot{\sigma}'_t dz}{\int_0^h \dot{\sigma}'_t dz}, \quad \Omega_{22} = \frac{\int_0^h (A_{22}^{max} - A_{22})\dot{\gamma}_{tn} dz}{\int_0^h \dot{\gamma}_{tn} dz}, \quad \Omega_{23} = \frac{\int_0^h (A_{23}^{max} - A_{23})\dot{\sigma}'_t dz}{\int_0^h \dot{\sigma}'_t dz},$$

$$\Omega_{33} = \frac{\int_0^h (A_{33}^{max} - A_{33})\dot{\sigma}'_t dz}{\int_0^h \dot{\sigma}'_t dz}, \quad \Omega_{44} = \frac{\int_0^h (A_{44}^{max} - A_{44})\dot{\sigma}'_y dz}{\int_0^h \dot{\sigma}'_y dz}. \tag{11}$$

By definition, $\lambda_i(\boldsymbol{A}^g)$ are smaller than $\lambda_i(\boldsymbol{A}^{max})$, since $\lambda_i(\boldsymbol{\Omega})$ are always non negative. As a consequence, when local instability takes place (i.e. when one eigenvalue of the local constitutive matrix $\boldsymbol{A}$ and, consequently, one eigenvalue of $\boldsymbol{A}^{max}$ become non-negative) $\boldsymbol{A}^g$ is not necessarily non-negative. Therefore, the first local and the global instability are not simultaneous. In other words, a time lag between the first local and the global instability exists and the first local instability always anticipates the onset of the global one. This is testified in Fig. 1b where the evolution in time (t) of slope displacements (u_t) numerically obtained by considering an infinite slope constituted of a strain softening elastic-viscoplastic material (a Mohr-Coulomb type yield function is employed) and resting on a rigid bedrock subject to an instantaneous increase in the water table level is considered. Point A corresponds to $\ddot{u}_t$=0 (global onset of instability), whereas point B to the first local onset of instability ($\ddot{\gamma}_{tn} = 0$). As is evident, the local instability severely anticipates the global one.

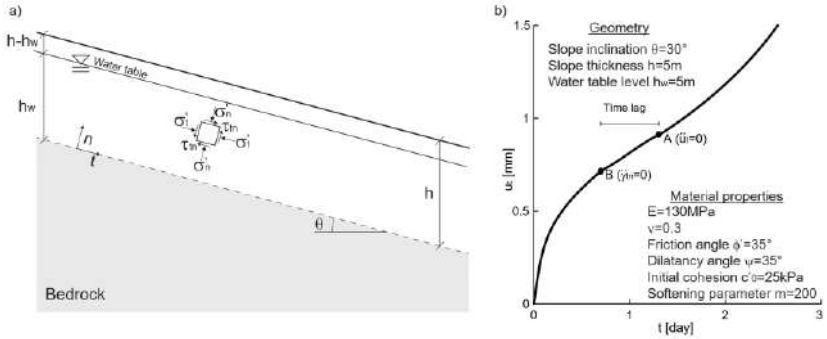

Figure 1. a) Geometrical scheme of the infinite slope and b) evolution in time of the slope displacements [5

CONCLUSIONS

The authors take into consideration the case of progressive failure in slopes constituted of elastic-viscoplastic materials. For the sake of simplicity, the case of an infinite long slope is taken into account. By employing the controllability theory, applied both on representative elementary volumes and on the global slope response, the authors conclude that: (i) the first local instability anticipates the global one, (ii) the occurrence of local instability is necessary condition for the global instability to take place and (iii) local instability is a precursor of the global one.

FRACTURE PROPAGATION ALONG A FAULT – STRESS HYSTERESIS EFFECT

Clément Cardon[1] and Pierre Cerasi*[2]
[1]Ecole Polytechnique, Palaiseau, France
[2]Petroleum Department, SINTEF Industry, Trondheim, Norway

Summary A bespoke fracturing software combining finite and discrete elements is used to assess the leakage risk along a fault adjacent to a CO_2 storage reservoir. A 25 m large process zone containing pre-existing fractures is modelled, with idealized fracture patterns of a typical deformation zone. Simulations are performed to compare a storage reservoir as hanging wall versus footwall. Two stress path scenarios are looked at, depletion of the reservoir with subsequent re-pressurization, and injection into a normally pressured reservoir. Results show that hanging wall reservoirs undergoing depletion are the most at risk of developing continuous fracture paths, potentially leading to leakage to shallower permeable layers. Sensitivity analysis is also performed, showing that shallower reservoirs are more at risk, in that less depletion is supported prior to fracture propagation along the fault. Although simple, the model suggests that care should be taken when selecting depleted gas reservoirs for CO_2 storage, to avoid leakage along faults.

INTRODUCTION

According to the 2018 Intergovernmental Panel on Climate Change (IPCC) report, to keep temperature rise under 1.5 °C compared to pre-industrial level, no credible emission scenario can be considered without Carbon Dioxide Removal (CDR), CCS and afforestation being the only two solutions available. CCS on the scale of hundreds of gigatons of CO_2 will be needed to reach these goals, with tens of thousands of suitable reservoirs to be found and exploited to store CO_2. Two main types of geological formations are considered for storage: deep saline aquifers with thick sealing caprock and depleted oil or gas fields, already proven natural reservoirs. Several demonstration facilities have already proved feasibility of CO_2 storage. However, storing carbon dioxide underground may not be as safe as producing oil and gas in the long term, as it is mainly about increasing pressure in a reservoir rather than decreasing it. Therefore, when purely considering pore pressure change scenarios, depleted oil and gas reservoirs are the preferred storage choice, since one can limit the pressure increase to reach back the original pressure in place when the reservoir was discovered. This pressure had been maintained over geological time without any leakage of the pore fluid and should therefore be ideal to store CO_2. Another argument in favour of depleted reservoirs is the presence of existing infrastructure in place, which could probably be used with minor modifications, compared to virgin aquifer targets. On the other hand, the very presence of wells penetrating the underground dramatically increases the risks of leakage, principally along these wells, where many of them could be old and in poor condition.

These considerations about depleted oil and gas fields do not however take into account non-elastic associated effects in the proposed pore pressure rebound scenario. These effects are translated into stress hysteresis and stress concentration, which could exceed the strength of the formations in and around the proposed reservoir. Many oil and gas reservoirs are compartmentalised in pressure cells bound by sealing caprock and lateral faults. Stress changes accompanying depletion when the reservoir was in production mode may not be evenly distributed but concentrate on the bounding faults. Hysteresis related to plastic yielding (non-recoverable deformation) may also aggravate the solicitation of the faults upon CO_2 injection into the reservoir and lead to reactivation of the faults and hence leakage out of the intended reservoir.

In this paper, we implement a simple scenario looking at a fault on the side of a sandstone reservoir and simulate a depletion and recharge of the reservoir while monitoring stress evolution on the fault. A process zone around the fault core is explicitly implemented in the simulations, by assigning the zone weaker mechanical properties as compared to intact rock and placing in the zone pre-existing fractures.

NUMERICAL METHOD

An in-house explicit fracturing code is used for the fault reactivation simulations [1]. Reactivation is looked at here in more detail, as the fault has a given thickness, 25 m, with pre-existing fractures modelled in different patterns, such that these may further propagate and link to new fractures. The goal of the simulations was to investigate under which conditions (which reservoir pore pressure change history), fractures in the fault's process zone may form a percolating pathway along the fault to shallower layers, which would then be interpreted as a significant leakage risk from the reservoir. The software used was developed at SINTEF and combines finite element and discrete element methods. The simulation domain is initially discretized into triangular finite elements, with linear elastic behaviour, until local stress conditions exceed either tensile or compressive shear conditions. At that point, the discretisation scheme is changed to discrete elements, defined by the failed interfaces of the original finite elements. Fluid flow can be simulated by coupling the code to a CFD code such as TOUGH2 or SINTEF's MRST reservoir simulator. Fractures are monitored in terms of opening mode (tensile or shear) with accompanying permeability related to opening degree.

The simulation domain was assigned different properties for the reservoir sandstone and surrounding shale, consistent with typical values for North Sea sedimentary formations analysed in geomechanical testing. The top boundary was then lowered until the desired stress state was accomplished in the domain, compatible with offshore depth of target reservoirs (Figure 1). A half reservoir was simulated, where reflection of the fault about the centre vertical line provided two cases, one (shown in Figure 1) where the reservoir is in the footwall of the fault, and the other when the reservoir is in the

hanging wall. Simulations consisted in lowering the pore pressure in the reservoir to simulate depletion and monitor stresses at the fault and potential fracturing there. A depletion of up to 10 MPa was applied, in steps of 1 MPa. Pore pressure was then increased back by up to 15 MPa, simulating the injection of CO_2 inside the reservoir, and further evolution at the fault was monitored.

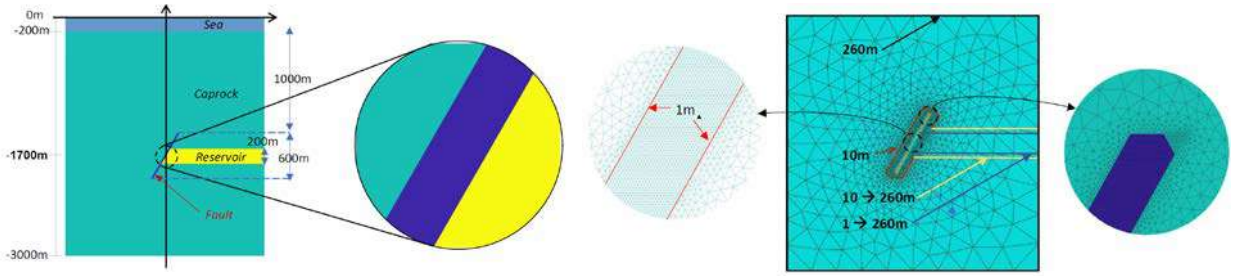

Figure 1. Left: Schematic representation of the sandstone reservoir, in yellow surrounded by shale (green) and bound by a fault (blue). Right: adaptative meshing ranging from 1 m triangle side in the fault to 260 m at the boundaries.

RESULTS

All cases of reactivation of the fault occurred as stepwise propagation of fractures in the fault, not wholescale failure of the fault as is customary in simulations with no fault structure. All cases of fracturing occurred during the **depletion** phase, **none during pressurisation**, confirming previous initial work [2]. Reducing the **stiffness** in the fault zone led to earlier fracturing in terms of depletion magnitude; this corresponds to a high shale gouge ratio in terms of our chosen stiffnesses for sandstone and shale. The **presence of fractures** in the fault zone led to **later** fracturing when these were aligned with the fault, simulating a weak fault core, as compared to cross patterns and horizontal fractures at the reservoir to fault border. Fractures were seen to propagate upwards (to shallower levels) in the **hanging wall** case, while downwards for the **footwall** case (Figure 2).

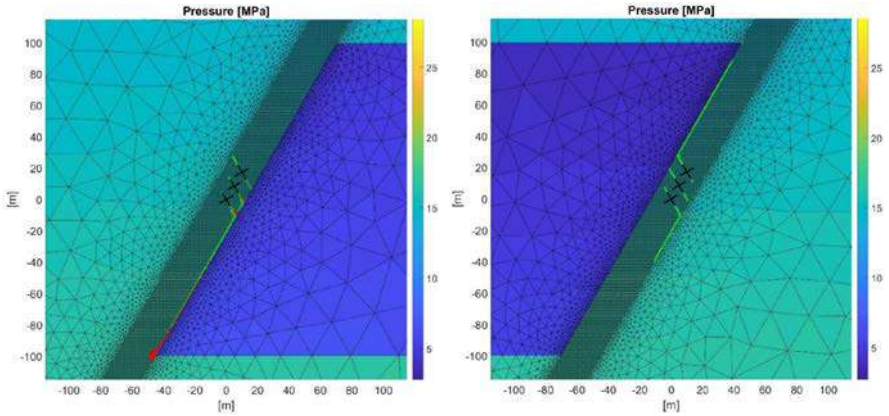

Figure 2. Fracture propagation along the fault for a reservoir is in the footwall (left) and hanging wall (right). Red and light green lines visualize shear and tensile failure, respectively. The depletion is 11 MPa in both cases.

CONCLUSIONS

Modelling fault reactivation taking into account the structure of the fault, even in a greatly simplified manner, shows that this process is not a simple on/off event. The results can be taken to imply that depleted reservoirs may be more leakage-prone than normally pressured aquifers; however, the depletion modelled was very large while fracture propagation not extreme, provided no other high-permeability layers juxtapose the fault.

CONVECTIVELY COUPLED EQUATORIAL KELVIN WAVES IN THE UPPER TROPOSPHERE NEAR SUMATRA AND THEIR INTERACTIONS WITH LOCAL DIURNAL CYCLE

Wojciech Szkolka, Dariusz B. Baranowski
[1]Institute of Geophysics, Polish Academy of Sciences

Summary This research have proved that Equatorial Kelvin waves are present in the upper troposphere over Indian Ocean. Various methods of data analysis were used, especially calculating filtered anomalies and EOF-analysis. We have used data from reanalysis ERA-5 as well as Equatorial Atmospheric Radar on Sumatra. The huge impact of Kelvin waves on the atmosphere dynamics over Sumatra and diurnal cycle in Maritime Continent is easily visible.

The Earth's atmosphere is characterized by weather phenomena, which occur at various spatial scales – from a small (about 1mm) to a large (about 10 000km) scale. Therefore, the nature of a phenomenon of interest determines scales that should be considered. Hence, different approximations can be used to describe dynamics of specific events.
One of typical approximate models for large-scale dynamics is based on shallow water approximation to governing equations. When such model is applied in equatorial zone, the Matsuno model can be derived, and wave solutions can be obtained. One of the important types of these solutions are equatorial Kelvin waves. Although it is a theoretical solution of an approximate model, it can be shown that such waves really exist in the atmosphere. Using appropriate methods of data analysis applied to meteorological data, we may find structures resembling theoretical structure of Kelvin waves.

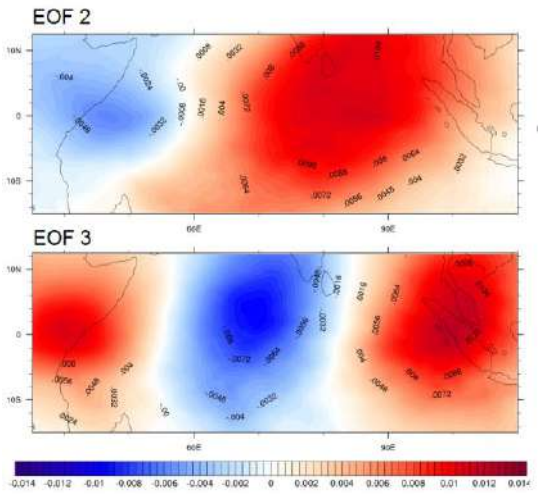

Fig. 1. Results of EOF-analysis on filtered anomalies of wind data ERA-5 over Indian Ocean.

This research focuses on occurrence of atmospheric convectively coupled Kelvin waves (CCKWs) in the upper troposphere (200mb) over Indian Ocean. The analysis is based on 2000-2018 ERA-5 upper level (200mb) wind data and techniques, which allow extraction of specific modes of variability, such as temporal and spatial filtering, and EOF analysis. Spatio-temporal evolution of 2-20 day band pass filtered anomalies of upper level zonal wind matches theoretical structure of Kelvin waves. (Fig. 1)

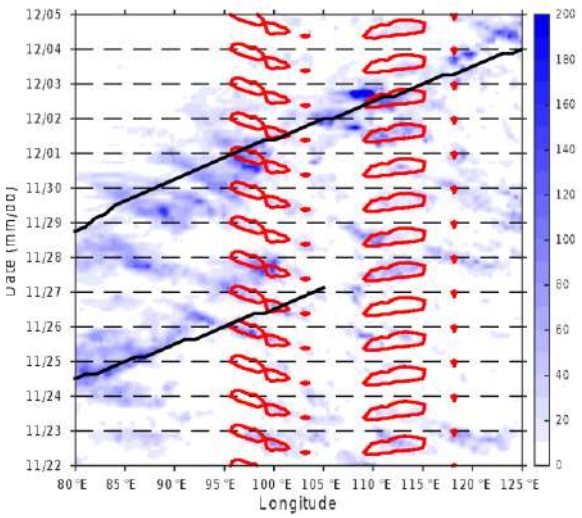

Fig. 2 Hovmoller diagram of total precipitation rate (mm day^{-1}) for the period 22 November to 5 December 2011. The two black lines indicate the propagation of the two CCKWs embedded in an MJO event. The red lines show the 12.5 mm day^{-1} contour from the mean diurnal cycle [from Baranowski et al. (2016)].

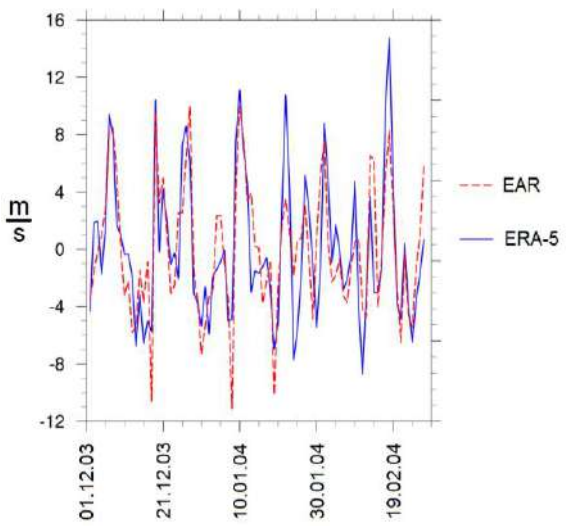

Fig. 3 Comparison between filtered anomalies of ERA-5 data and Equatorial Atmospheric Radar.

THEMATIC SESSION SM

The CCKW upper level anomalies from ERA-5 were augmented with independent upper level wind data measured by Equatorial Atmospheric Radar (EAR), located at the equator, near the west coast of Sumatra, Indonesia. The diurnal cycle of zonal winds at different levels was extracted from EAR data. It is shown that propagation of upper level anomalies associated with CCKWs not only correlate with zonal wind variability over Sumatra, but impact diurnal evolution of the dynamical field across atmospheric column. These results indicate dynamical coupling between larger scale propagating phenomenon (CCKWs) and local processes (diurnal cycle).

To further investigate dynamical feedback between local diurnal cycle and large scale variability, CCKWs trajectories were utilized. The trajectories are based on TRMM, a satellite-based precipitation estimation and allow tracking CCKWs in space and time. Results indicate that CCKW events which propagate across the island of Sumatra (and Maritime Continent) have stronger coupling than those that dissipate within the region.

INTERROGATION OF CRACK TIP FIELDS AND FRICTION THROUGH ULTRAHIGH-SPEED DIGITAL IMAGE CORRLEATION

Vito Rubino*[1], Ares J. Rosakis[1], and Nadia Lapusta [2,3]
[1]Graduate Aerospace Laboratory, California Institute of Technology, Pasadena, CA, USA

Summary Dynamic shear ruptures are characterized by highly variable spatiotemporal features. Understanding the behaviour of dynamic ruptures and the frictional processes controlling their propagation is relevant to various fields, such as fracture mechanics and earthquake physics. Until recently, it was not possible to quantify experimentally the full-field behaviour of dynamic ruptures due to metrological limitations. In this study, we present our recent advances in investigating the near-tip fields of dynamic ruptures and elucidate the frictional processes governing their propagation. Our experimental measurements, based on ultrahigh-speed digital image correlation technique, reveal the intricate structure of sub-Rayleigh and supershear ruptures improving our understanding of the physics of rupture propagation with important implications for evaluating earthquake hazard.

INTRODUCTION

Understanding the behaviour of dynamic shear ruptures is important for applications ranging from the failure of composite structures, to car brakes and earthquake physics. Capturing the temporal evolution of propagating dynamic ruptures poses a metrological challenge, as ruptures propagate at speeds close to the Rayleigh wave speed or even exceed the shear wave speed. Recently, we have been able to quantify the full-field structure of dynamic frictional ruptures by combing digital image correlation [1] and ultrahigh-speed photography [2-7]. Here, we focus on the description of near-field features and the evolution of dynamic friction, in various experimental configurations.

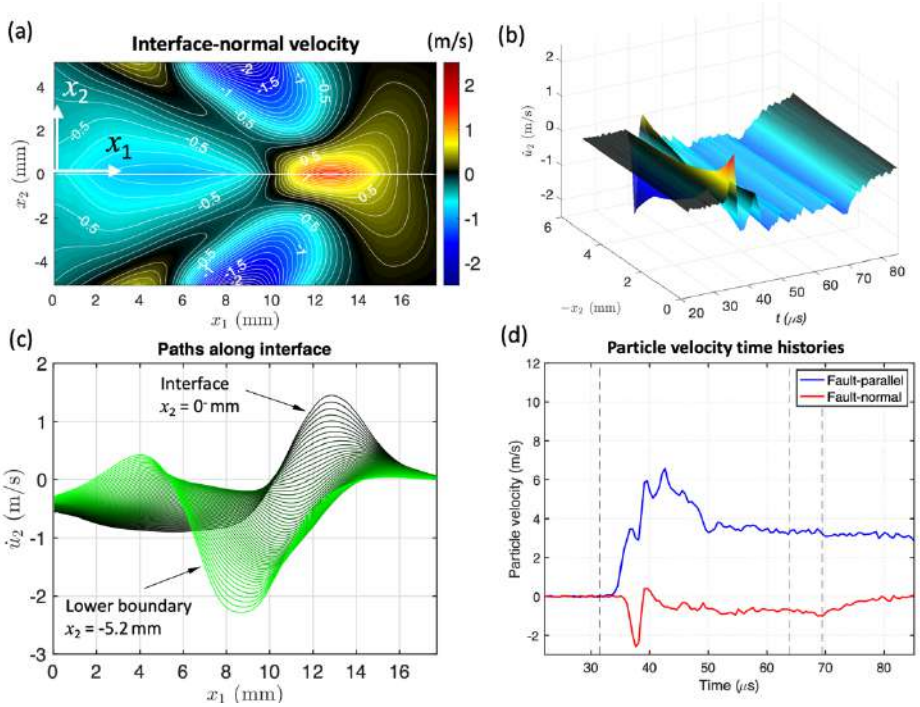

Figure 1. Capturing the near-field structure of shear cracks showing the interface-normal particle velocity. (a) Full-field map, (b) spatiotemporal plot, the fault-normal velocity is plotted vs. time and vs. distance from the interface, (c) interface-normal velocity along the interface plotted at various distances from the interface, (c) particle velocity time history for both the interface-parallel (blue) and interface-normal (red) components. Modified from [7].

EXPERIMENTAL APPROACH

Dynamic shear cracks, representative of earthquake ruptures, are produced in our laboratory setup as frictional ruptures propagating along the inclined interface of two quadrilateral plates of Homalite-100 [6,8]. Ruptures are nucleated by the small burst of a NiCr wire placed across the interface, and once nucleated they propagate under the

*Corresponding author. E-mail: vito.rubino@caltech.edu

applied level of static normal and shear pre-stress levels. A ultrahigh-speed camera records a sequence of images of the propagating ruptures on a portion of the specimen covered by a characteristic pattern, at 1-2 million frames/second (200 ns exposure time). The images are analysed with the digital image correlation method to infer the time evolution of full-field displacements, particle velocities, and strains [4]. Stress fields are computed from the strain fields assuming linear elastic constitutive models, friction is then obtained as the ratio of shear to normal stress along the interface [2].

QUANTIFYING RUPTURE BEHAVIOR AND FRICTION EVOLUTION

We have characterized the behavior of dynamic ruptures ranging from sub-Rayleigh to supershear speeds and comprising both cracks and pulses. The sequence of full-field displacements and particle velocity reveal the complex dynamics at a unique level of detail. In this presentation, we concentrate on describing the near-field spatiotemporal features obtained by dedicated experiments performed with a field of view focusing in the near-tip region. The interface-parallel velocity component of supershear ruptures are characterized by pronounced shear motion and by marked shock fronts extending into the far field [7]. The interface-normal velocity presents a complex behavior with an initial (upward) positive motion followed by a negative (downward) motion along the interface (Figure 1). These features are very distinctive in the near-tip field but attenuate very quickly with distance from the interface. Two wedge regions, characterized by negative (downward) motion, radiate away from the crack tip and are parallel to the shock fronts displayed by the interface-parallel velocity and maximum shear stress. By contrast, these features propagate into the far-field regions (Figure 1a and 2b). We will present our findings for sub-Rayleigh ruptures as well as our current work on quantifying the decay of the fields away from the interface..

Friction is a key process controlling rupture propagation and how earthquake ruptures release waves that cause destructive shaking. Nonetheless, it is one of the least constrained ingredients in earthquake physics. Our measurements allow us to infer the local evolution of friction associated with spontaneously propagating ruptures [2] and to characterize the evolution of frictional resistance in response to rapid normal stress variations [9], which we have done for analog materials. However, earthquake ruptures in mature faults propagate in gouge, which is a powdered rock material. In order to better study the rheology of natural faults in the Earth's crust, we have been performing dynamic rupture experiments using a hybrid configuration featuring quartz gouge embedded along the interface of a Homalite specimen. This configuration enables to use the advantage of smaller nucleation length scales provided by Homalite, while capturing the evolution of friction in quartz gouge. We will report our current observations of rapid and pronounced dynamic weakening as well as dynamic triggering in this configuration.

CONCLUSIONS

Our highly instrumented experiments allow us to quantify dynamic rupture behaviour of sub-Rayleigh and supershear ruptures and to infer the local evolution of the friction coefficient for a wide range of loading conditions. A new configuration featuring quartz gouge embedded in a Homalite specimen reveals a much more complex rupture behavior controlled by the gouge rheology, which we simultaneously measure and characterize. These results contribute to our understanding of dynamic rupture propagation and friction evolution with important implications for earthquake physics.

DYNAMIC STRENGTH OF MATERIALS AT HIGH STRAIN RATES AND PRESSURES

Guruswami Ravichandran
Division of Engineering and Applied Science, California Institute of Technology, Pasadena, California, USA

Summary Impact, blast, and other dynamic loading events can result in extreme loading conditions of high strain-rates and pressures in materials. The work described here focusses on measuring the dynamic strength of materials using plate impact techniques at strain rates of up to ~10^7/s and pressures of up to ~50 GPa. Recent advances in extending the pressure shear plate impact technique to measure the strength of materials and characterizing their constitutive response at high pressures are discussed. Results are presented for a variety of materials, including copper, magnesium, and soda lime glass. The work presented here was performed at Caltech by Christian Kettenbeil, Zev Lovinger, Suraj Ravindran, Vatsa Gandhi, and Michael Mello.

INTRODUCTION

Dynamic events such as impact and blast of materials and structures involve the propagation of stress waves in solids, which results in high pressures and high strain rates [1]. Knowledge of the response of solids at high strain rates and pressures would help advance our fundamental understanding of material behavior under extreme conditions. Experimental data obtained by studying the response of solids at high pressures and strain rates are needed for validating constitutive and failure models. Such models would aid in the design and analysis of structures subjected to transient loading. Investigating the response of materials at high strain rates and pressures is an active field of research. Experimental techniques for direct measurement of dynamic strength of materials include the split Hopkinson (Kolsky) bar (SHPB) [2] and the pressure shear plate impact (PSPI) technique [3,4]. These techniques rely on a relatively thin sample of interest sandwiched between rods/plates, which remain elastic during the dynamic deformation of the sample. The SHPB typically uses a cylindrical sample, which is nominally in a state of uniaxial stress. The PSPI technique uses a thin disk as the sample, which is subjected to combined normal and shear loading. The gage section in a shear compression specimen (SCS) used in an SHPB is subjected to multiaxial loading [5]. The state of stress and strain in the deforming sample in SHPB and PSPI are inferred based on the analysis of elastic waves propagating in bars/plates. Typical pressures and strain rates that are currently achievable are <1 GPa and 10^4/s in the SHPB and ~10 GPa and ~10^6/s in PSPI. The need for strength measurements at higher pressures is motivated by applications such as inertial confinement fusion [6], earth and planetary interiors [7], and defense and security [1]. The current work focusses on extending the range of the PSPI technique to higher pressures (~50 GPa) and strain rates (~10^7/s).

EXPERIMENTAL

In the pressure shear plate impact experiments, a thin disc of the material of interest is sandwiched between hard anvil plates. It is impacted at an oblique angle by a hard flyer plate, and the normal and transverse particle velocities are measured on the rear free surface [3,4]. PSPI experiments are typically conducted using single-stage gas guns, which limit the pressures that can be achieved. In this work, PSPI experiments are extended to higher pressures, approaching 50 GPa by employing higher impact velocities. The impact facility consists of a single-stage powder gun, with a 38.7 mm in diameter and 3 m long barrel with a keyway, capable of launching projectiles at velocities in the range of 200-2,000 m/s.

The high-pressure and high-velocity impact regimes pose several challenges for measurement and interpretation of the free surface velocities. At high pressures (above the Hugoniot Elastic Limit, HEL), the anvils yield and undergo inelastic deformation, which precludes traditional elastic analysis from extracting the normal stress and material's strength from the measured free surface particle velocity signals [3]. The higher impact velocities also require accurate measurement of the transverse velocities at large normal displacements, resulting from the higher impact velocities. An all fiber-optic heterodyne velocity interferometer system has been developed to simultaneously measure both normal and transverse velocities at high impact velocities [8]. Higher pressures in PSPI experiments are achieved by increasing the velocity of the flyer plate impacting standard anvil materials such as tungsten carbide and tool steel, which can undergo significant inelastic deformation at pressures beyond the HEL.

A new hybrid numerical/experimental approach has been developed to extract the strength of the material of interest when the anvil and flyer plates no longer remain elastic. The inelastic response of anvil plates of interest is characterized by conducting symmetric pressure shear plate experiments at pressures of interest. A material model for describing the inelastic response of the anvil material is calibrated by comparing numerical simulation results with the experimentally measured free surface velocity signals. Requiring the simultaneous matching of both the normal and the transverse signals between experiments and simulations provides a strong constraint in calibrating the constitutive model for the anvil material. Once the constitutive model for the inelastic high-pressure response of the anvil material is established, sandwich configuration PSPI experiments are conducted wherein the material of interest is sandwiched between the anvil plates. Finally, the strength of the material of interest is extracted by simulating the sandwich configuration experiments and matching the normal and transverse velocity measurements from the PSPI experiments with the simulation results. Since the anvil material model has been calibrated previously, only the strength model for the material of interest remains to be calibrated. The pressure and strain rate in the sample are computed as part of the numerical simulations. For a given impact velocity, the pressure is relatively unaffected by the presence of the material of interest in the sandwich

configuration. The hybrid procedure has been used to determine the high-pressure strength of copper with tool steel anvils, magnesium with tool steel anvils [9], and soda lime glass with tungsten carbide anvils [10].

CONCLUSIONS

A new hybrid methodology based on PSPI experiments and numerical simulations has been developed for the extraction of material strength at high pressures and strain rates. The method relies on the ability to account for the inelastic response of the flyer and anvil plates at pressures exceeding their HEL. The successful implementation of the high-pressure PSPI technique to extract the strength of materials at high pressures of up to ~50 GPa and strain rates of up to 10^7/s has been demonstrated for quasi-brittle and ductile materials.

ACKNOWLEDGMENTS

The authors are grateful for support from the Office of Naval Research (Award No. N00014-16-1-2839) for the development of the PSPI capability at high pressures and the Air Force Office of Scientific Research and the Air Force Research Laboratory (Award No. FA955012-1-0091) for development of the PDV-HTV interferometer system. The PSPI work on magnesium was supported by the Army Research Laboratory and was accomplished under Cooperative Agreement No. W911NF-12-2-0022. The authors thank Professor R. J. Clifton and Dr. T. Jiao of Brown University for many helpful discussions and assistance in developing the high-pressure PSPI experimental capability by generously sharing their vast experience.

STABILITY OF THE TIME DOMAIN BOUNDARY INTEGRAL EQUATION FOR ACOUSTICS AND ELASTICITY REVISITED

Ryota Misawa[1], Kazuki Niino[2], Toru Takahashi[3], and Naoshi Nishimura*[2]
[1]Graduate School of Science and Engineering, Saitama University, Saitama, Japan
[2]Graduate School of Informatics, Kyoto University, Kyoto, Japan
[3]Graduate School of Engineering, Nagoya University, Nagoya, Japan

Summary This study considers the stability of the traditional time domain collocation BIEMs (boundary integral equation methods) for acoustics and elasticity. We show that the question of stability of time domain BIEMs is reduced to a nonlinear eigenvalue problem related to frequency domain integral equations. We propose to solve this eigenvalue problem numerically with the Sakurai-Sugiura method (SSM). The proposed approach is validated numerically with standard BIEs for exterior and transmission problems for the wave equation and the Navier-Cauchy equation for elastodynamics. We also investigate fast methods for solving boundary integral equations for acoustics based on the interpolation technique.

INTRODUCTION

It is unfortunate that the stability issues of the collocation boundary integral equation methods (BIEMs) for the wave equation in time domain have remained unsolved for decades. Although recent developments of CQM by Lubich[1] provided a partial solution to this instability problem, there still remain demands for simpler traditional methods. In examining the stability of the traditional collocation BIEM, however, one has few effective alternatives than to solve large eigenvalue problems for the space-time discretised system matrices. The situation becomes even worse in 2D problems in which such eigenvalue problems become huge because of the infinite "tail" of the fundamental solution in time domain.

In view of this, we have proposed to carry out the required stability analyses in frequency domain rather than in time domain[3]. This approach converts the stability analysis for BIEMs in the wave equation to a non-linear eigenvalue problem similar to those for the Helmholtz equation and solves it with the Sakurai Sugiura method (SSM)[2]. In addition, this approach makes the relation between eigenvalues of the integral operators in frequency domain and the stability of the time domain BIEM clearer thus providing insights into the choice of accurate and stable formulations. In the proposed presentation, we use the proposed technique to investigate stability of various time domain integral equations for exterior and transmission problems of acoustics and elasticity. We also discuss fast methods using stable formulations thus obtained.

STABILITY ANALYSIS

Theory

We consider the following integral equation with respect to the time variable t:

$$f(t) = \int_0^t K(t-s)v(s)\,ds \tag{1}$$

obtained typically by discretising the time domain BIEs for the wave equation in the spatial direction using N collocation points, where K is a given $N \times N$ matrix, f is a given N-vector and v is an unknown N-vector function. Discretising the unknown function $v(s)$ in (1) using time interpolation functions $\phi_m(s)$ as $v(s) \approx \sum_m \phi_m(s) v_m$ ($v_m \in \mathbb{R}^N$), we obtain the following algebraic equation:

$$f(l\Delta t) = \sum_{m=1}^{l} \int_0^{l\Delta t} K(l\Delta t - s)\phi_m(s)\,ds\, v_m \qquad l = 1, 2, \cdots \tag{2}$$

where $\phi_m(s) = \phi_{\Delta t}(s - m\Delta t)$ and $\phi_{\Delta t}(t)$ is a basis function which satisfies $\phi_{\Delta t}(k\Delta t) = \delta_{k0}$ (where δ_{ij} is the Kronecker delta), respectively. One shows that the question of the stability of the scheme in (2) is now reduced to the following non-linear eigenvalue problem: find $\Omega \in \mathbb{C}$ with which the following equation

$$0 = \sum_{m=-\infty}^{\infty} \frac{1}{\Delta t} \hat{K}(\Omega_m)\hat{\phi}_{\Delta t}(\Omega_m)\, v \tag{3}$$

has a non-trivial solution $v \in \mathbb{C}^N$, where $\Omega_m = \Omega - \frac{2m\pi}{\Delta t}$ and $\hat{}$ stands for the Fourier transform with respect to time. One shows that the scheme in (2) is stable (unstable) if $\mathrm{Im}\,\Omega \le 0$ ($\mathrm{Im}\,\Omega > 0$) holds for all the eigenvalues (an eigenvalue) of (3). One may use solvers of non-linear eigenvalue problems such as the Sakurai-Sugiura method (SSM) in the solution of the problem in (3). In the special case where the boundary of the domain is a unit circle Γ, one may simplify (1) using the Fourier series with respect to the angular variable. See Fukuhara et al.[3] for further details.

*Corresponding author. E-mail: nishimura.naoshi.8r@kyoto-u.jp

Numerical experiments

We now carry out numerical experiments to see if the stability analysis given in the previous section can predict the behaviour of the time domain BIEM correctly. We consider an elastodynamic scattering problem in 2D in which an incident plane wave u^{inc} impinges upon a fixed circular scatterer Γ. The radius of this scatterer is 1 (arbitrary unit). One may reduce this problem to the solution of the following time domain integral equation of the Burton-Miller (BM) type:

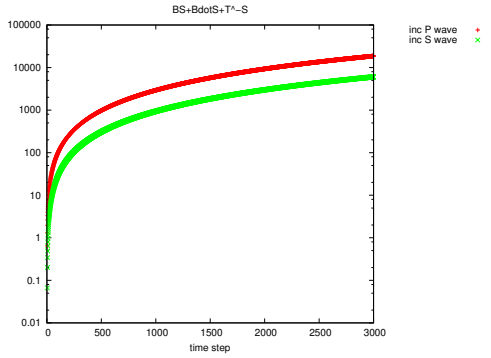
$$\left(B\left(a+\frac{\partial}{\partial t}\right)+T^{-}\right)Sq(t,x)=\left(B\left(a+\frac{\partial}{\partial t}\right)+T\right)u^{\mathrm{inc}}(t,x)\qquad x\in\Gamma \tag{4}$$

where Sq, T, $^{-}$, a and B, respectively, stand for the single layer potential for elastodynamics with the unknown traction q on the boundary, traction operator, limit from the interior of the scatterer, a constant and the matrix given by

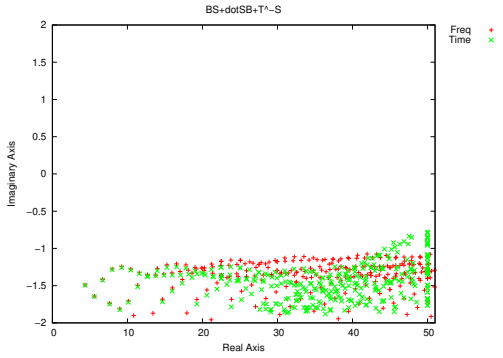
$$B=\rho(c_L n\otimes n+c_T(1-n\otimes n)),\qquad \rho:\ \text{density},\quad c_L:\ \text{P wave velocity},\quad c_T:\ \text{S wave velocity}. \tag{5}$$

Note that our stability analysis[3] shows that a non-zero a in (4) improves the accuracy of the solution. We use piecewise constant boundary elements, piecewise linear time elements and the collocation method to discretise the BIE in (4).

Fig.1 (a) shows the plot of the magnitude of q at a certain point on the boundary obtained with time domain BIE vs time step. We see that (4) leads to stability, which is consistent with the distribution of the eigenvalues given in Fig.1 (b).



(a) q vs time step



(b) green: eigenvalues of (3), red: eigenvalues of the frequency domain BIEM ($m=0$ term in (3))

Figure 1: Stability of time domain BIEM for elastodynamics in 2D. $\rho=\lambda=\mu=1$ (arbitrary unit), 100 boundary elements, $\Delta t=\pi/50$, $a=1$.

Motivated by the stability of the BM type formulation for the exterior Dirichlet problems in 2D shown above, we have tested a similar approach in acoustics in 3D using an interpolation based fast multipole method (FMM) in time domain proposed in [4]. We consider a spherical sound soft scatterer having a unit diameter subjected to a plane incident wave. This problem is solved with a conventional BIEM and an interpolation based FMM using the BM type formulation. Fig. 2 shows the time history of $\partial u/\partial n$ at a certain point on the boundary. It is seen that the numerical results agree with the analytical solution. It is also seen that the FMM solutions remain stable regardless of the degrees of the spatial interpolation (p) in spite of sporadic disturbances caused inevitably by the interpolation used in this approach. These numerical results clearly show the effectiveness of the proposed stability analysis.

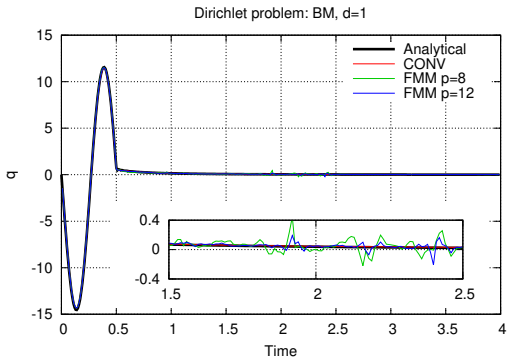


Figure 2: $\partial u/\partial n$ on boundary of a sound soft scatterer in 3D vs t. 5120 elements, $\Delta t=0.01$, 400 time steps

Summary We provide a comprehensive theoretical and numerical framework to understand the emergence of cracklike behaviour of frictional rupture. We discuss the origin of stress drop behind the slip front and show that, in the presence of such a stress drop, energy balance controls slip front propagation for generic rate and state friction laws.

ABSTRACT

The process of frictional rupture, i.e., the failure of frictional systems, abounds in the technological and natural world around us, ranging from squealing car brake pads to earthquakes along geological faults. A general framework for understanding and interpreting frictional rupture commonly involves an analogy to ordinary crack propagation, with far-reaching implications for various disciplines from engineering tribology to geophysics. An important feature of the analogy to cracks is the existence of a reduction in the stress-bearing capacity of the ruptured interface, i.e., of a drop from the applied stress, realized far ahead of a propagating rupture, to the residual stress left behind it. Yet, how and under what conditions such finite and well-defined stress drops emerge from basic physics are not well understood.

In the first part of this talk, we show that for a rapid rupture a stress drop is directly related to wave radiation from the frictional interface to the bodies surrounding it and to long-range bulk elastodynamics and not exclusively to the physics of the contact interface. Furthermore, we show that the emergence of a stress drop is a transient effect, affected by the wave travel time in finite systems and by the decay of long-range elastic interactions. Finally, we supplement our results for rapid rupture with predictions for a slow rupture. All of the theoretical predictions are supported by available experimental data and by extensive computations.

In the second part, we show that for generic and realistic frictional constitutive relations, and once the necessary conditions for the emergence of an effective crack-like behavior are met, frictional rupture dynamics are approximately described by a crack-like, fracture mechanics energy balance equation. This is achieved by independently calculating the intensity of the crack-like singularity along with its associated elastic energy flux into the rupture edge region, and the frictional dissipation in the edge region. We further show that while the fracture mechanics energy balance equation provides an approximate, yet quantitative, description of frictional rupture dynamics, interesting deviations from the ordinary crack-like framework — associated with non-edge-localized dissipation — exist. Together with the results about the emergence of stress drops in frictional rupture, this work offers a comprehensive and basic understanding of why, how and to what extent frictional rupture might be viewed as an ordinary fracture process [1,2].

MODELLING OF DYNAMIC BEHAVIOUR OF INHOMOGENEOUS ELASTIC MEDIA

Chen Wang, Zhengwei Li, and Xiaodong Wang*
Department of Mechanical Engineering, University of Alberta, Edmonton, Canada

Summary The dynamic response of periodic elastic materials with multiple interaction is discussed to explore the relation between the local property of the material in the representative volume elements (RVEs) and the overall effective properties when dynamic loads are applied. Attention is paid to the modelling and numerical simulation of the dynamic behaviour of such materials when a large number of inhomogeneities are involved. Using the general idea of Pseudo-incident wave method to deal with the multiple interaction the effective material properties are calculated. The results are validated by comparing the result from homogenization with that obtained directly by using RVE with periodic boundary conditions. It is shown that the current method is effective in analyzing the dynamic behaviour of periodic materials.

INTRODUCTION

The understanding of the elastic wave propagation in heterogeneous materials is essential for their applications in a variety of engineering structures involving dynamic loading. More recently, the artificially structured metamaterials have attracted extensive attention because of their exotic dynamic properties. The modelling of their elastodynamic behaviour plays a significant role in their design and optimization. Because of the substantial separation of scales, the pure numerical simulation becomes prohibitive when both the local and global responses are important. Therefore, for material systems with complex structures in various scales, it is usually necessary to use multiscale models in which local structures are replaced by homogeneous materials with effective properties.

For dynamic problems of periodic materials, models based on Bloch waves are admitted as the solution for wave propagation problems. In recent studies on phononic crystals, the periodicity of the local structures and the waveforms are assumed inherently, and various numerical techniques have been developed to determine the resulting dispersion relations. In these studies since the works are mainly focused on the band structures [1,2], the Bloch wave vector is prescribed and the frequency of the incident wave is computed as the eigenvalue. In addition, the Bloch wave vector is usually limited to the boundary of the irreducible Brillouin zone. So the existing methods are inefficient to determine the effective wave fields under prescribed incident waves. This paper presents a computational framework for the elastodynamic homogenization of heterogeneous materials based on the optimization of boundary integrals of explicitly computed wave fields.

MODELLING OF THE PERIODIC ELASTIC MEDIA

To illustrate the current method, consider the dynamic behaviour of a periodic elastic medium subjected to a general incident wave, as shown in Fig. 1. The properties of macroscopically homogeneous materials can be approximated by those of their representative volume elements (RVE). For the periodic heterogeneous material, a repeating volume composed of one or multiple unit cells can be considered as a RVE, as shown by the boxes in Fig. 1. A RVE with one unit cell is shown in Fig. 2. With defined RVEs, the response of the heterogeneous material can then be treated by considering the interactions among multiple RVEs under the prescribed loads. Since the RVEs interact with each other only through the surfaces, the mechanical behaviour of a RVE can be encapsulated by its boundary response, which can be represented by the relation between the surface displacement and the traction. For example for antiplane problems with multiple inhomogeneities the property of the RVE selected will be determined by the antiplane displacement w.

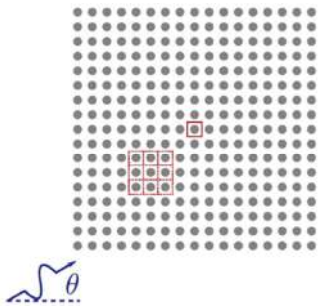

Figure 1 Periodic material subjected to an incident wave.

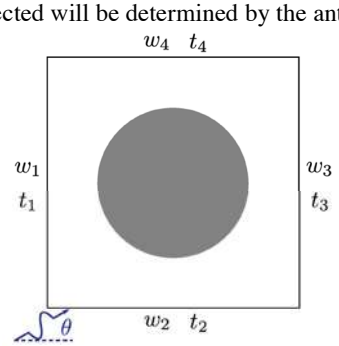

Figure 2 Unit cell under periodic boundary condition

EFFECTIVE PROPERTY OF THE RVE

The wave field in RVE subjected to typical incident waves are determined by using a Pseudo-incident wave method [3]. The resulting wave field is then used to evaluate the dynamic effective property of the RVE. If the RVE is modelled

*Corresponding author. E-mail: xiaodong.wang@ualberta.ca.

as a homogeneous effective medium, the relation between the boundary displacement w and the traction t can be expressed by the boundary integral equation, as

$$c(\boldsymbol{x})w(\boldsymbol{x}) + \int_S \frac{\partial G(\boldsymbol{x},\boldsymbol{y})}{\partial \boldsymbol{n}(\boldsymbol{y})} w(\boldsymbol{y}) ds(\boldsymbol{y}) = \int_S G(\boldsymbol{x},\boldsymbol{y}) t(\boldsymbol{y}) ds(\boldsymbol{y}) \tag{1}$$

where S is the boundary of the RVE with $\boldsymbol{n}$ being the outward normal vector. $c(\boldsymbol{x})$ depends on the geometry of the boundary at position $\boldsymbol{x}$. $G(\boldsymbol{x},\boldsymbol{y})$ is the Green's function of the effective medium.

For homogeneous media, the solution from (1) will be exactly same as that from the solution by Pseudo-incident wave method. But for the current periodic media, since the RVE is not composed of the homogeneous material with the same properties upon which the Green's function is determined, the solution will be different and will be described by a residue function. The magnitude of the residual function depends on the material properties of the effective medium. The minimum residue occurs when the material properties of the fictitious homogeneous effective medium can best represent the boundary response of the RVE. Accordingly, the effective properties of the heterogeneous material are determined by adjusting the effective properties to minimize the residual function. In the numerical implementation, the boundary is discretized into segments, and the boundary integrals are computed by using Gaussian quadrature.

RESULTS AND DISCUSSION

This section will present the verification and the evaluation of the accuracy of the developed homogenization algorithm, and the application of the algorithm to general examples. The homogenization results are verified by comparing the direct numerical simulation results of the wave fields of interacting inhomogeneities with that based on the effective properties obtained by the proposed procedures. As shown in Fig. 3, the multiple scattering model is composed of *20X20* identical circular inhomogeneities arranged in a rectangular lattice. The radius of the inhomogeneities is *6 mm* and the size of a cell is *20 mm*. The density and shear modulus of the matrix are *7670 kg/m*^{3} and *84.3GPa*, and the corresponding values for the inhomogeneities are *11400 kg/m*^{3} and *8.43GPa*.

The normalized amplitude of the displacement along the horizontal line marked in Fig. 3 is plotted in Fig. 4, where w^0 represents the displacement caused by the original incident wave. From the comparison of the results, it can be observed that the displacement matches well outside the region of inhomogeneities ($-10 < x < 10$). Inside the region, deviation is observed but the results still agree reasonably well. The use of homogenized model in simulating the multiple scattering in larger scale is also conducted and validated by the comparison between the numerical simulations of the two models. Excellent agreement of the predicted wave is also observed for both displacement and stress fields.

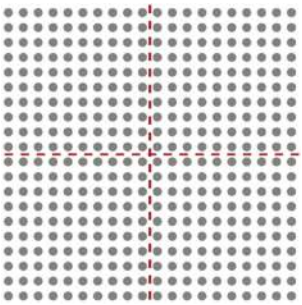

Figure 3 Multiple scattering model

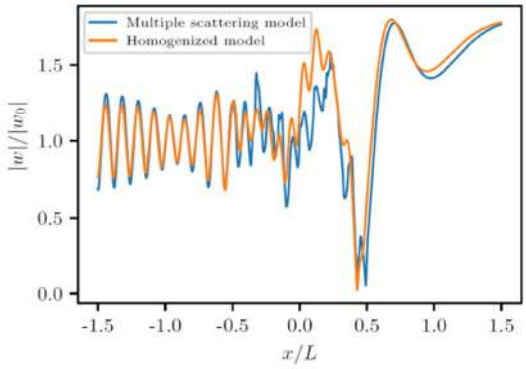

Figure 4 Normalized displacement amplitude

CONCLUSIONS

A computational homogenization method is presented to evaluate the dynamic effective properties of periodic elastic media. The method makes use of the optimization of the boundary integral of the RVEs with periodic boundary conditions based on the explicitly solved multiple scattering wave fields. The residue function, which indicates the mismatch between the boundary responses of the RVE and the homogenized substitution, is defined as the objective function to be minimized over the material properties. Similar simulations conducted indicate that for difficult frequencies the periodic material will show pass-band or stop-band, as well understood for other similar structures. The RVE is defined as multiple unit cells surrounded by a number of identical cells for approximating the ambient wave field in infinitely periodic structure. The approximation is validated by comparing the homogenization results with the ones obtained by using RVE with periodic boundary conditions. The results indicate that the current method is effective in determining the dynamic effective properties of periodic elastic materials.

STUDY ON THE PENETRATION OF A JACKETED ROD INTO SEMI-INFINITE TARGET

Jinxiang Wang*, Kui Tang
National Key Laboratory of Transient Physics, Nanjing University of Science and Technology, Nanjing, China

Summary A combined experimental, numerical and theoretical study is conducted herein on the penetration of semi-infinite targets by jacketed rods with two types of jacket materials. Specially, the damage mode of the 93W/1060Al jacketed rod changed from "bi-erosion" to "co-erosion" at a striking velocity of 936 m/s. While, for other striking velocities, only "co-erosion" damage was observed. Two kinds of jacketed rods presented completely different damage mechanisms for striking velocity less than 2.0 km/s, due to the differences in material properties of the jacket. For striking velocity lager than 2.0 km/s, the penetration performance of the two types of jacketed rods is the same as that of the unitary 93W rod. Meanwhile, the kinetic energy and the strength of the jacket have a significant effect on the penetration performance of the jacketed rod. Based on the detailed analysis of the damage mode and the failure mechanism of the jacketed rod by combining the experimental and numerical results, the analytical model for penetration depth was modified, and the predicted results of the modified model were in good agreement with the experimental results.

Jacketed projectile is usually consists of a central high-density rod surrounded by a low-density jacket. Recently, a series of numerical simulations[1-5] and experiments[1,2,5-7] have been performed to examine the ballistic performance of the jacketed rod. And, Wen et al.[4] have developed an analytical model to predict the penetration depth of jacketed rod into semi-infinite target. However, almost all these experiments carried out above had controlled the striking velocity around 1.6 km/s and 2.5 km/s. In addition, only a few types of jacket materials are used in these tests. Therefore, we carried out series of experimental and numerical study on the penetration of two types of jacketed rods into semi-infinite 4340 steel targets, in which the striking velocity was extended to 0.9-3.3 km/s and two kinds of new jacket materials were considered. And, the penetration depth model presented by Wen et al.[4] was modified.

EXPERIMENTAL PROCEDURE

In this study, 93W4.9Ni2.1Fe (93W) is used as the central core, as to jacket material, 1060 aluminum and TC4 titanium alloy are considered. The total length (L), the diameters of the core (d) and the jacket (D) of the jacketed rods tested are 70 mm, 5 mm and 7 mm, respectively. In addition, the homogeneous 93W rod with the same shape and size as that of the jacketed rod is tested. And, 4340 steel target is used. The striking velocity was during 0.9-3.3 km/s.

NUMERICAL SIMULATION

To supply sufficient data for the analysis of the damage mechanism and the penetration performance of the unitary 93W projectiles and jacketed projectiles, AUTODYN was adopted to simulate the penetration process. The Smoothed Particle Hydrodynamics method (SPH) was employed for the projectile. And, the Lagrange solver was employed for the target to improve computing efficiency. Fig. 1 shows the comparison of experimental and numerical simulation results under one of the conditions. It is evident that the numerical results are in good agreement with the experimental results.

DAMAGE MECHANISM

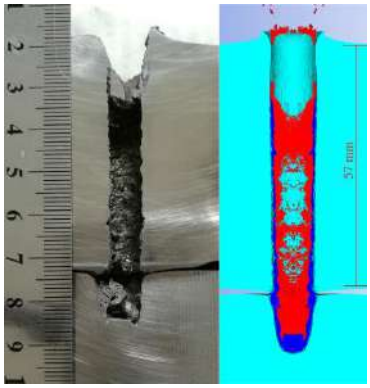

Fig. 1 Comparisons of experimental and simulated results of Shot 1-6

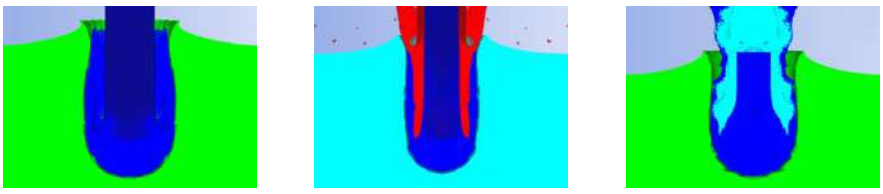
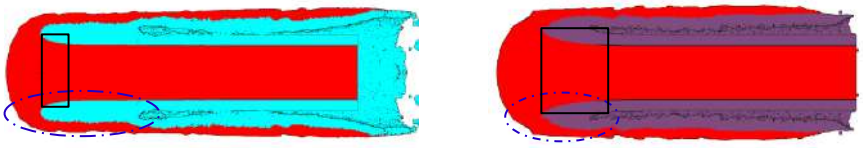


(a) 93W rod, 949m/s (b) 93W/1060Al rod, 936m/s (c) 93W/TC4 rod, 930m/s



(d) 93W/1060Al rod, 1654m/s (e) 93W/TC4 rod, 1521m/s

Fig. 2 Morphology of 93W and jacketed rods

The typical morphology of the unitary 93W rod and the jacketed rods under different striking velocity is shown in Fig. 2. It can be found that the unitary 93W rod formed a "mushroom head" during penetration. Specially, the damage mode of the 93W/1060Al jacketed rod change from turns from "bi-erosion"[4] at early penetration stage to "co-erosion" [4] at late penetration stage at a striking velocity of 936 m/s. While, typical "co-erosion" damage mode was observed in other cases for two types of jacketed rods. In addition, there are significant differences in the damage mechanisms of the two kinds of jacketed rods, the core of the 93W/TC4 jacketed rod formed an obvious bulges between the rigid tail and the head as shown in Fig. 2 (c), while it was not observed in Fig. 2 (b). As shown in Fig. 2 (d) and (e), the deformation of the core for 93W/TC4 jacketed rod in the box is still larger than that of the 93W/1060Al jacketed rod. Meanwhile, the jacket of the 93W/1060Al jacketed rod is more serious and the deformation area is much bigger than that of the

* Corresponding author. E-mail: wjx@njust.edu.cn

93W/TC4 jacketed rod. However, the difference in the damage mechanisms of the jacket and core of the jacketed rod decreases with increasing incident velocity.

PENETRATION PERFORMANCE

It was found that the penetration performance of the two types of jacketed rods is less than that of the unitary 93W rod for striking velocity lower than 1.65 km/s, while it is the same for striking velocity larger than 2.0 km/s. As a typical kinetic energy penetrator, the kinetic energy has a great effect on the penetration performance of the jacketed rod. For example, the penetration performance of the 93W/1060Al jacketed rod is about 43.5% higher than that of the unitary 93W rod at an initial incident kinetic energy of 36.55 kJ. But, this advantage gradually decreases as the incident kinetic energy increases. The strength of the jacket has a significant effect on the penetration performance of the jacketed rod, compared to the density of the jacket. The lower the strength of the jacket, the better the penetration performance is.

ANALYTICAL MODEL FOR PENETRATION DEPTH

In the case of "co-erosion" penetration, assume that at time t, the length and velocity of the rigid body of the jacketed rod are l and v, respectively. And the penetration velocity is u. Wen et al.[4] have developed an analytical model to predict the penetration depth of jacketed rod into semi-infinite target as follow.

The momentum balance of the rigid part of the rod gives: $Y_c A_{c0} + Y_j A_{j0} = -\left(\rho_c A_{c0} + \rho_j A_{j0}\right) l \mathrm{d}v / \mathrm{d}t$ (1)

Let $\lambda = A_{j0} / A_{c0}$, and divide both ends of equation (1) by (1+λ), then it can be rewritten as: $Y_{eq} = -\rho_{eq} l \mathrm{d}v / \mathrm{d}t$.

The rod erodes as: $\mathrm{d}l / \mathrm{d}t = -(v-u)$ (2)

The v~u relationship is given as: $\rho_{eq}(v-u)^2/2 + Y_{eq} = \rho_t u^2/2 + R_t$ (3)

where, the R_t is defined as a piecewise function by Wen et al.[4], herein, a continuous function R_t=7$Y_t$ln(α)/3 that given by Walker and Anderson[8] is used, which agree better with the experimental results. Thus, the penetration depth is

$$P = \frac{\rho_{eq}}{Y_{eq}} \int_{V_c}^{V_0} u l \mathrm{d}v = \frac{\rho_{eq} L_0}{Y_{eq}} \int_{V_c}^{V_0} u \exp\left[\int_{V_0}^{v} \frac{\rho_{eq}}{Y_{eq}} (v-u) \mathrm{d}v\right] \mathrm{d}v \quad (4)$$

The prediction results obtained by the above model are shown in Fig. 3 as dotted lines. It can be seen that there is a large error between the theoretical prediction result and the experimental result. Therefore, equation (1) was modified by us based on the numerical simulation results. The modified equation is: $Y_c A_{c0} + Y_j A_j = -\left(\rho_c A_{c0} + \rho_j A_j\right) l \mathrm{d}v / \mathrm{d}t$, where A_j is an effective area of the jacket during penetration, it is given as: $A_j = \frac{Y_j \rho_j}{Y_c \rho_c} A_{j0}$ (5)

After modification, the predicted results are given in Fig. 3 as solid lines, it can be found that good agreement between the theoretical prediction result and the experimental result are obtained.

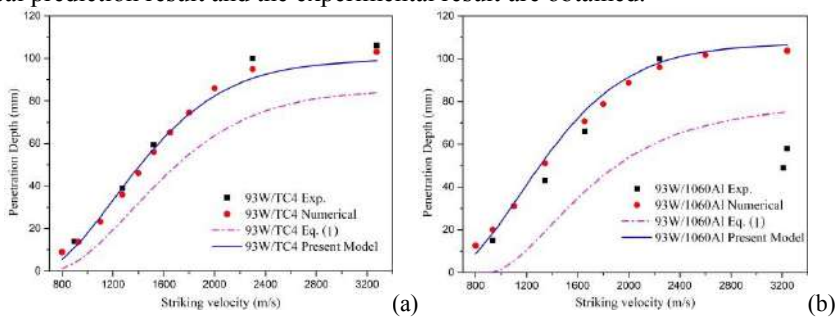


Fig. 3 Comparison of the predicted penetration depth with experimental data for (a) 93W/TC4 and (b) 93W/1060Al jacketed rods

CONCLUSIONS

Two types of jacketed rods presented typical "co-erosion" damage for striking velocity at 0.9-3.3 km/s, except for the 93W/1060Al jacketed rod at a striking velocity of 936 m/s. Due to the differences in material properties of the jacket, the core and the jacket of the jacketed rod show different damage mechanisms. Under the same initial kinetic energy, penetration performance of the jacketed rod is significantly better than that of the unitary 93W rod, but this advantage decreases as the incident kinetic energy increases. Compared to the density of the jacket, the strength of the jacket has a more significant effect on the penetration performance of the jacketed rod. The analytical model for penetration depth of the jacketed rod was modified, and good agreement between the predicted and experimental results are obtained.

DYNAMIC STRESS EVALUATION DUE TO HYPERVELOCITY IMPACT USING TIME GATED RAMAN SPECTROSCOPY

Abhijeet Dhiman[1] and Vikas Tomar[1]
[1]School of Aeronautics and Astronautics, Purdue University, West Lafayette, IN, 47907, USA

Summary In this work, an experimental setup based on time-gated Raman spectroscopy for impact-induced local stress evolution measurements is presented. The setup is used to obtain local Raman shift variation as a function of time at strain rates approaching 10^6 s-1. Based on an analytical expression, stress evolution as a function of time under dynamic impact loading is presented. The setup is shown to be able to measure the local in-situ evolution of dynamic stress in a Hydroxyl-terminated polybutadiene (HTPB) sample induced by an impact from 250 micron-sized microsphere using a pulse laser.

INTRODUCTION

Application such as Armor design and meteor impact resistant structure design require high-performance composite materials resistant to impact failure. Under impact, stress-wave interacts with the material interfaces and defects that play an important role in determining the material performance. Material behavior under shock is entirely different from materials behavior under static loading. Understanding of material behavior in-situ under shock can lead to important new advances in material development not currently possible. It is, therefore, important to investigate the dynamic behavior of materials under shock at fundamental interface level in an in-situ manner. One aspect of such an understanding is stress-strain behavior at a local microscale material length scale under hypervelocity (> 1 km/sec) impact-induced shock. This work presents real-time measurements of stress evolution under impact shock loading at micron length scale.

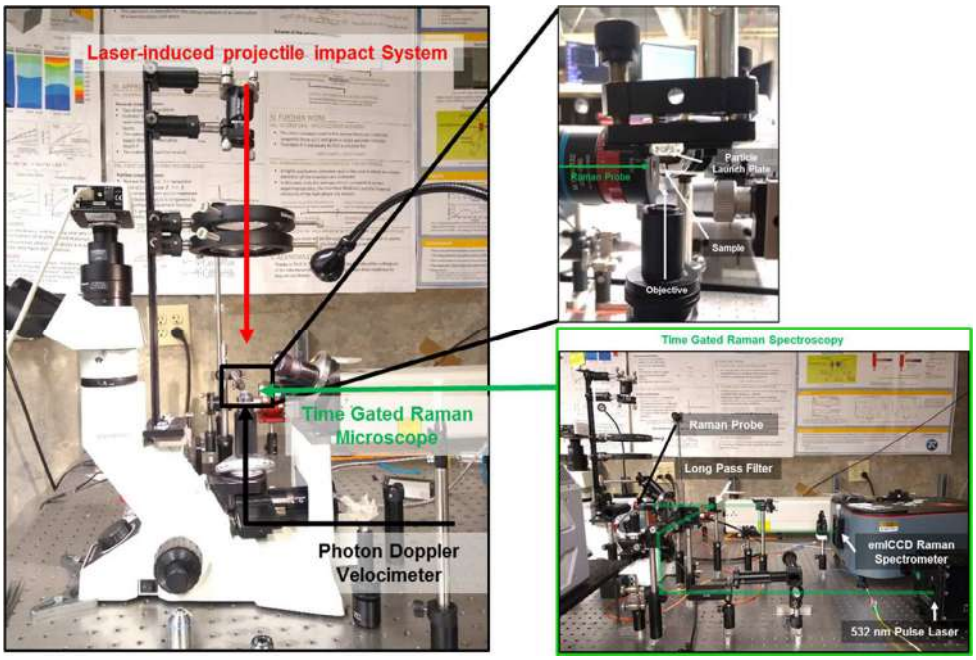

Figure 1: Micro-particle impact Raman microscope

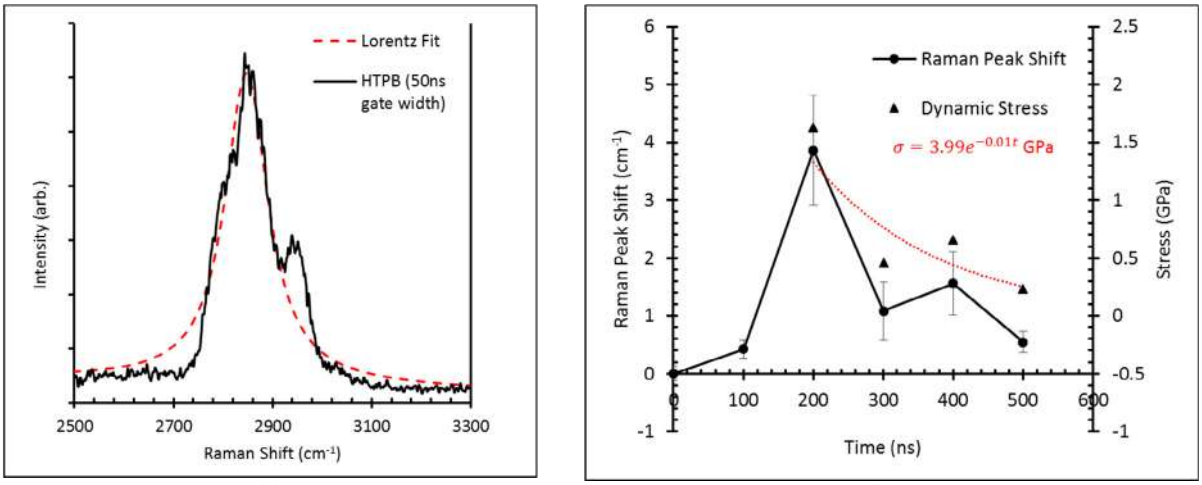
There are several experimental tests that have been used to characterize a material's response to an impact or shock loading. Drop weight test, light gas gun-based Taylor Impact test, Split Hopkinson Bar test are some of the specialized experimental techniques that are primarily used. The outcome of such tests are the deformation and strain as well as strain rates which can be used to obtain strain rate dependent material constitutive behavior [1]. The measurement techniques used in these experiments involve strain gauges, digital image correlation, Xray diffraction (XRD), Photonic Doppler Velocimetry (PDV) or the electron diffraction based methods. These methods are either of insufficient time and length resolution (strain gauge etc.) or are based on large-scale facilities (XRD, phase contrast imaging, etc.)[2]. Also, these methods can only measure strains directly and stress is a derived quantity [3] using the constitutive models of the respective materials. Currently the only laboratory method available, which can directly measure stresses in the material without using a constitutive model, is mechanical Raman spectroscopy (MRS) developed by Tomar and co-workers [4, 5]. Several previous works [4, 5] have established the robustness and repeatability of MRS for stress measurement without constitutive models under quasi-static loading conditions in different materials by comparing the results with constitutive model based predictions. However, when it comes to the direct stress measurement at microscale under hyper-velocity impact conditions, there are no established experimental techniques available. In this work, time gated Raman

spectroscopy is extended for direct in-situ measurement of stress evolution at microscale under hyper-velocity particle impact loading using a MRS setup developed earlier [6]. Figure 1 shows the experimental setup developed to preform dynamic stress evolution under shock loading.

KEY RESULTS

The particle launch system with 250 μm zirconia microspheres and 75 μm aluminum layer was used to induce shock in Hydroxyl-terminated polybutadiene (HTPB) samples with impact velocities of 543.52 ± 6.74 m/s. The impact behavior of HTPB due to impact was recorded using high speed camera with frame rate of 900 kHz. Figure 2(a) shows Raman spectra of HTPB for CH_2 stretching and peak fitting using Lorentz curve for 2848.95 cm^{-1} peaks corresponding to CH_2 stretching accumulated over 40 impacts.



(a) (b)

Figure 2: (a) Raman spectra of HTPB collected over 40 accumulations (b) Raman peak shift and dynamic stress evolution over impact time history.

The analytical solution for 1D longitudinal stress propagation in a rod due to spherical ball impact is given by [7]:

$$\sigma_{\max} = \rho U_s u_{p\_\max} \tag{1}$$

Raman shift due to 543.52 ± 6.74 m/s impact using 250 μm microsphere can be calibrated as

$$\sigma = 0.44\Delta w[GPa] \tag{2}$$

Figure 2(b) shows the change in Raman peak due to shock loading which lasts for less than 100 ns. Similar results have been observed by other researchers . Based the Raman shift at different impact time history, the stress evolution after the impact is given by exponential fitting as:

$$\sigma(t) = 3.99e^{-0.01t}[GPa] \tag{3}$$

CONCLUSION

In this work, the stress evolution due to shock-induced by microparticle impact on Hydroxyl-terminated polybutadiene was characterized using time-gated Raman spectroscopy. The current works provide further opportunities to evaluate stress using Raman shift under different loading scenarios. Future work will involve increasing the impact velocities for bigger size microspheres and integrating Photon Doppler Velocimetry system to obtain time-resolved deformation on the sample.

Summary In the present paper we demonstrate application of 2D spectral characteristics for examining of space-time behaviour of complex wave structures that can be formed from different initial pulses. Temporal periodicity and temporal symmetry of the solution as well as recurrence phenomenon will be discussed in case of 2D wave propagation.

INTRODUCTION AND STATEMENT OF THE PROBLEM

We have demonstrated earlier that in case of 1D models of wave propagation the discrete spectral analysis is very helpful tool in order to analyse the space-time behaviour of different wave structures [1, 2]. Here the method is generalised to 2D case and we demonstrate application of 2D spectral characteristics for analysis of time-space behaviour of complex wave structures. In the present short paper we consider the KPI equation

$$(u_t + \alpha_1 u u_x + \alpha_2 u_{xxx})_x - \alpha_3 u_{yy} = 0, \tag{1}$$

as a model equation. Here α_1, α_2 and α_3 can be called as the nonlinear coefficient, the dispersion coefficient and the transverse perturbation coefficient, respectively. In order to generate a complex wave structure the initial wave is given in form of bended sinusoid:

$$u(x, y, 0) = \sin(a_x x + \beta \cos(a_y y)), \tag{2}$$

where a_x and a_y define the number of periods per 2π, and β is arbitrary parameter. For numerical integration the pseudospectral method is applied. Details of the numerical scheme and some results on the application of 2D discrete spectral analysis can be found in [3]. Temporal periodicity, temporal symmetry, and recurrence phenomenon will be discussed in the presentation.

DISCUSSION

An example of the initial bended sinusoidal wave and the emerged complex wave structure that consist of several interacting solitary waves is presented in Fig. 1. In the present case, (i) soliton trains (similar to the KdV solitons) are propagating along x axis, and (ii) breather like solitonic structures are formed along y axis.

The solution of Eq. (1) has form $u(x, y, t)$ and spectral amplitudes $a_k(y, t)$ are defined as follows:

$$\begin{aligned} a_k(y,t) &= \frac{2|U(k,y,t)|}{N}, \quad k = 1, 2, ..., \frac{N}{2} - 1, \\ a_k(y,t) &= \frac{|U(k,y,t)|}{N}, \quad k = 0, \frac{N}{2}. \end{aligned} \tag{3}$$

Here $U(k, y, t) = F_x(u(x, y, t))$ and F_x denotes the Fourier transform with respect to space variable x.

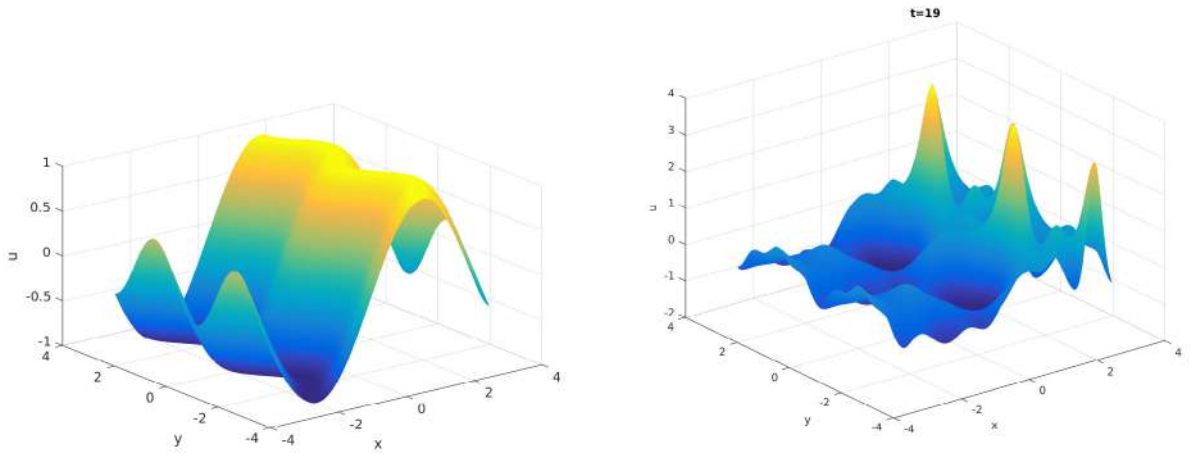

Figure 1: Initial bended sinusoid (the left panel) and solution at $t = 19$ (the right panel); $a_x = 1$, $\beta = 0.4$, $a_y = 2$ and $d_l = 1.4$

.

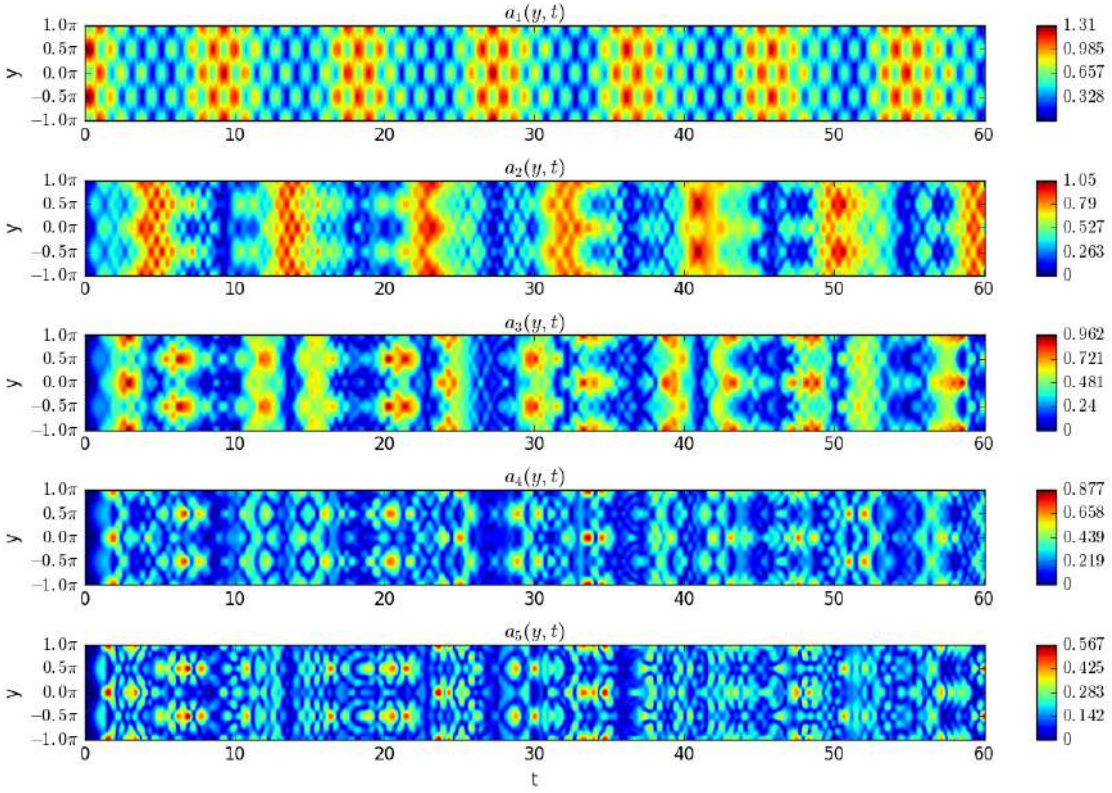

Figure 2: Spectral amplitudes $a_1(y,t) \ldots a_5(y,t)$ for $a_x = 1$, $\beta = 0.4$, $a_y = 2$ and $d_l = 1.3$.

In the case of 1D waves spectral amplitudes depend only on time variable t and therefore plotting all of them in one 2D figure is very easy. However, in the case of 2D waves spectral amplitudes (3) depend on two variables: t and y. Therefore we had to work out a different technique for plotting of them. We are using 3D pseudocolor plots for this reason – a 3D pseudocolor plot is formed for each spectral amplitude. An example of such a depiction is given in Fig. 2, where the horizontal axis refers to time t while the vertical axis refers to the spatial variable y. Image of this kind shows how different 2D spectral amplitudes behave in the considered time interval.

In the presentation we will analyse several numerical examples and demonstrate how to use spectral amplitude plots for estimating whether or not the solution has (quasi)periodic behaviour, and how to find temporal symmetries of solutions. In addition, we will demonstrate that for detection of recurrence phenomenon it is useful to average the individual spectral amplitudes over y, i.e. to introduce averaged spectral amplitudes.

CONCLUSIONS

Similarly to the 1D waves the 2D spectral characteristics carry additional information about the internal structure of 2D waves. Therefore, the 2D discrete spectral analysis is a helpful tool for analysing spatio-temporal behaviour of 2D waves.

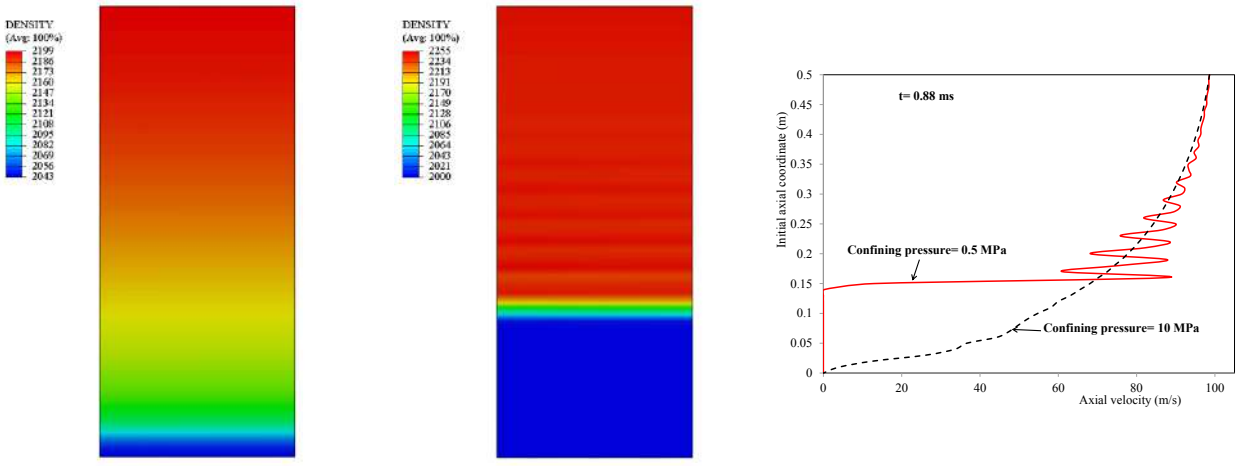
NUMERICAL INVESTIGATION REVEALING KEY FACTORS ASSOCIATED WITH INSTABILITIES IN GRANULAR MATERIALS DURING IMPACT

Benoit Revil-Baudard*[1] and Oana Cazacu[1]
[1]Department of Mechanical& Aerospace Engineering, University of Florida/REEF, 1350 N. Poquito Rd., Shalimar, Fl 32579, USA

Summary In general, elastic/plastic models for granular materials have been developed for geotechnical applications, and as such the constitutive laws are defined and calibrated from tests at low confining pressures (of the order of kPa). Dynamic applications such as penetration and impact in granular media require models valid for very high pressures (of the order of GPa) and very high strain rates. This leads to the need to provide constitutive laws valid for this pressure range, and require the development of new numerical strategies that could account for the pronounced precompaction that occurs at the beginning of the penetration event. In this paper, we investigate the effect of dynamic precompaction on the development of instabilities in soils. For this purpose, the Lade [1] model for soils has been revisited and modifications have been implemented such as to account for high-pressures and high-strain rates. Moreover, the model was implemented using a F.E. implicit procedure and most importantly, a new precompaction procedure involving the shift of the yield surface and the plastic potential has been integrated to allow the simulation of the influence of dynamic precompaction on the inception of instabilities. A sample of the results of this investigation are presented in the following.

KEY RESULTS ON THE EFFECTS OF INITIAL PRECOMPACTION ON LOCALIZATION DURING PENETRATION INTO SAND

Highlights of key findings revealed by the high-rate virtual tests are presented in the following. Fig.1 presents high-rate densification simulations that show the paramount influence of the initial state (precompaction level) on wave propagation. Note that for the same imposed velocity depending on the initial precompaction level (0.5 MPa vs. 10 MPa), the shape of the wave through the specimen is completely different (see Figure 1(c)). While for a higher initial confining pressure, the wave front is "smooth", for a low initial confining pressure, the wave front is very sharp. Due to the sharp front wave, oscillations of all field variables occur. Because of the different nature of the wave that propagates inside the specimens, the density map is totally different. For 10 MPa precompaction, the wave is smooth and leads to a "continuous" variation of density (see Figure 1(a)). In contrast, for 0.5 MPa precompaction, there are jumps in density. Almost two-third of the specimen is highly compacted, (densification of 13%) while in the other third of the specimen the density is unchanged (density= 2000 kg/m^3), there are also small oscillations of the density at the back of the front wave (see Figure 1(b)).



(a) Confining pressure: 10 MPa (b) Confining pressure: 0.5MPa (c) Velocity profile

Figure 1. Isocontours of the density (initial density = 2000 kg/m3) for loading with Vmax =100 m/s at t = 0.88ms: (a) Initial confining pressure of 10 MPa; (b) Initial confining pressure of 0.5 MPa; (c) Distribution of the axial velocity in the sand specimen at a given time for an imposed velocity Vmax = 100m/s

A sample of the results of the F.E. simulations of impact of a rigid object into a Sacramento River sand are presented in Fig.2. The impact velocity is 50 m/s. Simulations were run for the case of sand targets of different initial states: one target precompacted at 0.5 MPa, the other at 20 MPa. Our main goal being the assessment of the influence of the precompaction level of the sand on its subsequent plastic dissipation and densification, only the initial phase of the penetration event is analyzed. Isocontours of the plastic dissipation at 35μs after the impact are shown in Figure 2. For a loose sand (precompacted at 0.5 MPa), it is worth noting that multiple localization bands develop, while if the same material has a higher initial density (same material precompacted at 20 MPa), only a primary localization band develops

*Corresponding author. E-mail: revil@ufl.edu.

at a later stage (35ms after impact), which is followed by secondary localization bands. These results indicate that the initial confinement pressure has a very strong influence on the inception and nature of the localization bands that develop. Also, note that the less precompacted is the material, the slower is the wave, and the sharper is the wave front.

STRAIN BASED HAMILTONIAN FORMULATION AND APPLICATION TO SUPERSHEAR CRACK PROPAGATION

Summary We derived momentum-strain ($p-\epsilon$) form of the Hamiltonian equations for elastic solids, and applied to simulate supershear rupture of earthquake faults. We prove that the $p-\epsilon$ form is symplectic, even though its conjugate variables do not introduce equal number of dimensions to the corresponding phase space, and the Hamiltonian equations do not possess the typical antisymmetric structure. Numerical implementation is validated by comparing the speed and the stress field of crack tip with those of high speed (1Mfps) phtoelastic observations of a propagating mode-I crack. We simulate the super-shear earthquake rupture, modeling the contact at the fault surface by a linear slip weakening friction law. The Burridge-Andrews mechanism naturally appears in the simulations, making the crack front jump from the sub-Rayleigh regime to the intersonic regime.

INTRODUCTION

Simulating extreme events occurring in large domains, such as supershear earthquakes, is a challenging task due to the presence of cracks propagating at intersonic speeds, shock waves, etc. Due to high computational demand, widely used implicit time integration techniques like Newmark-β are not attractive choices for long period simulations of large-scale domains. We seek to utilize large pool of explicit symplectic algorithms available in Hamiltonian mechanics, which are higher order accurate, momentum conserving, suitable for steep potentials, and stable in long period time integration. Instead of the standard $p-u$ form of the Hamiltonian equation for wave propagation in solids, we derived $p-\epsilon$ form to directly compute strain[1], which is one of the main variable of interest in crack propagation problems. The $p-\epsilon$ form requires some investigations since it does not have the structure of typical Hamiltonian equations, especially in proving its symplecticity.

MOMENTUM-STRAIN FORM OF HAMILTONIAN EQUATIONS

Starting with the density of the Hamiltonian for an elastic solid continuum $h(p,\epsilon) = p.\dot{u} - l(\dot{u},\epsilon)$, where the density of the Lagrangian $l(\dot{u},\epsilon) = \frac{1}{2}(\rho\dot{u}^2 - \epsilon : C : \epsilon)$ and momentum $p = {}^{\partial l}/_{\partial \dot{u}}$, and applying the Hamilton's principle (i.e. $\delta \int_{t,V} p.\dot{u} - h(p,\epsilon)\mathrm{d}V\,\mathrm{d}t = 0$), the $p-\epsilon$ form of the Hamiltonian equations can be obtained as

$$\begin{cases} \dot{p} = \nabla.\frac{\partial h}{\partial \epsilon} \\ \dot{\epsilon} = sym\{\nabla \frac{\partial h}{\partial p}\} \end{cases} \tag{1}$$

Compared to typical $p-u$ form of Hamiltonian equations, the above form has several differences. ϵ contributes three time more dimensions to the corresponding phase-space than its conjugate variable p, whereas the conjugate variables of a typical Hamiltonian equations introduce equal number of dimensions to the corresponding phase space. Instead of the standard antisymmetric structure, the right hand side of the $p-\epsilon$ form consists of linear combinations of partial derivatives with respect to spatial coordinates (i.e. ${}^{\partial}/_{\partial x}$). These differences raise the question whether the $p-\epsilon$ form is symplectic. We demonstrated the symplecticity of this non-standard form by proving that the Jacobian of its phase space flow is independent of time.

NUMERICAL IMPLEMENTATION AND SIMULATION OF SUPER-SHEAR EARTHQUAKES

A symplectic algorithm equivalent to the classical Stomer-Verlet scheme and a bi-symplectic algorithm[2], which is suitable for problems with steep potentials, are derived for the $p-\epsilon$ form and implemented in PDS-FEM[3]. PDS-FEM is a finite element method which uses characteristic function of the elements of conjugate tessellations for approximating displacement and strain. The numerous discontinuities in the approximated displacement field, which are introduced by the use of characteristic functions, can be utilized to numerically efficiently model propagating cracks.

To validate the implemented time integration schemes, simulated crack tip stress field and propagation speed of a mode-I crack are compared with the photoelastic observations of a mode-I crack recorded with a high-speed camera (1Mfps). Figure 2 shows photoelastic fringe patters from the experiment and the simulation, at two stages. We use

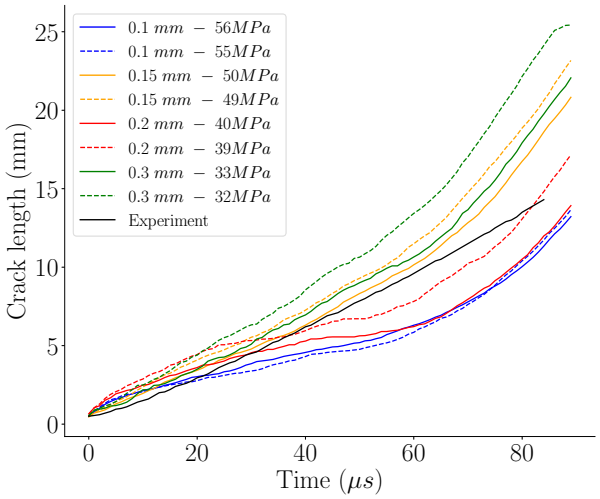

Figure 2: Time history of crack lengths with different mesh refinements and the corresponding σ_c.

the maximum principal stress criterion since the evaluation of J-integral in parallel computing environments introduces significant load imbalances to CPUs. In order to control the dependency of crack speed on mesh size, the average tensile strength of an element is estimated as $\sigma_c \approx {}^{K_c\sqrt{2}}/_{\sqrt{\pi l}}$, where l is the element size and K_c is the critical stress intensity factor. Figure 2 shows the time history of the crack length with different mesh sizes. These results indicate that the numerical implementation can reproduce crack tip stress field and the speed to a reasonable accuracy. Further, comparing with the photoeastic observation of a shear crack with frictional interface, we validated that the numerical implementation can accurately reproduce stress field around pre-existing shear cracks[4].

Simulation of supershear earthquake rupture

In order to demonstrate that the developed system can reproduce supershear earthquake rupture, we simulate the rupture along a straight fault plane in a crust layer of dimensions 10 km $\times$ 4 km $\times$ 0.1 km. The fault is assumed to be homogeneous and a linear slip weakening law is used. The simulations naturally reproduced the Burridge-Andrews mechanism[5], which classically explain the transition from the initial sub-Rayleigh propagation to supershear rupture in a homogeneous materials, making the crack front jump from the sub-Rayleigh regime to the intersonic regime, and propagate producing shear Mach cones. This further validates the implemented $p-\epsilon$ based time integration scheme. Further, we simulated the supershear rupture earthquake along the Palu-Koro fault, which produced a supershear earthquake in 2018, in Sulawesi, Indonesia.

CONCLUSIONS

We derived a momentum-strain form of Hamiltonian equations for elastic continuum, and implemented symplectic time integration algorithms in PDS-FEM framework to conduct large scale simulations of dynamic crack propagation. Good agreement with high speed photoelastic observations, and the natural emergence of Burridge-Andrews demonstrate that the implemented numerical scheme has reasonably high accuracy for simulating extreme events involving high speed crack propagation and shockwaves.

AN IMPACT HAMMER AS A DECISION SUPPORT SYSTEM FOR SURGEONS DURING OSTEOTOMY

Léo Lamassoure[1], Giuseppe Rosi[1], Justine Giunta[2], Romain Bosc[2], and Guillaume Haïat*[1]
[1]CNRS, Laboratoire Modélisation et Simulation Multi Echelle (MSME UMR 8208 CNRS), Université Paris-Est, 94010 Créteil Cedex, France

Summary Osteotomies are used to cut cartilage and bone tissues using a surgical mallet and a bone chisel (osteotome). However, it is still difficult to assess the properties of the osteotomy site during the procedure. This study aims at investigating whether an instrumented hammer could be used to retrieve information on the tissue located around the osteotome. A first study used plates of composite materials and evidenced that this device can be used to predict the material of a plate and to estimate its thickness. The second study was performed *ex vivo* on an animal model and suggests that this device is sensitive to the displacement of the osteotome and to the transitions between different materials (e.g., between the nasal and frontal bones). This study paves the way for the development of a medical device aiming providing a decision support system to surgeons performing an osteotomy.

INTRODUCTION

An osteotomy is a surgical procedure used to cut and reshape cartilage and bone tissues. Osteotomy is commonly performed using a surgical mallet and a chisel-like tool called osteotome, in various fields such as orthopaedic and maxillofacial surgery [1,2]. They are delicate interventions, during which the surgeon usually has no visibility of the osteotomy site. Therefore, the procedure remains mostly based on the surgeon proprioception, and a mispositioning of the osteotome or too strong impacts may lead to uncontrolled bone fractures, which may have dramatic consequences [3,4]. The objective of this study is to determine whether a hammer instrumented with a piezoelectric force sensor can be used to retrieve information on the mechanical properties of the tissue located around the tip of the osteotome.

METHODS

In a first study [5], 100 samples made of different composite materials and of different thicknesses were impacted with the instrumented hammer. The time dependence of the force applied to the osteotome was measured for each impact of the instrumented hammer with the sensor mentioned above, leading to a signal $s(t)$. A dedicated signal processing technique was applied to $s(t)$ using information derived from the different peaks obtained in the signal. The first two peaks of $s(t)$ were approximated using a Gaussian function. The data was analysed using the two following indicators. The first one, τ, is the difference between the times of the second and first peaks of $s(t)$, referred to as the *second peak time* in what follows. The second one, λ, is the ratio of the second peak integral I_2 on the first peak integral I_1 and is referred to as the *impulse ratio* in what follows.

Support Vector Machines (SVM) learning techniques [6] were applied to our dataset. Considering the two dimensional space (τ, λ), each plate sample #i was characterized by an averaged pair of coordinates (τ_i , λ_i) derived from the 30 impacts. SVM compute hyperplanes separating the space into regions of interest corresponding to the different material classes. The data were partitioned into five disjoint folds of 20 samples chosen randomly. Four folds were used iteratively as training data to determine the boundaries while the last fold was retained as the validation data. The model was tested on the validation data to estimate the prediction performances of the algorithm.

In a second study, a model closer to clinical conditions was considered. Four heads of New Zealand white rabbits were collected from the National Veterinary School of Alfort (Maisons-Alfort, France). This animal model is widely used to simulate rhinoplasty because of its convenience and of the similarities with the human anatomy [7]. The aim of this study was to determine whether it was possible to assess the displacement of the osteotome as well as changes of bone properties located around the osteotome. Therefore, the osteotomy path was set to begin at the frontal end of the nasal bone and to end when the osteotome reached the nasofrontal suture (i.e., the transition between the nasal and frontal bones). The same instrumented hammer as the one used in the first study was used to perform osteotomies on each nasal bone of the rabbit heads, and a video was recorded to track the progression of the osteotome. The same signal processing as the one employed in the first study was employed. A parameter Δ (referred to as *displacement*) was defined and corresponds to the absolute distance travelled by the tip of the osteotome with each impact, and its values were measured using the Tracker software and the video recordings of the experiments.

RESULTS

The results from the first study shows that the material type has a significant effect on both the second peak time τ and the impulse ratio λ, which is confirmed by ANOVA (p-values for τ : $p < 10^{-42}$ and λ: $p < 10^{-35}$). It was possible to predict the material of a sample impacted by the osteotome with an estimated 89% prediction performance, and to estimate its thickness with an error below 10% [5].

The results obtained in the second study shows that when the osteotome arrives at the frontal bone, the second peak time undergoes a significant decrease and reaches values below a threshold equal to 0.65 ms, as shown on Figure 1. Moreover, the second peak time is correlated with the displacement of the osteotome Δ (with typical R^2 values comprised between 0,6 and 0,8).

* Corresponding Author. E-mail: guillaume.haiat@cnrs.fr

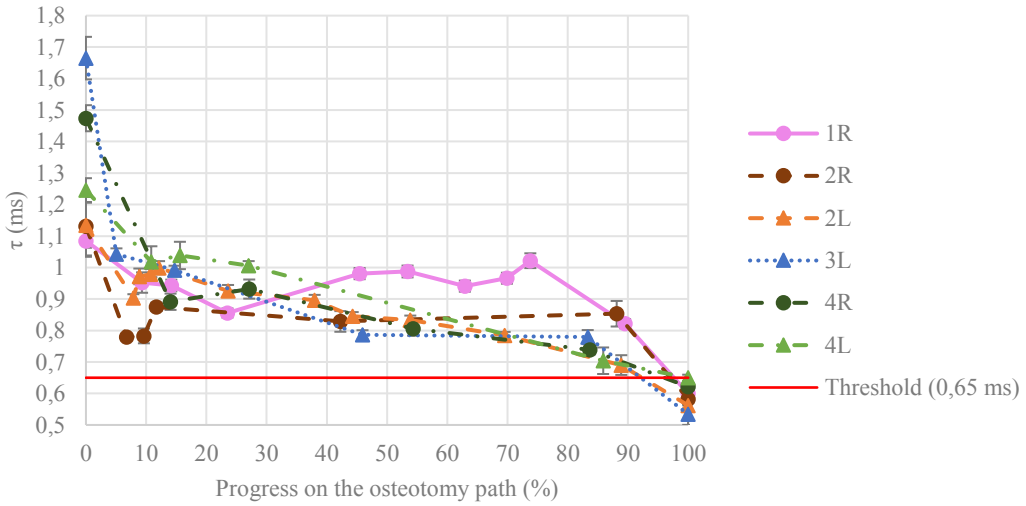

Figure 1. Variation of τ while progressing on the osteotomy path, from the frontal end of the nasal bone (0%) to the nasofrontal suture (100%). For each osteotomy, the lowest values of τ are reached at the nasofrontal suture, below a threshold of 0,65 ms.

DISCUSSION

The mechanical behavior of the osteotome could be modeled using an analytical model considering a damped system oscillating between the sample and the hammer. The second peak time τ could be approximated by its period of oscillation T_o. The results show that τ increases when the Young's modulus of the materials increases, confirming that the second peak time is a relevant indicator to assess the dynamic behavior of the system. The impulse ratio is the ratio of the energy exchanged during the second and first contacts, which is related to the material viscoelasticity. Therefore, λ was used in combination with the second peak time τ to classify the different materials.

The second study confirmed that the instrumented hammer could be used to detect the moment when the osteotome reaches the frontal bone. The frontal bone being stronger than the nasal bones (for both rabbits and humans), the mechanical properties of the environment around the tip of the osteotome suddenly change at the frontonasal suture, hence explaining the change obtained for the values of τ. Nonetheless, this animal model presented some limitations. First, the rabbit nasal bones are softer than the ones of humans (especially for the elderly where they tend to be particularly brittle), which explains why we did not observe the apparition of cracks as expected. Therefore, this part of the study will require further research with a better model. Second, due to the complexity of the architecture of the rabbit's nasal cavity (especially the presence of the nasal conchae), it was impossible to estimate bone thickness during the osteotomies.

CONCLUSION

This study paves the way for the development of an instrumented hammer to perform biomechanical measurements during an osteotomy. Future experiments on anatomical subjects will be determinant to confirm the results obtained on the animal model, as well as to study crack initiation and propagation. From the results, navigation and decision-support systems could be developed based on this approach to allow surgeons to adapt their surgical strategy in a patient-specific manner.

BLAST LOADING OF CONCRETE PIPES - EXPERIMENTS AND SIMULATIONS

Martin Kristoffersen*[1], Arianna Minoretti[2], Knut Ove Hauge[3], and Tore Børvik[1]
[1]Structural Impact Laboratory, Norwegian University of Science and Technology, Trondheim, Norway
[2]Norwegian Public Roads Administration (NPRA), Trondheim, Norway
[3]Norwegian Defence Estates Agency (NDEA), Oslo, Norway

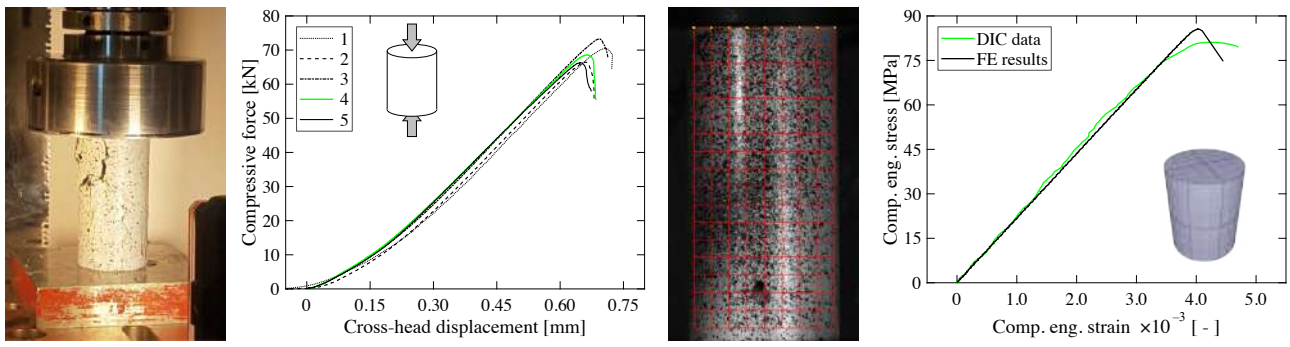
Summary Blast loading of concrete structures like columns and plates has been studied extensively in the open literature. Tubular structures are studied to a much lesser extent, so the goal of this work was to establish a large experimental database for blast loading of concrete pipes. Different charge positions were used, (i) centre of the pipe, (ii) contact inside, (iii) contact outside. Position (ii) was the most harmful. The pressure measured inside the pipe was considerably higher than immediately outside, suggesting major confinement effects. Reinforcement greatly improved the pipes' performance as expected. Material tests on both the reinforcement bars and the concrete were used to calibrate material models for use with finite element simulations. The blast load was described by a particle-based method. The structural response from the simulations showed good agreement with the tests.

INTRODUCTION

The E39 coastal highway route in Norway is envisioned a future without ferries. Some fjord crossings are too wide and deep for conventional bridges or underwater rock tunnels. A possible solution to crossing these fjords is a submerged floating tube bridge (SFTB) in concrete [1]. Blast loading against SFTBs could have disastrous consequences and has only been studied numerically [2]. Full-scale testing of a detonation in an SFTB is not a feasible option, thus physical testing must be carried out on smaller samples. This study examined tubular concrete structures (plain and reinforced) subjected to blast loading. The first goal was to build a large experimental database for this topic [3], and the second was to investigate whether state-of-the-art finite element (FE) simulations could reproduce some key experimental results. The explicit FE code IMPETUS AFEA Solver [4] was used for all simulations herein, providing good overall results.

MATERIAL TESTING AND CALIBRATION OF CONSTITUTIVE RELATIONS

Cylinders and cubes were cut from the concrete pipes for cylinder compression (Fig. 1(a)), cube compression, and tensile splitting tests. The uniaxial compressive and tensile strengths were f_c = 76.1 MPa and f_t = 3.2 MPa, respectively. A load cell measured the force and digital image correlation (DIC) measured the axial strain (Fig. 1(b) and (c)). This data was used to establish engineering stress-engineering strain curves (Fig. 1(d)), which in turn were used as target curves for the calibration of the IMPETUS concrete model [4]. An LS-OPT procedure was set up to obtain the material parameters by inverse modelling. Since no dynamic material data was available, default strain rate parameters were used.



(a) Experiment (b) Force-diplacement curves (c) DIC (d) Model calibration

Figure 1: Material calibration procedure from (a) compression test and (b) force-displacement curves to (c) DIC and (d) FE model.

Smooth axisymmetric specimens were machined from both the hoop (D_{hoop} = 6 mm) and longitudinal (D_{long} = 8 mm) reinforcement bars for quasi-static tension testing. The longitudinal bars had a yield stress of 417.1 MPa, and the hoop bars 517.3 MPa. Lasers were used to measure the minimum diameters in two perpendicular directions. The minimum diameters were measured continuously throughout the tests, thereby providing true stress-true strain curves beyond necking all the way to failure. A modified Johnson-Cook J_2 plasticity model was calibrated by a least squares fitting.

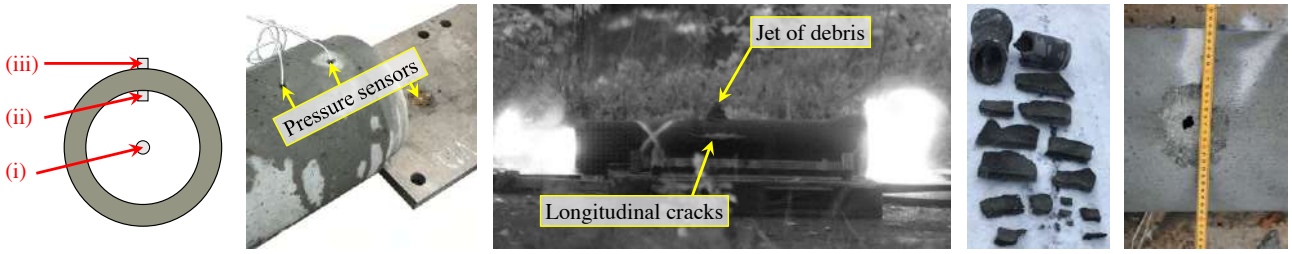
BLAST TESTING OF CONCRETE PIPES

Description of concrete pipes and test setup

The test components were standard off-the-shelf concrete pipes intended for drainage. Using mass produced pipes ensures consistent material properties and geometry. Pipes with internal diameter D_i = 200 mm and 400 mm were used, with respective lengths 1560 mm and 2350 mm. The wall thicknesses were 41 mm and 85 mm. Each end of the pipe had

*Corresponding author. E-mail: martin.kristoffersen@ntnu.no.

flanges which enabled connecting the pipes to form a continuous pipeline. The smaller of the two geometries was without reinforcement and was used to investigate the effect of charge placement; (i) centre of the pipe, (ii) contact inside, (iii) contact outside as sketched in Fig 2(a). The larger was tested both with and without reinforcement, but only from position (i). The charges used were composition C-4 detonated by an electrically ignited blasting cap. Two high-speed cameras filmed the tests, while pressure sensors monitored the pressure both inside and outside the pipe (see Fig 2(b)).



(a) Charge positions (b) Pipe and sensors (c) High-speed image from position (ii) (d) Fragments (e) Crater/hole

Figure 2: Summary and illustrations of component test setup and results.

Results

From position (i), the D_i = 200 mm plain concrete pipes first suffered longitudinal cracking before oblong fragments formed (illustrated in Fig. 2(c) and (d)). Larger charge sizes produced more and smaller fragments. The same behaviour was observed when detonating from position (ii) with the addition of a jet of debris from where the charge was placed (Fig. 2(c)). Charges placed at position (iii) simply produced cratering and spalling at the charge position without any fragmentation as seen in Fig. 2(e). Position (ii) was by far the most destructive, because only half the explosive amount was needed to breach the pipe compared with the other two positions.

The D_i = 400 mm plain concrete pipes generally behaved similarly to the 200 mm pipes. The reinforced 400 mm pipes had a substantially larger capacity as expected. It was interesting to note that the connecting flange broke off as shown close to the arrows in Fig. 3, likely due to reflecting stress waves in the thickness transition area. The pressure data showed that the pressure dropped orders of magnitude just outside the pipe, confirming the confinement effect.

Figure 3: Images of tests and simulations of D_i = 400 mm pipe 10 ms after detonating a 150 g C-4 charge at position (i).

FINITE ELEMENT SIMULATIONS

The IMPETUS code [4] offers GPU acceleration, fully integrated higher order Lagrangian volume elements, and node splitting for describing fracture. Higher order elements represent the curved surfaces of the cylinder and pipe accurately. A particle-based method was used to emulate the blast load. The particles were able to account for the confinement and captured the results from the contact charges well. The damage patterns were recreated nicely by the node splitting technique as shown in Fig. 3. Setting all strain rate parameters to zero increased the damage to unrealistic extents, which shows the importance of including strain rate sensitivity.

CONCLUDING REMARKS

The blast tests showed that there is a significant confinement effect arising from detonating the charge inside the pipe, both in terms of structural response and pressure magnitude. This is important when designing structures like SFTBs. The concrete model in IMPETUS was calibrated to fit experimental data and provided good results in the FE simulations of the blast experiments. Particles proved to be a robust and powerful way of accounting for contact charges and confinement. Obtaining material data at elevated strain rates and performing a proper load characterisation are important future tasks.

ACKNOWLEDGEMENTS

We thank the NPRA for funding through the E39 Coastal Highway Route project, the NDEA for providing equipment for conducting the tests, and the Norwegian Research Council for funding through CASA by project number 237885.

Summary An enriched finite element (FE) is developed to solve axisymmetric wave propagation problems of generalized piezothermoelasticity. The FE equations for the extended Lord–Schulman (L–S) theory are derived, wherein the interpolation functions for temperature, potential and displacement fields are enriched with element domain spatial sinusoidal functions and solved using direct time integration. The problem of axisymmetric thermal shock waves in a piezoelectric hollow cylinder is studied. The finite speed propagation of temperature and the associated sharp wavefronts are shown to be captured accurately by the enriched FE solution.

INTRODUCTION

Generalized piezothermoelasticity theories [1, 2] have been proposed to overcome the limitation of the classical theory predicting heat transport at infinite speed. The one dimensional (1D) thermal shock problems in piezoelectric media have been investigated using the L–S theory [3] and two-temperature theory [2], by employing the Laplace transform and the state space method. A hybrid FE-Laplace transform technique has been employed for solving the 1D problem of axisymmetric thermal shock in functionally graded piezoelectric cylinder using the L–S theory [4]. Accurate numerical evaluation of inverse Laplace transforms required for these solutions is computationally intensive and often unsteady. No solutions for the 2D problems of axisymmetric thermal shock based on the generalized piezothermoelasticity can be found in literature. The authors [5] have recently presented a novel enriched FE formulation for generalized thermoelasticity, which accurately captured the discontinuities at the wavefronts for thermal shock problems, using direct time integration. In this paper, an enriched FE formulation based on the L–S theory of generalized piezothermoelasticity is presented for accurate solution of 2D axisymmetric electrothermal shock wave propagation problems in piezoelectric media.

ENRICHED FE FORMULATION

The extended Hamilton's principle for the L–S theory of generalized piezothermoelasticity in absence of body forces, internal heat source and free charge can be written as

$$\int_{t_1}^{t_2}\Big[\int_\Omega\Big(\delta\mathbf{u}^{\mathrm{T}}\rho\ddot{\mathbf{u}}+\delta\boldsymbol{\varepsilon}^{\mathrm{T}}\boldsymbol{\sigma}+\delta\boldsymbol{\theta}'^{\mathrm{T}}(\mathbf{q}+\tau_0\dot{\mathbf{q}})-\delta\theta\rho T_0(\dot{\eta}+\tau_0\ddot{\eta})-\delta\mathbf{E}^{\mathrm{T}}\mathbf{D}\Big)\,\mathrm{d}V-\int_{S_\sigma}\delta\bar{\mathbf{u}}^{\mathrm{T}}\bar{\mathbf{f}}_{\mathbf{s}}\,\mathrm{d}S-\int_{S_q}\delta\theta^{\mathrm{T}}\bar{\mathbf{q}}.\bar{\mathbf{n}}\,\mathrm{d}S$$
$$-\int_{S_\phi}\delta\phi^{\mathrm{T}}\bar{D}_n\,\mathrm{d}S\Big]\,\mathrm{d}t=0\quad\text{for}\;\forall\,\delta\mathbf{u},\delta\theta,\delta\phi\mid\delta\mathbf{u}(t_1)=\delta\mathbf{u}(t_2)=\delta\theta(t_1)=\delta\theta(t_2)=\delta\phi(t_1)=\delta\phi(t_2)=0 \tag{1}$$

where $\mathbf{u}$, $\boldsymbol{\sigma}$, ε, $\mathbf{q}$, $\mathbf{D}$ and $\mathbf{E}$ denote displacement, stress, strain, heat flux, electric displacement and electric field intensity vectors, respectively. η, ϕ and ρ denote, respectively, the entropy density, electric potential and mass density. θ is the temperature rise above the stress-free reference temperature T_0 such that the absolute temperature $T=T_0+\theta$. τ_0 is the first order time delay. $\bar{\mathbf{f}}_{\mathbf{s}}$ is the traction vector prescribed over surface S_σ, $\bar{\mathbf{q}}$ and $\bar{\mathbf{n}}$ are the prescribed heat flux vector and unit normal vector, respectively, over boundary S_q, and, $\bar{D}_n$ is the prescribed charge density normal to the surface S_ϕ.

To obtain the FE formulation, the axisymmetric domain is discretized into quadrilateral finite elements within which the displacement components u, w, potential ϕ and temperature θ are related to the corresponding nodal values u^e, w^e, ϕ^e and θ^e by interpolation functions. In the enriched FE presented here, the interpolation functions are extrinsically enriched with sinusoidal functions. A typical solution variable ϑ in a four-node enriched element is interpolated as

$$\vartheta=\sum_{i=1}^{4}\Big[N_i\vartheta_i+\sum_{j=1}^{N_{F_r}}\Big(N_{ij}^{\xi c}\vartheta_{ij}^{\xi c}+N_{ij}^{\xi s}\vartheta_{ij}^{\xi s}\Big)+\sum_{k=1}^{N_{F_z}}\big(N_{ik}^{\eta c}\vartheta_{ik}^{\eta c}+N_{ik}^{\eta s}\vartheta_{ik}^{\eta s}\big)$$
$$+\sum_{j=1}^{N_{F_r}}\sum_{k=1}^{N_{F_z}}\Big(N_{ijk}^{c+}\vartheta_{ijk}^{c+}+N_{ijk}^{s+}\vartheta_{ijk}^{s+}+N_{ijk}^{c-}\vartheta_{ijk}^{c-}+N_{ijk}^{s-}\vartheta_{ijk}^{s-}\Big)\Big] \tag{2}$$

where

$$N_i=N_i^\xi N_i^\eta,\quad N_i^\xi=\frac{1}{2}(1+\xi_i\xi),\quad N_i^\eta=\frac{1}{2}(1+\eta_i\eta)$$
$$N_{ij}^{\xi c}=N_i[\cos(\bar{k}_{j_r}N_i^\xi)-\cos(\bar{k}_{j_r})]\qquad N_{ij}^{\xi s}=N_i[\sin(\bar{k}_{j_r}N_i^\xi)-\sin(\bar{k}_{j_r})]$$
$$N_{ik}^{\eta c}=N_i[\cos(\bar{k}_{k_z}N_i^\eta)-\cos(\bar{k}_{k_z})]\qquad N_{ik}^{\eta s}=N_i[\sin(\bar{k}_{k_z}N_i^\eta)-\sin(\bar{k}_{k_z})] \tag{3}$$
$$N_{ijk}^{c+}=N_i[\cos(\bar{k}_{j_r}N_i^\xi+\bar{k}_{k_z}N_i^\eta))-\cos(\bar{k}_{j_r}+\bar{k}_{k_z})]\qquad N_{ijk}^{s+}=N_i[\sin(\bar{k}_{j_r}N_i^\xi+\bar{k}_{k_z}N_i^\eta))-\sin(\bar{k}_{j_r}+\bar{k}_{k_z})]$$
$$N_{ijk}^{c-}=N_i[\cos(\bar{k}_{j_r}N_i^\xi-\bar{k}_{k_z}N_i^\eta)-\cos(\bar{k}_{j_r}-\bar{k}_{k_z})]\qquad N_{ijk}^{s-}=N_i[\sin(\bar{k}_{j_r}N_i^\xi-\bar{k}_{k_z}N_i^\eta)-\sin(\bar{k}_{j_r}-\bar{k}_{k_z})]$$

*Corresponding author. E-mail: kapuria@am.iitd.ac.in

N_i is the Lagrangian shape function and (ξ_i, η_i) are the normalized coordinates of ith node. N_{F_r} and N_{F_z} denote the number of harmonics in ξ and η directions, respectively. $\bar{k}_{j_r} = 2\pi j \nu_r$ and $\bar{k}_{k_z} = 2\pi k \nu_z$, ν_r and ν_z being constant enrichment parameters. Substituting the approximations and summing up the contributions from all n_e number of elements, the discretized form of the variational equation (1) is obtained as

$$\sum_{e=1}^{n_e} \left(\begin{bmatrix} \mathbf{M}^e_{\sigma\sigma} & \mathbf{0} & \mathbf{0} \\ \mathbf{M}^e_{\theta\sigma} & \mathbf{M}^e_{\theta\theta} & -\mathbf{M}^e_{\theta\phi} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{Bmatrix} \ddot{\mathbf{u}}^e \\ \ddot{\boldsymbol{\theta}}^e \\ \ddot{\boldsymbol{\Phi}}^e \end{Bmatrix} + \begin{bmatrix} \mathbf{0} & -\mathbf{C}^e_{\sigma\theta} & \mathbf{0} \\ \mathbf{C}^e_{\theta\sigma} & \mathbf{C}^e_{\theta\theta} & -\mathbf{C}^e_{\theta\phi} \\ \mathbf{0} & \mathbf{C}_{\phi\theta} & \mathbf{0} \end{bmatrix} \begin{Bmatrix} \dot{\mathbf{u}}^e \\ \dot{\boldsymbol{\theta}}^e \\ \dot{\boldsymbol{\Phi}}^e \end{Bmatrix} + \begin{bmatrix} \mathbf{K}^e_{\sigma\sigma} & -\mathbf{K}^e_{\sigma\theta} & \mathbf{K}_{\sigma\phi} \\ \mathbf{0} & \mathbf{K}^e_{\theta\theta} & \mathbf{0} \\ \mathbf{K}^e_{\phi\sigma} & \mathbf{K}^e_{\phi\theta} & \mathbf{K}^e_{\phi\phi} \end{bmatrix} \begin{Bmatrix} \mathbf{u}^e \\ \boldsymbol{\theta}^e \\ \boldsymbol{\Phi}^e \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}^e_{\sigma} \\ -\mathbf{F}^e_{\theta} \\ \mathbf{F}^e_{\phi} \end{Bmatrix} \right) \tag{4}$$

The FE equations are obtained in non-dimensionalized form and solved using Newmark-β direct time integration.

NUMERICAL STUDY AND CONCLUSIONS

Consider a radially polarised thick hollow cylinder of Cadmium Selenide subjected to thermal shock in the form of $\theta(t) = H(z-a)H(t)$ imposed on the inner circumferential surface, $H(t)$ being the Heaviside unit function. For the FE solution, a symmetric zone OABC with $r_i = 0.5, r_o = 1.5$ and OA$= 1$ is considered. The L-S theory solution is obtained using $\tau_0 = 0.5$ and $a = 0.3$. The enrichment parameters are taken as $\nu_r = \nu_z == 0.3, N_{F_r} = N_{F_z} = 1$ for displacement, potential and temperature fields. The distributions of temperature rise, hoop stress, radial electric field along OC obtained using the present enriched FE are compared with the conventional FE solution in Figs. 2(a), (b) and (c). The total number of DOFs for enriched and conventional FE are 34596 and 40804, respectively. The present solution captures the second sound effect clearly showing the jumps at the thermal wavefront in temperature, stress and electric field distributions. Whereas the conventional FE solution shows quite extensive spurious oscillations at the wavefronts in these distributions, the enriched FE solution removes the oscillations thereby giving the accurate estimates of the location and magnitude of the jumps at wavefronts. The change in jumps at the wavefronts as they propagate is shown in Figs. 2(d) and (e). The amplitude of jumps at both wavefronts reduces with time. The effect of pyroelectric constant p_3 on the potential distribution is shown in Fig. 2(f). The induced potential is higher in presence of the pyroelectric effect.

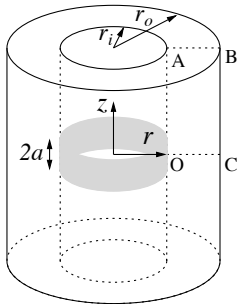

Figure 1: Hollow piezoelectric cylinder subjected to thermal shock

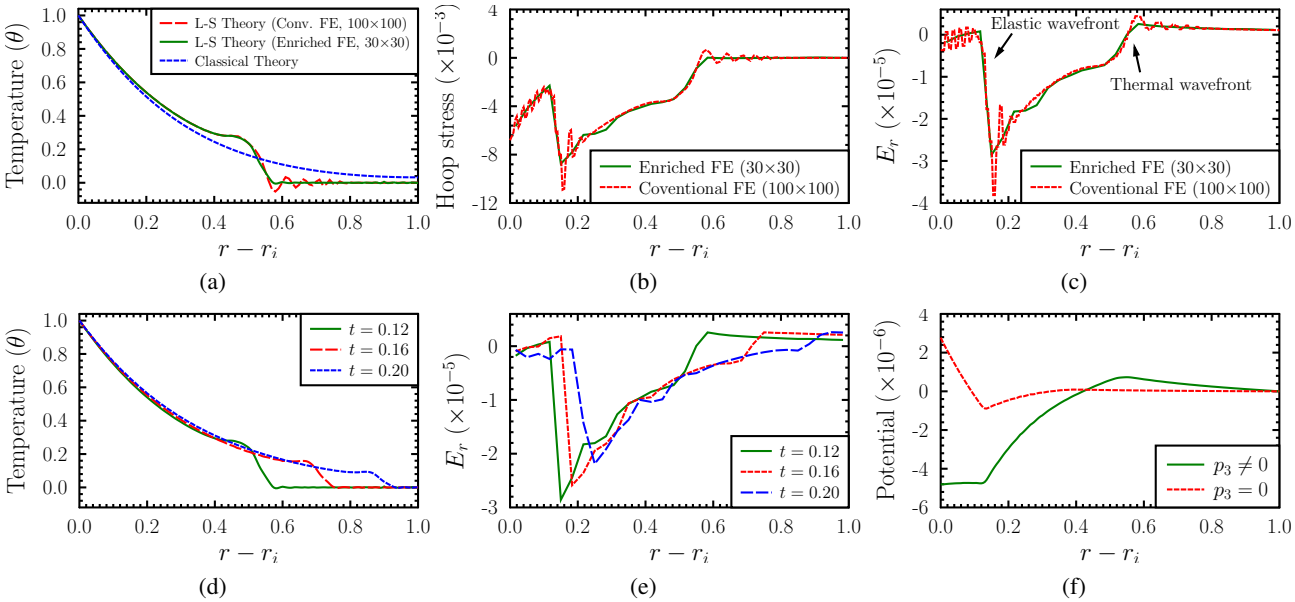

Figure 2: Distributions of temperature, hoop stress, radial electric field and potential along OC. $t = 0.12$ if not mentioned otherwise.

TRANSIENT DYNAMIC RESPONSES OF A PLATE SUBJECTED TO IMPACT LOADINGS WITH FLUID STRUCTURE INTERACTION

Ming Ji[1] and Kazuaki Inaba*[2]
[1]Sch. of Engineering, Tokyo Institute of Technology, Tokyo, Japan
[2]Sch. of Environment and Society, Tokyo Institute of Technology, Tokyo, Japan

Summary This talk addresses an analytical approach and an effective finite element method for transient dynamic responses of a circular plate subjected to impact loadings. The mode superposition method is used. The method is available for various types of impact loadings. The Mindlin plate theory is used to calculate the natural frequencies and mode shapes of the plate. Considering a small oscillating induced by the plate vibration in fluid, velocity potential function is used to describe the fluid motion. To validate the analytical results, an efficient and flexible MATLAB finite element procedure using fully vectorized codes is developed. MITC4 element is used to simulate the plate, and the acoustic pressure element is used to simulate the fluid. The results are compared with the transient responses for displacement and natural frequencies.

RESEARCH OBJECTIVE AND MOTIVATION

Plates are widely used for structural members in all branches of engineering such as automotive, civil, naval, etc.. Lyon [1] and Pretlove [2] first gave the analytical solutions for a flexible plate coupled with a fluid containing cavity under weak coupling assumption. Soedel [3] presented a closed form solution of the natural frequencies and modes of the plate-liquid combination for a simply supported rectangular plate, carrying liquid with reservoir conditions at its edges. The harmonic response of the plate-liquid system to a dynamic pressure distribution (and also point load) on the plate is expressed in terms of the orthogonal plate-liquid modes. Cho et al. [4] developed a procedure to solve the free and forced vibration analysis. The procedure is based on the assumed mode method for free vibration calculation and mode superposition method for forced vibration analysis. Zienkiewicz and Newton [5] solved the coupled vibrations of the fluid-structure interaction system using the finite element method. For the structural field, the variable considered was displacement. For the fluid field, the unknown variable was in the form of pressure. Under the same assumption, Craggs [6] used the plate and acoustic finite elements to simulate the behaviour of a window-room system. In his paper, the equations were solved for a simple window-room system being excited by a sonic boom. Olson and Bathe [7] presented a symmetric finite element method for solving fluid–structure interaction problem based on the fluid velocity potential. Several tests cases showed that the approach worked well for static, transient, and frequency analyses. Wang and Bathe [8] presented reliable finite element discretization based on displacement/pressure interpolations for the analysis of acoustic fluid-structure interaction problems. They showed that with their analysis procedure no spurious non-zero frequencies are encountered. Ohayon [9] reviewed several reduced order models for linear vibration analysis of bounded fluid–structure systems for low modal density situations. These methods were based on the Ritz-Galerkin projection using appropriate Ritz vectors. He constructed reduced models expressed in terms of physical displacement vector field u in the structure, and generalized co-ordinates vector r describing the behaviour of the fluid.

Despite a variety of the abovementioned methods, there is a strong need in analytical methods applicable for transient responses of a plate coupled with fluid subjected to impact loadings. This talk addresses an analytical approach for transient dynamic responses of a circular plate subjected to impact loadings. The normal mode method is used to investigate the dynamic transient response of a plate coupled with fluid subjected to impact loadings. The method is available for various types of impact loadings such as concentrated force and surface pressure. The Mindlin plate theory is used to calculate the natural frequencies and mode shapes of the plate. Considering a small oscillating induced by the plate vibration in fluid, velocity potential function is used to describe the fluid motion. To validate the analytical results, an efficient and flexible MATLAB finite element procedure using fully vectorized codes is developed. MITC4 element is used to simulate the plate, and the acoustic pressure element is used to simulate the fluid. At last, the drop test of a plate coupled with fluid is conducted. The results are compared with the transient responses for displacement and natural frequencies.

FORMULATION OF THE PROBLEM AND THE SOLUTION TECHNIQUE

A circular plate with the radius a and the thickness h and a cylindrical cavity with the height H are considered. The walls of the cavity are rigid except for the top, on which a flexible plate is placed. The plate is completely clamped. The Mindlin plate theory is used to obtain the natural frequencies and mode shapes. The fluid is assumed to be compressible, inviscid and irrotational. Due to the effect of added mass, there is no the orthogonality of wet modes. Wet modes mean the modes of the plate coupled with fluid. The wet mode is assumed to be the superposition of the modes of the dry modes. The dry modes mean the modes of the plate in air. The forced vibration of the plate coupled with fluid is assumed to be the superposition of the wet modes. The solutions of the coupled system can be obtained by applying the orthogonality of dry modes.

To validate the results obtained by the analytical method, an efficient and flexible MATLAB finite element procedure using fully vectorized codes is developed. Time performance of FEM assembly in MATLAB is comparable with other techniques for purely elastic stiffness matrices [10]. The technique is proved to be effective and flexible. The 4-node

*Corresponding author. E-mail: inaba.k.ag@m.titech.ac.jp

MITC4 element is used to simulate the plate without the shear locking problem, and the 8-node acoustic pressure element is used to simulate the fluid. The coupled system can be written in the following form.

$$\begin{bmatrix} M_S & 0 \\ \rho_0 c_0^2 H_{SF}^T & M_F \end{bmatrix} \begin{bmatrix} d_S \\ p_F \end{bmatrix} + \begin{bmatrix} K_S & -H_{SF} \\ 0 & K_F \end{bmatrix} \begin{bmatrix} d_S \\ p_F \end{bmatrix} = \begin{bmatrix} F_S \\ F_F \end{bmatrix}$$

Here M_S and K_S are the mass and stiffness matrix of the plate using MITC4 plate element. M_F and K_F are the mass and stiffness matrix of the fluid. H_{SF} is the coupling matrix of the system. F_S and F_F are the external forces applied on the plate and the fluid, respectively. d_S and p_F are the unknown displacements of the plate and the unknown pressure of the fluid, respectively. The Newmark's method is used to solve the coupled system. In the example, a circular plate with radius 0.1 m and thickness 0.002 m is made of the material with density 1200 kg/m^3, Young's modulus 2 GPa and Poisson ratio 0.37. The height of the fluid with density 1200 kg/m^3 and sound speed 1500 m/s is 0.1 m. A rectangular pulse with amplitude 15 N and period 70 μs is applied downwards at the centre of the plate. The displacement history of the point which is 0.02 m away from the centre is shown in Figure 1. It is reasonable to use the analytical method and the numerical method to predict the transient response of a plate coupled with fluid.

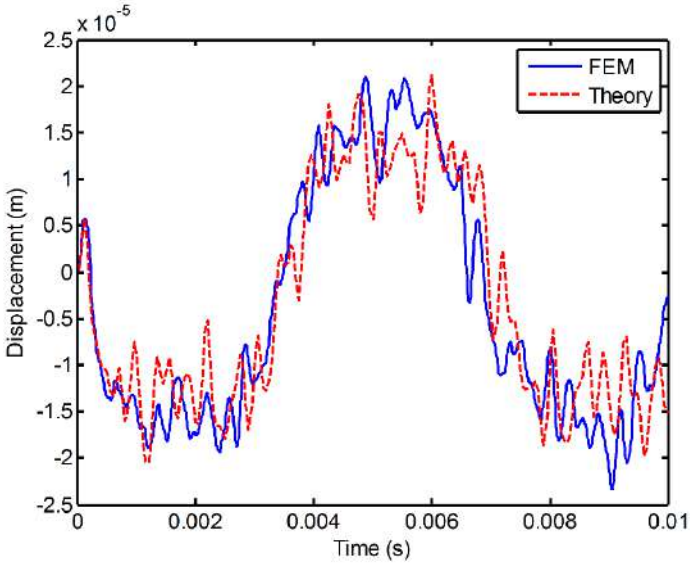

Figure 1. Displacement histories vs. time. The blue solid line is the FEM result, and the dashed red line is the theoretical result.

CONCLUSIONS

An analytical approach and an effective finite element method for transient dynamic responses of a circular plate subjected to impact loadings are proposed. The analytical method can solve the transient fluid-structure interaction problem for various types of impact loadings. It is valid for not only the thin plates but also the thick plates. The effect of the thickness of the plate on the transient responses is discussed. The developed FEM procedure is proved to be effective and flexible.

IMPACTS OF BI-LAYERED PROJECTILES

Christophe D'Angelo*[1], Christophe Raufaste[1] and Franck Celestini [1]
[1]Institut de Physique de Nice, Université Côte d'Azur, Nice, France

Summary We investigate the impact of bi-layered elastic projectiles made of a soft layer standing on top of a rigid one. Taken separately these two layers bounce relatively well on a substrate and have a coefficient of restitution (COR) close to 1. We study the COR as a function of the soft material proportion for low velocity to prevent irreversible deformation (elastic regime). We observe that the COR is significantly smaller than the one of the homogeneous projectiles. A part of kinetic energy is transferred to the deformation modes of the projectile. The trend of the restitution as a function of the soft material proportion is complex and exhibits a minimum around 0.2. We also highlight the presence of multiple bounces during the impact and a theoretical model recovers the features observed experimentally. It shows that the deformation waves inside the material are of paramount importance.

CONTEXT OF THE STUDY

In the context of contact mechanics, the study of the impact of heterogeneous projectiles is complex. It is a problem with a large number of unknowns, exacerbating geometrical effects [1], very often coupled with a high degree of disorder [2].

These particularities play a role in the study of the coefficient of restitution of a heterogeneous projectile on a substrate. In the elastic limit, if we can neglect the deformation of the substrate [3, 4, 5, 6], we can expect the dynamics of the projectile to exhibit different time scales and some energy to be trapped in the deformation modes of the projectile [7, 8]. Such effects have not been studied experimentally.

Here we investigate both experimentally and theoretically the impact between a bi-layered elastic projectile and a substrate. The study reveals how the contact dynamics is affected by the two-time scales inherent to the coupling between the rigid and soft layers.

EXPERIMENTAL METHOD

Our projectiles are made of two parts: a soft layer on top of a rigid one. The rigid layer is made of a rigid plastic. By varying the nature of the material, the Young modulus is varied in the range 10 MPa- 4 GPa and the COR between 0.4 and 0.9. The shape of this layer is spherical at the contact point to control the nature of the Hertz-like contact. The soft layer is a cylinder to ensure a good contact with the rigid layer, made of hydrogel or PU (Polyurethane) with the Young modulus in the range 50 kPa - 1 MPa.

The typical length of the projectiles is 50 mm. Velocities before and after the impact are recorded with a highspeed camera (up to 16 000 fps) and the bounce is characterized by its global coefficient of restitution. We study the restitution as a function of the soft material proportion.

RESULTS AND DISCUSSION

Figures 1 and 2 present the results for a bi-layered projectile with a soft part made of hydrogel and a rigid one made of Peek (Polyetheretherketone). Taken separately, these two layers bounce relatively well and have a restitution close to one. We clearly see that the proportion of soft part as an effect on restitution (Fig.1 Left). The COR as a function of soft material proportion p exhibits a complex trend (Fig.2). A minimum restitution of 0.2 is found for p=42. Several local extrema are observed as well.

We also highlight the unexpected occurrence of multiple micro-bounces at the impact (Fig.1.Right). During a macro-bounce (defined as the time spent between the first contact and the final take-off) we have observed that the rigid layer can leave the substrate and reconnect several times before the final take-off. These micro-bounces are due to the elastic force of the soft layer that push back the rigid layer toward the substrate.

In this case it is relevant to note that there are two characteristic times. On the one hand, the time of contact of the rigid layer and, on the other hand, the wave propagation time in the soft layer.

A theoretical model is also proposed. It considers two aspects of the dynamics. The first one is the coefficient of restitution and the time of contact of the rigid layer. The second one is the elastic force, due to the wave propagation, related to the deformation of the soft layer at the contact area between the two layers.

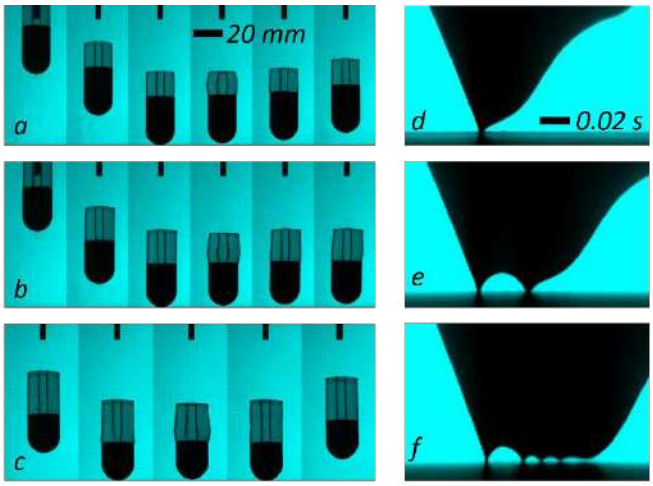

Figure 1. Image sequences (left) and space-time diagrams (right) ($\Delta t = 0.01s$) (zoom centred around the contact zone) of an impact and a bounce of our projectiles with a proportion of soft material p=34% (a, d), p=52 % (b, e) and 60% (c, f). We clearly see the effect of the proportion on the height of the bounce and with the multiple bounces in cases e and f.

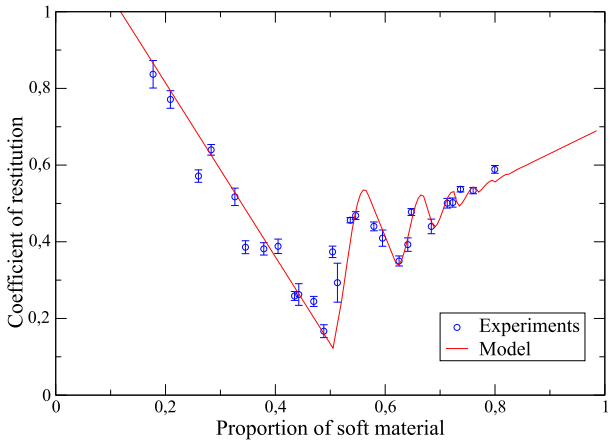

Figure 2. Coefficient of restitution as function of the proportion of soft material. Comparison between experiments and model.

CONCLUSIONS

In our experimental system we combine two elastic materials and by tuning the proportion we are able to control the restitution. The restitution is smaller than the one expected by Hertz theory because a significant part of the initial kinetic energy is transferred to the vibration modes. This study shows that the elastic waves inside the material are of paramount importance for the energy restitution.

THE LOW VELOCITY IMPACT RESISTANCE OF THERMOPLASTIC COMPOSITE CORRUGATED SANDWICH PANELS

Xin Pan[1,2], Liming Chen [*1,2], Shiwei Peng [1,2]
[1]College of Aerospace Engineering, Chongqing University, Chongqing 400030, China
[2]Chongqing Key Laboratory of Heterogeneous Material Mechanics, Chongqing University,Chongqing 400030, China

Summary The impact behavior of thermoplastic composite corrugated sandwich panels under low velocity loadings is investigated by experimentally and numerically. The face-sheets and the corrugated cores are both fabricated from glass fiber reinforced polypropylene prepregs by hot-pressing method. The dynamic response process, load-carrying capacity and energy absorption capacity of corrugated sandwich panels with three different kinds of core configurations namely regularly-arranged (REG), symmetrically-arranged (SYM) and perpendicularly-arranged (PER) under different impact energies were compared. The results showed that thermoplastic corrugated sandwich panels spring back after the impact, maintaining a good structural integrity. The core configuration has a certain influence on its dynamic properties. Among them, the perpendicular one has the biggest peak impact force, while most impact energy is absorbed by the symmetrical one.

INTRODUCTION

The corrugated sandwich panel (CSP) as a typical sandwich structure, has better deformation resistance and energy absorption ability. Thermoplastic composites (TPC) have attracted more and more attention for they have the property advantages of reforming and repeated processing that thermosetting composites do not have, which makes it easy to recycle and reduce the cost. The corrugated sandwich panels made of thermoplastic composites combine the advantages of functional characteristics of light materials and excellent structure performance [1]. In practical application, these composite structures, as the external components of aircraft or ship devices, will inevitably be affected by impact loads [2]. A substantial number of works on exploring the impact resistance of the sandwich panels and composites laminates have been done at present. But the work in area of the CSP made of fiber-reinforced thermoplastic thermoplastic composites under impact loadings is still at the stage of basic research. Therefore, it is necessary to carry out more in-depth researches in this area. The aim of this paper is to analyze the dynamic mechanical behavior of the glass fiber reinforced polypropylene (GF/PP) corrugated sandwich panels under low velocity impact loadings. The effects of loading intensity and the arrangement of two corrugated cores were carried out to identify and quantify the failure mode, and energy absorption efficiency of sandwich structures.

METHODS

The face-sheets and cores of corrugated sandwich panels are both fabricated from glass fiber reinforced polypropylene prepregs by hot-pressing method and bonded by hot-melting bonding technique. The stacking sequence of the face-sheet and corrugated core is $[0/90/0/90/0/90]_s$.

The JSL-3000 drop-weight impact testing machine, shown in Fig 1, is used in the experimental investigation to carry out the low-velocity impact tests. The total mass of the impactor remains constant as 35.4 kg, different impact energies can be adjusted via changing the drop height of the impactor.

The finite element calculation software, ABAQUS/Explicit, is used in this investigation. The REG CSP model shown in the Fig 2, as an example of finite element models for the simulation. In order to reflect typical mechanical features of thermoplastic composites, the 3D-Hashin failure criteria [3-4] are adopted to analyse the damage initiation of CSPs like tensile and compressive failure of fiber and matrix by a user-defined subroutine VUMAT in ABAQUS.

RESULTS AND DISCUSSION

As can be seen from Fig 3, the impact damage of CSPs are mainly as follows: cracks occur in the polypropylene matrix of the face-sheets and cores, a pit is formed in the impact center area of the top face-sheet, and partial debonding between the face-sheets and cores occurs. With the increase of impact energy, the damage to the structure is intensified. The fracture of the top face-sheet is increased and the crack traverses the entire face-sheet, the central area of the upper core is depressed inward, and the whole lower core is collapsed. The specimens all spring back after the impact. Among the sandwich panels with three configurations, the impact loading causes relatively serious damage to the REG and SYM CSPs, while the PER CSP can rely on the configuration characteristics to unload impact loading through the whole structure and so the local damage of components is reduced.

Fig 4 shows the force-time curves of the specimens under 400J impact energy in the experimental results. It illustrates that the PER one has the biggest peak impact force. This is also verified in other experiments and finite element simulation results.Thermoplastic composite corrugated sandwich panels have large elastic strain energy due to the advantages of material and the structural characteristics. The polypropylene matrix has good ductility and can absorb energy better. As shown in Fig 5, the energy absorbed by all specimens increases with the increase of impact energy. The SYM one has the best energy absorption effect, with the energy absorption efficiency of 61-75%. There is not much difference in energy absorption between the REG and PER CSPs, and energy absorption efficiency of the two is between 56-66%.

Figure. 3 The (a) impact damage and (b) response process of REG CSP under the impact energy of 400 J

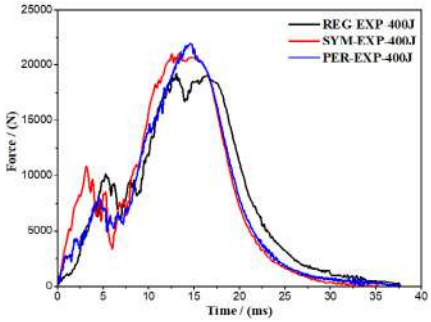

Figure. 4 Force-time curves of sandwich panels with different configurations subjected to 400J impact energy

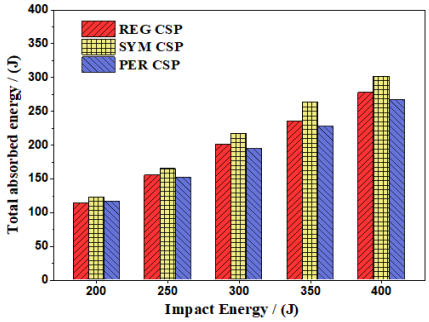

Figure. 5 Energy absorption comparison of CSPs with different configurations under different impact energies

CONCLUSIONS

Thermoplastic composite corrugated sandwich panels have certain resilience, maintaining a good structural integrity. Under impact loadings, local damages mainly occur in the top face-sheet and the upper core of TPC-CSPs, while the lower core collapses as a whole. The thermoplastic matrix has good ductility and can absorb more energy than the thermosetting one. The impact peak force and the absorbed energy keep increasing with the increase of impact energy. Among three configurations, the PER one suffers the least damage and has the optimal impact load-carrying capacity, while the SYM one suffers most severe impact damage but can absorb up to about 75% of the impact energy.

EFFECTS OF THERMAL SOFTENING AND STRESS STATE ON THE FORMATION OF ADIABATIC SHEAR BAND

Shengxin Zhu[1], Yazhou Guo[2], Haosen Chen[*1], and Daining Fang[1]
[1]Institute of Advanced Structure Technology, Beijing Institute of Technology, Beijing 100081, China
[2]School of Aeronautics, Northwestern Polytechnical University, Xi'an 710072, China

Summary Adiabatic shear band (ASB) is an important type of failure under dynamic loading conditions. However, clear knowledge regarding the true mechanisms is still lacking and experimental research is especially needed. A novel in-situ experimental setup was developed to observe the deformation localization and temperature evolution of the ASB simultaneously, by using the high-speed photography and high-speed infrared radiation. The effect of the temperature increase and stress state on the initiation of the ASB was studied. It is found that before the initiation of the ASB, the temperature of the deformed region does not increase rapidly. Rather, it might be the result of adiabatic shear localization. And the critical shear strains for ASB initiation was different. Micro-geometrical imperfection could be regarded as the softening mechanism, which leads to the initiation of ASB.

EFFECTS OF THERMAL SOFTENING AND STRESS STATE ON THE FORMATION OF ADIABATIC SHEAR BAND

It is well known that adiabatic shear localization (ASL) is an important type of failure mode for materials under impact loading. ASL normally leads to catastrophic failure of a structure with sudden loss of bearing capacity, and thus, attracts considerable interest within the scientific community[1–3]. It was widely believed that both the thermal softening[4] and stress state exert great influence on the initiation of the ASB. Many researchers tried to clarify the role of thermal softening or stress state[5] in the process of ASB by determining the temperature rise itself or different loading method. For thermal softening, all this experimental evidence seems to have shown that temperature rise and ASB formation occur simultaneously (or almost simultaneously), but they did not provide clear evidence of their causal relationship. For stress state, many experimental results indicated that the stress state has an impact on the initiation of ASB formation, while most experiments could not provide a proper instability moment of ASB and stress state quantitatively.

Combining high-speed photography and temperature measurement into one mechanical test is very helpful toward this purpose. Modified shear-compression[6], shear-tension[7] and thin-walled tubular are designed for analysing the effect of the thermal softening and stress state on ASB. The formation of the shear band was observed by taking a series of high-speed photographs of specimens with grids previously deposited on the surfaces. Simultaneously, the temperature increase during the ASL process was determined. By examining the deformation, temperature increase, and ASB initiation, the causal relationship between the temperature increase and the formation of the ASB was clarified. The critical shear strain is obtained by analysing the evolution of prefabricated grids on the surface of the gauge section. A phenomenological model for ASB initiation with dependence on stress triaxiality and Lode parameter is proposed using a hybrid experimental–numerical method.

EXPERIMENTAL RESULTS

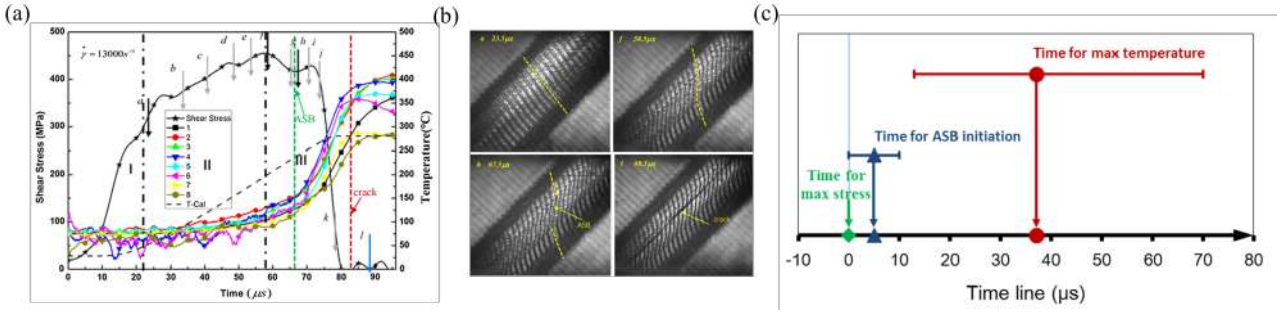

Figure 1. Effect of thermal softening on the formation of ASB, (a) deformation history of a shear-compression specimen, showing the time, shear stress, and temperature, (b) our representative high-speed photographic snapshots to show the deformation of a shear-compression specimen under dynamic loading, (c) Occurrence of important events in dynamic shear failure process. The time for maximum stress was set to be zero and the scatter of the data was also presented.

The shear stress and temperature evolution with respect to time are presented in Figure 1(a). The deformation of the shear-compression specimen could be divided into three stages, i.e., (i) uniform deformation, (ii) nonuniform deformation, and (iii) shear localization. The characteristics of deformation at these different stages are given in Figure 2(b). Severe shear localization is identified by examining the discontinuity of the strips or the grid lines. It should be pointed out that no visible discontinuity of the strips (or ASB) was observed at the maximum stress, which indicates that ASB should initiate after the peak stress. The temperature rise was measured before and after intense shear localization, as shown in Figure 1(a). The times for ASB initiation, maximum stress and maximum temperature are recorded by a synchronized system of photography, temperature and dynamic loading measurements. A summary of the measured time sequences is displayed in Figure 1(c). It is obvious that ASB initiates after the stress peak. What causes the stress drop? In our opinion, there are two potential reasons: thermal softening and large strain-induced damage. The experimental results in the present

*Corresponding author. E-mail: chenhs@bit.edu.cn

work show that temperature rise at the peak stress is only about 50–90 °C. Thermal softening itself is not sufficient for the stress drop or ASB initiation. Moreover, about 37 μs after the stress collapse, the maximum temperature rise was measured. The accelerated temperature elevation corresponds to the formation and propagation of ASB. If we rank these events chronologically, it should be: stress collapse, ASB initiation, ASB evolution and temperature elevation, maximum temperature and macro crack formation. The observed evidence that temperature rise is quite behind ASB initiation indicates that it should not be the trigger of ASB. The other candidate of softening mechanism, i.e., ASB initiation induced by the micro damage.

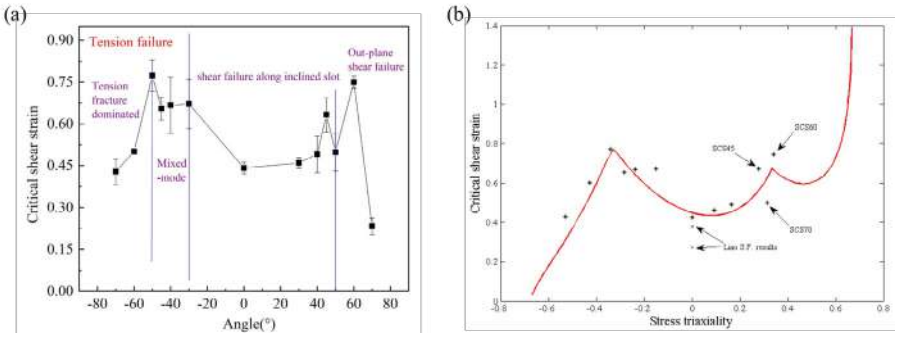

Figure 2. Effect of stress state on the formation of ASB, (a) failure-mode phase diagram and the critical shear strain with respect to different slot angles., (b) comparison of the critical shear strain constructed by a new criterion to experimental results as a function of stress triaxiality under plane stress condition

The micro damage could be the softening mechanism inducing ASB initiation, which was also proposed by some researchers[8,9]. If thermal softening is the only mechanism of ASB initiation, the critical shear strain should not sensitive to the stress state, which is contrary to our experimental observations. The failure-mode phase diagram showing the critical shear strain as a function of slope angle is obtained and presented in Figure 2(a). The different zones can be decided by using the high-speed photography as well as the fracture morphology of the specimens after tests. A positive value of the angle indicates shear-compression tests, while a negative value indicates shear-tension tests and zero degrees indicates torsion test. Obviously, due to the change in angles (or stress state), the failure mode of the specimen is different, and the critical shear strain is not a constant value. To the best of our knowledge, the present criteria for ASB initiation, such as Culver criterion[10], cannot describe the change in critical shear strain with respect to stress state. We have presented a phenomenological criteria model[11] based on our experimental results by using a hybrid experimental–numerical method. Figure 2(b) provides a comparison between the predicted shear failure strain and the experimental results in the space of stress triaxiality for the plane stress condition, which can describe the change in failure behaviours in SCS and STS

CONCLUSIONS

A novel in-situ experimental setup was developed to observe the deformation localization and temperature evolution of the ASB simultaneously, by using the high-speed photography and high-speed infrared radiation. The effect of the temperature increase and stress state on the initiation of the ASB was studied with the modified shear-compression/tension specimens of different degrees. It is found that before the initiation of the ASB, the temperature of the deformed region does not increase rapidly. Rather, it might be the result of adiabatic shear localization. A phenomenological criteria model was proposed based on our experimental results by using a hybrid experimental–numerical method.

IMPACT OF HANGING CABLES AND POWER TRANSMISSION LINES BY MIXED FLOWING/POWDER SNOW AVALANCHES

Perry Bartelt*[1], Andrin Caviezel[1], Marc Christen[1], and Othmar Buser[2]
[1]WSL Institute for Snow and Avalanche Research, SLF, Davos, Switzerland 2Meierhof, Davos, Switzerland

Summary Hydroelectric power is generated at high elevation pumping stations and then transported over land by a network of towers and conductors often through dangerous avalanche terrain. We derive and solve a system of partial differential equations describing the impact of hanging cables by snow avalanches. At impact the avalanche air-blast causes cables to vibrate, producing elastic deformation waves that travel back and forth between the cable-supporting towers. We show that the forces associated with these energy waves can be large causing the towers to collapse. Especially dangerous is the fact that the frequency of the applied cable loading is often near the natural vibration frequency of the towers making tall, cable-supporting structures particularly venerable to snow avalanche impact.

INTRODUCTION

Avalanche engineers are often confronted with the problem of finding safe locations for power transmission towers (Fig. 1). Direct avalanche impact of these tall, lightweight towers usually leads to immediate collapse, with the consequence that entire valleys can be cut-off from power for weeks [1]. To avoid tower impacts, the engineers often apply numerical simulation programs to model the behaviour of snow avalanches in three-dimensional terrain (Fig. 1). With these programs it is possible to identify safe tower locations,outside the reach of the core or powder air-blast [2, 3]. However, a particularly difficult problem still remains: the engineers need to quantify the effects of an avalanche-conductor impact. The conductors typically cross the avalanche track (Fig. 2) and, depending on the conductor sag, are exposed to the air-blast which can reach at least 50m above the ground. The simulation programs provide the force of the avalanche air-blast as a function of the terrain as well as the avalanche size and snow properties.

The avalanche air-blast deforms the cables and induces transverse elastic waves that propagate back and forth between the towers. Experiments conducted in the 1980s at the Norwegian Ryggfonn test site [4] indicate that the magnitude of the forces associated with the wave propagation are large–up to 100kN. In the following we develop a model of avalanche impact and transverse wave propagation in a hanging conductor that allows the engineers to both understand and quantify the cable pull and collapse forces acting on transmission towers.

AVALANCHE IMPACT AND TRANSVERSE WAVE PROPAGATION

The problem of avalanche impact of a hanging cable is analogous to the problem of "plucking" a vibrating string. However, there are three important differences. The first is that the initial cable tension T_0 is given by the cable self-weight, as well as the elevation of the mountain terrain. Secondly, the cable deformations are large and subsequently small-deformation theory cannot be directly applied to model the dynamic forces [5]. Finally, the applied avalanche loading is multi-directional; primarily in the transverse y (slope parallel) $f_y(x,t)$ and upward z (slope perpendicular) $f_z(x,t)$ directions. These functions are derived from avalanche dynamics simulations (Fig. 1)

The problem statement leads to a system of three partial differential equations in the cable x (displacement u), avalanche y (displacement v) and slope perpendicular z (displacement w) directions,

$$\frac{\partial^2 u}{\partial t^2} = c_l^2 \frac{\partial^2 u}{\partial x^2} + \frac{c_l^2}{2}\frac{\partial}{\partial x}\left[\left(\frac{\partial v}{\partial x}\right)^2 + \left(\frac{\partial w}{\partial x}\right)^2\right] \qquad \frac{\partial^2 v}{\partial t^2} = c_t^2 \frac{\partial^2 v}{\partial z^2} + f_y(x,t) \qquad \frac{\partial^2 w}{\partial t^2} = c_t^2 \frac{\partial^2 w}{\partial z^2} + f_z(x,t). \tag{1}$$

Appropriate boundary and initial conditions corresponding to the tower position and support are needed to close the problem. The quantities c_l and c_t represent the longitudinal and transverse wave speeds which are a function of the cable elasticity E, cross-sectional area A, initial tension T_0 and mass per unit length m,

$$c_l = \sqrt{\frac{EA}{m}} \qquad c_t = \sqrt{\frac{T_0(x,t)}{m}}. \tag{2}$$

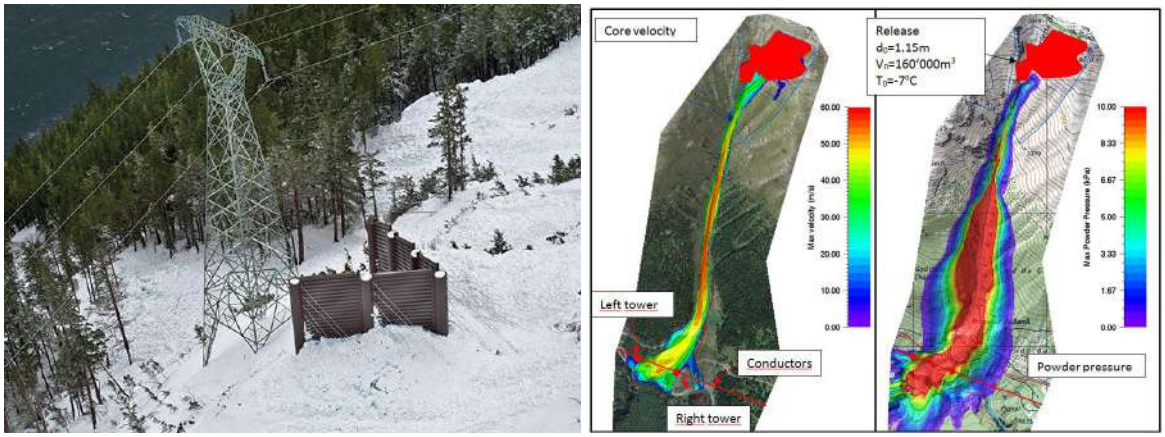

Figure 1: Left: Example of power transmission lines in avalanche terrain. Juneau, Alaska. The tower is part of the Snettisham transmission line [1]. The tranmission line was destroyed by avalanches in 2008. Right: Numerical avalanche dynamics models are used to calculate the motion of the core and cloud in general three-dimensional terrain. Example of a mixed flowing/powder avalanche calculation for an avalanche track near Zernez, Switzerland.

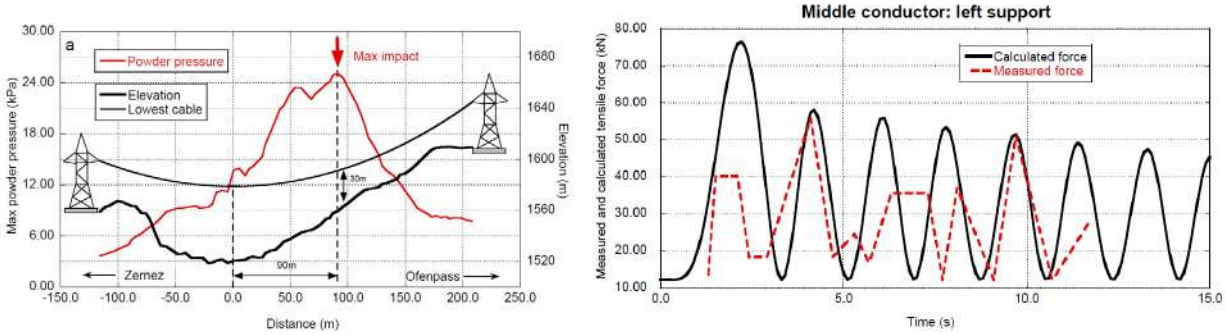

Figure 2: Left: Example of a power transmission line in avalanche terrain, Zernez, Switzerland. The towers are located over 300m apart. Note the position of maximum avalanche impact. Right: Example comparing measured and calculated avalanche forces in a 182m long conductor at the Ryggfonn test site [4].

NUMERICAL RESULTS

The partial differential equations are solved for a specific avalanche loadings. The duration of the impact usually lasts no more than 10s. Short duration blasts of only a few seconds are possible, depending on the location where the cable crosses the avalanche path. Again, depending on the particular avalanche track, the spatial distribution of the air-blast pressure can be localized (acting only over a specific cable length) or spread over the entire cable from tower to tower. Typical impact pressure values vary between 3kPa to 10kPa. In summary, we find two important results: (1) the magnitude of the forces matches the experimental observations, but is also surprisingly large, especially for low tension cables and (2) the frequency of the transverse waves matches the first bending mode resonance frequencies (1Hz - 5Hz) of many tubular steel and lattice-type tower constructions.

CONCLUSIONS

Although much effort has been made to place towers out of the reach of snow avalanches, power transmission lines and cableways must often traverse dangerous avalanche paths. When powder snow avalanche air-blasts impact hanging cables they can induce pull (cable direction) and collapse (downward) forces on the supporting structures reaching up to 10 tons. Furthermore, the frequency of the applied loading matches the natural vibration frequency of many tall, cable-supporting structures. Dynamic magnification effects clearly increase the vulnerability of the transmission line to avalanches.

MATHEMATICAL STUDY OF WAVE REFLECTION AND REFRACTION PHENOMENON AT THE INTERFACE OF TWO DISSIMILAR PIEZOELECTRIC FIBER-REINFORCED COMPOSITE HALF-SPACES

Sayantan Guha*[1] and Abhishek Kumar Singh[1]
[1]Department of Mathematics and Computing, Indian Institute of Technology (Indian School of Mines) Dhanbad, Jharkhand-826004, India

Summary The phenomenon of wave reflection/refraction at the interface surface of two dissimilar piezoelectric fiber-reinforced composite half-spaces is studied. The PFRCs are composed of piezoelectric fibers & piezoelectrically inactive matrix & have been modeled using the Strength of Materials technique & rule of mixtures approach. Some electro-mechanical advantages of PFRC over monolithic piezoelectric materials are graphically demonstrated. Due to the incidence of a qP wave, three reflected & refracted waves viz. qP, qSV, & EA waves are generated in the PFRCs. The closed-form expressions of amplitude ratios of all reflected/refracted waves are derived using appropriate electro-mechanical boundary conditions. The expressions of energy ratios of all reflected/refracted waves & interaction energy are derived & graphically illustrated, and the Law of Conservation of Energy is established.

INTRODUCTION

Several piezoelectric materials are widely available and have countless applications like manufacture of SAW devices, sensors, actuators, etc. Some notable works related to wave reflection/transmission in smart composite structures have been performed by Guo and Wei [1] and Pang et al. [2]. However, these piezoelectric materials are, by nature, brittle and mechanically stiff, and hence quite vulnerable to accidental breakage during handling and bonding procedures. In order to overcome these inhibitions & obtain improvised effective electro-mechanical properties in comparison to monolithic piezoelectric materials, PFRC materials have come to be of widespread use. The micromechanics model for PFRC has been developed by techniques like strength of materials, continuum mechanics approach etc. by Kumar and Chakraborty [3], Ray [4] and others. PFRC are at the forefront of being utilized in a multitude of engineering fields due to their superior mechanical and electrical properties can be achieved by systematically adapting the most profitable properties of the constituents of composite materials. They are also lightweight and flexible, thus being able to provide strength to materials. Not much mathematical work was conducted previously dealing with the phenomenon of wave reflection/refraction in such complex composite structures - this served as one of the prime sources of motivation which led to the findings of the present study.

GOVERNING EQUATIONS

The constitutive equations for piezoelectric fibers are given as

$$\left\{\tau^{f}\right\}=[c^{f}]\left\{s^{f}\right\}-[e^{f}]^{T}\left\{E^{f}\right\},\qquad \left\{D^{f}\right\}=[e^{f}]\left\{s^{f}\right\}+[\varepsilon^{f}]\left\{E^{f}\right\}, \tag{1}$$

and the constitutive equations for piezoelectrically inactive matrix are given as

$$\left\{\tau^{m}\right\}=[c^{m}]\left\{s^{m}\right\},\qquad \left\{D^{m}\right\}=[\varepsilon^{m}]\left\{E^{m}\right\}, \tag{2}$$

where the superscripts f and m depict the components of the fiber and matrix respectively.
The expressions of the material constants in the constitutive equations of the PFRC are derived, following some assumptions, using the Strength of Materials technique along with the Rule of Mixtures approach.

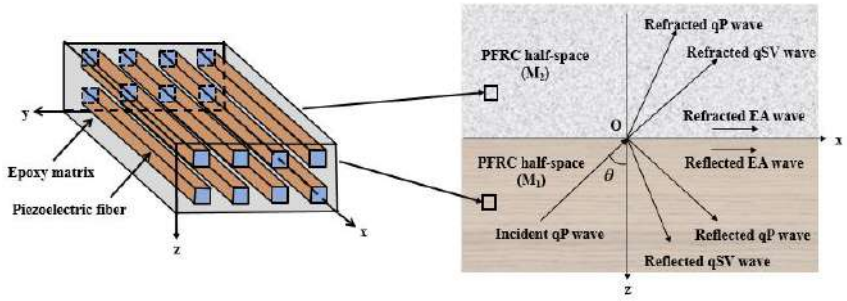

Fig.1. Geometry showing the micromechanics of PFRC and incident wave along with all reflected/refracted waves

The constitutive equations for the PFRC in the absence of body forces and electric forces are:

$$\sigma_{ij,j}=\rho u_{i,}\qquad D_{i,i}=0. \tag{3}$$

*Corresponding author. E-mail: **sayantanguha.maths@gmail.com**.

Using Equations (1)-(3) followed by proper boundary conditions, we derive the angles of reflected/refracted waves w.r.t. the angle of incidence of qP wave and also, the amplitude ratios of reflected/refracted waves. Using these, the expressions of energy ratios of all reflected/refracted waves & interaction energy are derived.

AMPLITUDE RATIOS

To obtain the amplitude ratios for incident qP wave, generalized Snell's law has been taken into account. After utilization of the boundary conditions, the finalized system of equations has been provided in matrix form as

$$\left[a_{ij}\right]_{6\times 6}=\left[\frac{A_1^{(1)}}{A_2^{(1)}}\quad \frac{A_3^{(1)}}{A_2^{(1)}}\quad \frac{A_5^{(1)}}{A_2^{(1)}}\quad \frac{A_2^{(2)}}{A_2^{(1)}}\quad \frac{A_4^{(2)}}{A_2^{(1)}}\quad \frac{A_6^{(2)}}{A_2^{(1)}}\right]^{T}=\left[b_{11}\quad b_{21}\quad b_{31}\quad b_{41}\quad b_{51}\quad b_{61}\right]^{T}, \tag{4}$$

The expressions of amplitude ratios for reflected/refracted waves are obtained using Cramer's rule from Equation (4) which exhibit their dependency on the various affecting parameters and incident angle.

ENERGY RATIOS

The energy shared among the incident wave and all reflected/refracted waves is evaluated across a unit area surface element of infinitesimal thickness on the interface (z = 0). Following Guo and Wei [1], the averaged energy flux across unit surface area and the general expression of energy ratios are

$$P_{\alpha\beta}^{(m)}=k^2c[D_{1\alpha}^{(m)}\overline{W_\beta^{(m)}}A_\alpha^{(m)}\overline{A_\beta^{(m)}}+D_{2\alpha}^{(m)}A_\alpha^{(m)}\overline{A_\beta^{(m)}}+\overline{D_{3\alpha}^{(m)}}\Phi_\beta^{(m)}\overline{A_\alpha^{(m)}}A_\beta^{(m)}]/2,\qquad E_{\alpha\beta}^{(m)}=P_{\alpha\beta}^{(m)}/P_{22}^{(1)}. \tag{5}$$

The expression of complete interaction energy considering incident wave & all reflected/refracted waves is

$$E_{int}=\sum_{\alpha=1,3,5}(E_{2\alpha}^{(1)}+E_{\alpha 2}^{(1)})+\sum_{\alpha=1,3,5}(\sum_{\beta=1,3,5}E_{\alpha\beta}^{(1)}-E_{\alpha\alpha}^{(1)})+\sum_{\alpha=2,4,6}(\sum_{\beta=2,4,6}E_{\alpha\beta}^{(2)}-E_{\alpha\alpha}^{(2)}), \tag{6}$$

and according to the Law of Conservation of Energy, we must have $\sum_{\alpha=1,3,5}E_{\alpha\alpha}^{(1)}+\sum_{\alpha=2,4,6}E_{\alpha\alpha}^{(2)}+E_{int}=1.$

CONCLUSIONS

- For the variation of angle of incidence of qP wave from $0<\theta<90$, the angle of reflection of qP wave has the same variation which shows that angle of incidence is equal to angle of reflection. The variation of angle of reflection for qSV wave is $0<\theta<24.7$, which proves the fact that reflected qSV wave travels with a lower velocity as compared to reflected qP wave. Reflected EA wave, being an evanescent surface wave, propagates along the interface.
- For the variation of angle of incidence of qP wave from $0<\theta<90$, the angle of refraction of qP and qSV waves range between $0<\theta<55.03$ and $0<\theta<24.08$ respectively, which shows that the refracted qP wave travels with a greater velocity as compared to refracted qSV wave. Refracted EA wave, also being an evanescent surface wave, propagates along the interface.
- The angle vs angle graphs demonstrate that that there is no critical angle when qP wave is incident in PZT-5A/epoxy composite. However, if qP is incident in CdSe/epoxy composite, a critical angle appears at 60.
- For the case of normal incidence $(\theta=0)$ of qP wave, no waves are reflected and only qP wave is refracted.
- For the case of grazing incidence $(\theta=90)$ of qP wave, no waves are refracted and only qP wave is reflected.
- Among all reflected and refracted waves, the energy ratios of reflected and refracted qP waves attain greatest magnitude.
- Throughout the entire range of the angle of incidence, the energy ratio of refracted qSV wave attains greater magnitude than the energy ratio of reflected qSV wave.
- The magnitudes of the energy ratios of reflected/refracted EA waves and the interacting energy are negligible.

GENERALIZATION AND VALIDITY OF MOTT'S WAVE CONCEPT

Don-Pierre Zappa*[1], Gilles Damamme[1], and Helmut Klöcker [2]
[1]CEA, DAM, CEA-GRAMAT, F-46500, Gramat, France
[2]EMSE, F-42023, Saint Etienne, France

Summary: Predicting fragment size is mandatory when analyzing possible consequences of explosions. Mott offered the first physically based fragmentation model. He considered strain rate discontinuities propagating in a straight bar. Tank or reservoir explosions may lead to strain rates up to 10^4 s^{-1} or $10^5 s^{-1}$. Under these particular loadings, due to experimental difficulties, neither the material behavior, nor possible strain rate discontinuities are easily analyzed. Present work offers a new analysis of ring fragmentation in 2 dimensions without any particular assumption concerning the ring geometry.

INTRODUCTION

In 1943, Mott and Linfoot extended Lienau's (1936) purely mathematical line break-up model. Soon after, Mott made a conceptual breakthrough by highlighting two main physical phenomena which control ring fragmentation. First, Mott introduced a probability distribution of initial defects which were activated as long as plastic strain was growing. Secondly, Mott introduced stress relaxation waves, which are now named in his honor. Mott waves are one of the keystones needed to predict fragmentation debris size because unloaded parts are prevented from further crack nucleation. Unfortunately, Mott needed to simplify wave propagation by neglecting curvature effects and strain rate evolution, given one of the computational limits of the 1940s.

Grady introduced an ad hoc correction (Grady 1982, 2006) considering non instantaneous failure. Damamme et al. (2019) reformulated fragmentation based on energy balance (Damamme 2019). To the best of our knowledge, curvature or strain rate effects on Mott's wave existence and propagation have not been analyzed.

ORIGINAL MOTT'S MODEL

Mott described fragmentations of long cylinders by ring breakup. He assumed instantaneous through thickness crack propagation. After through thickness crack propagation an unloading wave propagates. Mott assumed that curvature was negligible so that governing equations were reduced to the case of an extending straight bar. Moreover, he supposed constant strain rate during the fragmentation process. Supposing a rigid plastic metal behavior, the conservation of momentum on rigidified bar (rod) allows determining the wave front position X as a function of time t:

$$X^2 = \frac{2\sigma_0}{\rho\dot{\varepsilon}}t.$$

σ_0, ρ and $\dot{\varepsilon}$ represent respectively the yield stress, material density and strain rate (constant during the wave propagation). Based on a simple energy balance, Damamme et al. [4] showed that Mott's approach leads to an upper bound for the wave front position, i.e. in a straight bar, the discontinuity propagates always slower than predicted by Mott. In the following, we analyzed the influence of curvature on possible strain rate discontinuities.

CONDITIONS OF EXISTENCE

Considering a weighted string $\mathcal{C}$ moving in a plane, the system of governing equation is established, considering finite strains. Physical values considered are velocity vector, strain and rotation and independent variables are cumulated mass and time (Wilkins 1963). The string is supposed to be extending therefore shocks or discontinuities of physical values are not considered, but discontinuities of their derivatives are possible.

Admissible discontinuities are analyzed with no specific assumption on material behavior. Specific jump relations are then established. These relations generalize the Mott's wave as the propagation of strain rate jump, for which the propagation could differ from Mott's parabola.

MOTT'S WAVE DOMAIN OF VALIDITY

Governing equations are numerically solved with a specific elastic-plastic code developed for the sake. Code results are analyzed with a dedicated algorithm that tracks strain rate jump. The time evolution of the position of the strain rate jump is then compared with original Mott's wave. Curvature and finite length effect are analyzed through the evolution corrective terms relatively to Mott's original governing equation.

Present work, firstly proves the existence of strain rate discontinuities independently of the material behavior and particular geometry. Secondly, it constitutes the bases for analyzing the validity of dynamic fragmentation, especially ring expansion, experiments.

THERMOMECHANICAL CONSTITUTIVE RESPONSE OF A NEAR α TITANIUM ALLOY OVER A WIDE RANGE OF STRAIN RATES

Longhui Zhang[1*], Antonio Pellegrino[1], David Townsend[1]and Nik Petrinic [1]
[1]Department of Engineering Science, University of Oxford, Oxford, OX1 3PJ, United Kingdom

Summary The constitutive behaviour of a near α Ti3Al2.5V alloy is characterized at strain rates ranging from 10^{-3} s^{-1} to 10^{6} s^{-1} by using the cylindrical compression specimen and Shear Compression Specimen (SCS). The adiabatic heating effect from medium to high rates is evaluated experimentally. Digital Image Correction (DIC) technique is used to measure strain from recorded images. The Ti3Al2.5V alloy presents noticeable strain rate sensitivity. The experimental results are used to determine the material parameters of a simple constitutive model, which is incorporated in the ABAQUS/explicit code for numerical simulations of the Taylor impact tests. The model predicts the deformed specimen shapes from Taylor impact experiments with good agreement.

INTRODUCTION

Titanium alloys with excellent high strength to weight ratio have been used widely in aerospace engineering applications which are unavoidably subjected to impact loading. It is important to understand the mechanical response under dynamic deformation. At high strain rates, the adiabatic temperature rise is likely to affect the mechanical response of the material by causing thermal softening [1]. The traditional Hopkinson bar technique has been used to characterize the mechanical behaviour up to strain rate of several 10^{3} s^{-1}. However, this strain rate is an order of magnitude lower than those commonly encountered during severe high velocity impact such as bird strike on an engine blade, impact of debris or blast loading. A better understating of response over a wide range of strain rate can provide the guidance for tougher engineering structure design.

EXPERIMENTAL SETUPS

The Ti3Al2.5V alloy is used as a model material in the present study. The SCS specimen [2] was employed to investigate the high strain rate behavior at the level of 10^{4} s^{-1}. The quasi-static and medium rate compressive experiments were conducted using a screw-driven Zwick mechanical test machine and a hydraulic Instron machine 8850 respectively. The strain measurements were obtained via DIC analysis. Intermediate (500 s^{-1}) and high rate experiments were carried out using a bespoke developed Hopkinson compression bar synchronized with a Kirana camera. To monitoring the temperature at medium rate, a K-type thermocouple was spot wielded on the centre surface of the specimen. The high rate temperature evolution was monitored by Zhang et al. [3] using a non-contact infrared thermometry technique. Additional high strain rate tests at 100 °C and 200 °C were also performed by using an environmental chamber on the Hopkinson bar system to evaluate the (environmental) temperature effect on the mechanical behaviour. The Taylor tests were completed using a nitrogen 12mm bore gas gun synchronized with the Kirana camera.

EXPERIMENTAL RESULTS

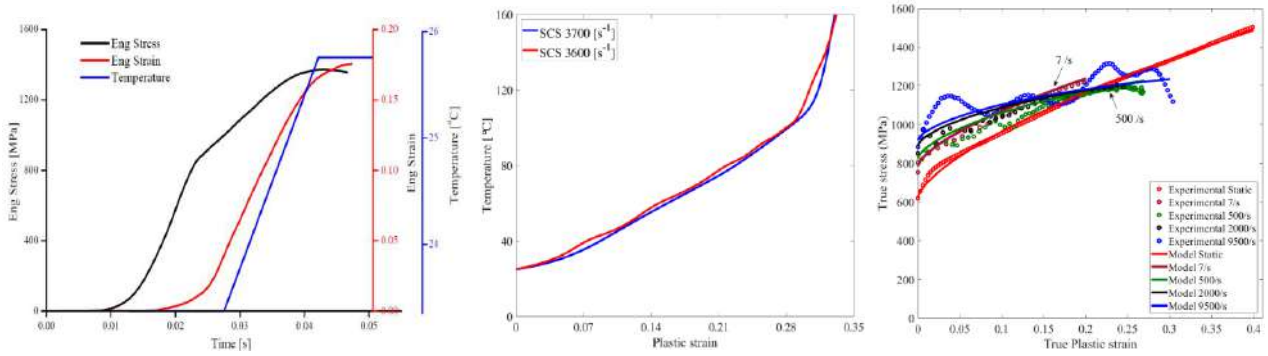

Figure 1. Temperature monitoring at medium rate 7 s^{-1}. (b) Temperature rise vs. plastic strain for Ti3Al2.5V at high strain rate 3600 s^{-1} (c) Comparison between the constitutive model and experimental data

The typical temperature recording at medium rate 7 s^{-1} (Figure 1a) shows a modest increasing temperature of the specimen, which cannot cause any thermal softening effects of the titanium alloy. Figure 1b presents the temperature vs plastic strain at strain rate of 3600 s^{-1}. The temperature rise increases to around 100 °C and ultimately soars up to several hundred degrees due to the strain localization, indicating the adiabatic heating characteristic at high strain rates. Figure 1c shows the stress-strain curves of Ti3Al2.5V at the various strain rates.

(a) (b)

Figure 2. (a) A montage of experimental images of the impact at 270 m/s with frame rate $1x10^6$ fps (b) Comparison between the experimental and numerical residual shape of the specimen impacted at 267 m/s.

Figure 2a shows photographs recorded at various stages during a Taylor test at 270 m/s. The deformation results in a high radial deformation at the impact end. The Combined advantages of Johnson-cook [4] and KHL model [5], namely CJK model, is designed to describe the strain rate and temperature dependent mechanical behaviour. A comparison between the experimental data and the calibrated model descriptions for Ti3Al2.5V is given in Figure 1c. Figure 2b shows a comparison of the experimentally observed residual shape with that predicted by the numerical simulations of the rod specimens impacted at around 267 m/s. The finite element model accurately predicts the overall geometry, including the final shortened length and the diameter along the length.

CONCLUSIONS

A wide range of strain rates is conveniently explored by using cylindrical and SCS specimens. A simple constitutive model with limited constants is employed to characterize the response under wide ranges of strain rates. The numerical predictions are made for the Taylor impact tests; good agreement is found between predicted and measured deformed shapes.

NONLINEAR ONE-WAY TWO-WAVE MIXING IN A MEDIA WITH RATE INDEPENDENT HYSTERESIS

Pravinkumar Ghodake[1], Saurabh Biswas[2]
[1]Department of Mechanical Engineering, Indian Institute of Technology Bombay, Mumbai, India
[2]Department of Mechanical Engineering, Indian Institute of Technology Jammu, Jammu,India

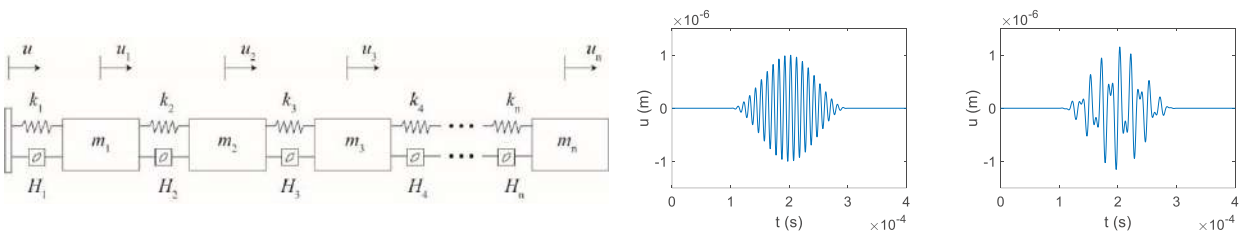
Summary One dimensional nonlinear one-way two-wave mixing in a media with rate-independent hysteresis models like Bouc-Wen and Two-states is presented systematically. In frequency response, sum and difference harmonics along with the original odd harmonics are accurately captured by both the hysteretic models. Both the hysteresis models captured minor, intermediate, and major loops in hysteresis curves effectively for Gaussian pulse as an incident wave. Various mixing studies are carried out for different combinations of amplitudes and frequencies of the incident wave to get an insight into the nonlinear wave mixing phenomenon in hysteretic material models.

INTRODUCTION

Interaction of single frequency wave with early-stage damages (micro-cracks, grains, dislocations, etc.) distorts the wave resulting in the generation of higher harmonics. Traditionally, the nonlinear wave propagation in damaged solids is described by modeling damages as quadratic, cubic, and hysteretic nonlinear materials. The theoretical and numerical studies show that the interaction of single frequency wave with Preisach-Mayergoyz [1-3] hysteretic nonlinearity generates only odd harmonics. Here in this wave propagation study, we are implementing the famous Bouc-Wen model [4,5] and a relatively new two-states hysteresis model [6]. To get more insight into the damage levels and damage mechanisms a one-way two-wave mixing is preferred due to some advantages like eliminating system harmonics etc. In mixing, a single wave with two different frequencies is sent pulse distorts and generates sum and difference frequencies as seen in quadratic and cubic nonlinear material models. Mixing in hysteretic material is explored systematically in this study.

NUMERICAL MODELS

To model one-dimensional wave propagation in a media, a long spring-chain with hysteresis elements is considered as shown in Figure 1(a). The hysteresis elements in a long spring-mass chain are modeled using the Bouc-Wen model and the two-state model. Input displacements u at is given at the left end of chain firstly as Gaussian pulse with a single input frequency (Figure 1(b)) and secondly as Gaussian pulse with two input frequencies (Figure 1(c)).



a) b) c)

Figure 1. (a) A spring-mass chain system, (b) Single-frequency (0.1 MHz) and (c) two frequency (0.06 and 0.1 MHz) Gaussian input pulses as two different input pulses (u) for a long spring-mass chain.

The original Bouc-Wen model is a scalar rate-independent hysteresis model with four free parameters. In the Bouc-Wen model, the hysteretic part of the force is given by a variable z driven by an input displacement u, as in

$$\dot{z} = \dot{u}(A - \alpha 3\mathrm{gn}(\dot{u}z)|z|^n - \beta|z|^n),$$

where the parameters satisfy

$$A > 0, \alpha > 0, \beta 3\epsilon 3[-\alpha, \alpha], n > 0.$$

Being a scalar model, the Bouc-Wen model is computationally simple and works fairly well for systems with single-frequency input. However, the model cannot capture small minor loops due to short loading-unloading within a larger load cycle, mainly in structural vibration applications where amplitudes of input signals are large and input frequencies are low as compared to the wave propagation studies.

The above drawback was addressed in the paper by Biswas and Chatterjee [6] and the authors there developed a new two-state hysteresis model that gives a more practical response than the Bouc-Wen model under multi-frequency inputs. The two-state model was originally developed from the famous Iwan model [7]. The model has system matrices $A3(23\times 32), 3\bar{K}\ (23\times 32), \bar{b}(23\times 32), 3$and the input u. The internal state vector is $q3(23\times 32)$. For the given parameters and the given input, an intermediate quantity is computed first,

$$\dot{s} = \left[\frac{\eta^T \bar{b}}{\eta^T \bar{K} \eta}\dot{u} - y|\dot{u}|\right].\{y \le 0\}.$$

Then finally,

$$\dot{q} = \eta \dot{s}.\{\dot{s} > 0\}.$$

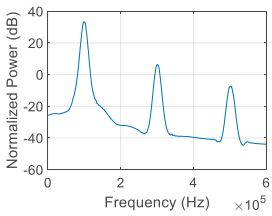
Here, η is the slip direction. The hysteretic force is given by

$$f = u - q^T \bar{b}.$$

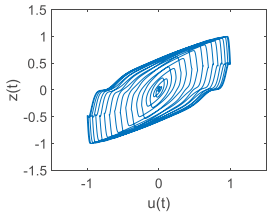
Where $\dot{s}$ is the slip rate and η can be found by solving a 4×4 eigenvalue problem [6]. We used both the models in our present study to generate a response of the one-way two-wave mixing in a media with rate-independent hysteresis.

SIMULATION RESULTS AND DISCUSSION

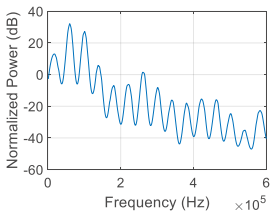
For a single frequency input pulse, both the models show the generation of only odd harmonics in their frequency responses (Figure 2(a) and Figure 3(a)). The corresponding hysteresis curves are captured nicely with increasing loop size from zero to a maximum and again back to zero as the amplitude of Gaussian pulse increases from zero to maximum amplitude and then coming back to zero (Figure 1(b)).



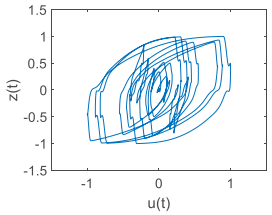
a) Single-frequency Gaussian input pulse frequency response



b) Single-frequency Gaussian input pulse hysteresis curves



c) Two frequency Gaussian input pulse frequency response



d) Two frequency Gaussian input pulse hysteresis curves

Figure 3. Nonlinear wave propagation in media with Two-State hysteresis model

Due to mixing, sum and difference frequencies (other than f_1 = 0.06 and f_2 = 0.1 MHz input frequencies) are observed by both the models (Figure 2(c) and Figure 3(c)). Both the models captured a wide range of possible mixing frequencies generated due to various combinations of input frequencies ($2f_1+f_2$, $2f_1-f_2$, f_1+2f_2, f_1-2f_2, $4f_1+f_2$, ..., *etc.*) excellently. From Figure 2(d) and Figure 3(d), at the low amplitude of Gaussian pulse, both models excellently captured minor loops that turns around and intersects with itself. Interestingly as the amplitude of Gaussian pulse increases (loops getting bigger), the medium size minor loops captured using the Bouc-Wen model are translated horizontally which is not the case in Two-States models where the medium size loops are observed within the big major loop. Both the models captured all possible minor and major loops effectively. To gain a detailed understanding of wave mixing studies, different practically possible combinations of input frequencies and amplitudes are also explored through several examples.

CONCLUSIONS

The Bouc-Wen and Two-states hysteresis models are successfully implemented for nonlinear wave mixing study. Both the models captured sum and difference frequencies along with original odd frequencies and all possible minor, intermediate, and major loops effectively. This study can be extended to understand wave mixing in a material with local hysteretic damage.

MICROMECHANICS ANALYSIS OF COMPOSITES VIA CARRERA UNIFIED FORMULATION AND NASA MULTISCALE ANALYSIS TOOL

Marco Petrolo*[1], Erasmo Carrera[1], Ibrahim Kaleel[2], Evan J. Pineda[3], Trenton M. Ricks[3], Brett A. Bednarcyk[3], and Steven M. Arnold[3]
[1]Department of Mechanical and Aerospace Engineering, Politecnico di Torino, Torino, Italy
[2]DLR, Institute of Test and Simulation for Gas Turbines, Augsburg, Germany
[3]NASA Glenn Research Center, Cleveland, United States of America

Summary This paper presents numerical analyses concerning the micromechanics of composite structures. The results stem from the synergistic use of the Carrera Unified Formulation (CUF) and NASA Multiscale Analysis Tool (NASMAT). CUF provides the structural theories to model the representative volume elements (RVE) via 1D finite elements with improved kinematics. NASMAT is the new state of the art multiscale framework developed at the NASA Glenn Research Center for high-performance computing systems. The numerical assessments focus on various RVE architecture with increasing complexity and including wovens. The accuracy and numerical efficiency are discussed for homogenization and localization of the entire 3D stress field. As multifold improvements in the computational time are obtained, extensions to nonlinear multiscale analyses are plausible and attractive.

INTRODUCTION

The multiscale nature of composites unleashes several challenges concerning the numerical modeling. Depending on the structural response of interest, various strategies are available. Unfortunately, the direct numerical simulation of a composite structure accounting for all scales concurrently is still not feasible, and choices are necessary to minimize the computational costs with acceptable accuracy penalties. For instance, the proper evaluation of free-edge effects requires layer-wise modeling in which each layer's structural behavior is directly modeled. [1]. On the other hand, the proper numerical prediction of matrix/fiber failure onset and propagation requires the modeling of the microscale characteristics [2]. The use of micromechanics is helpful to model a volume of the structure, including a representative description of the microscale architecture of the constituents, e.g., fibers, matrix, honeycomb packing, voids, defects. The aim is to provide homogenized material properties for the upper scales starting from the constituent properties; then, via localization, provide stress and strain fields at the microscale for a given macroscale load. The main challenge is to develop a model having accurate homogenization and localization while keeping the computational cost low to favor multiscale and nonlinear analyses. Several features of composites may increase the difficulties, e.g., the use of complex 3D woven architectures [3, 4].

OVERVIEW OF NUMERICAL FRAMEWORK AND RESULTS

This work presents a full numerical method based on advanced 1D structural theories and finite elements. The structural modeling adopts CUF to generate governing equations and FE arrays. In the 1D version of CUF, the displacement field may be written as follows [5]:

$$\mathbf{u}(x,y,z) = F_\tau(x,z)\,\mathbf{u}_\tau(y) \qquad \tau = 1,\ldots,M \tag{1}$$

where $\mathbf{u}$ is the generic displacement vector, F_τ is the cross-section expansion function of the beam defined over the plane $x-z$ with M terms, and Einstein notation acts on τ. The class of function adopted as F_τ determines the theory of structure. This work adopts Lagrange-based polynomials. Examples of advantages of the adopted 1D approach are to have pure displacement unknowns and the possibility of keeping the material and geometrical characteristics of individual constituents as depicted in Fig. 1. Also, the use of 1D models instead of 3D leads to superior localization and computational cost performances.
The modeling approach based on CUF is integrated with a fully into NASMAT using the NASMAT Micro API. An Abaqus GUI generates CUF meshes, whereas the NASMAT input file defines loading, material properties, material models, output, and the like. NASMAT can combine CUF models with any material model available in its libraries. Furthermore, a library of predefined CUF architectures is under implementation in NASMAT. Figure 2 shows an example of localization via NASMAT. The High fidelity Generalized Method of Cell serves as the verification tool as it another method available in NASMAT. Numerical results on more complex architectures are expected to lead to some The use of CUF led to some 5-10 times reductions in computational time as compared to 3D FE.

VOID GROWTH IN A LITHIUM SOLID STATE BATTERY

Norman A Fleck*[1] and Alan Cocks [2]
[1]Cambridge University Engineering Dept., Trumpington St., Cambridge, CB2 1PZ, UK
[2]Department of Engineering Science, University of Oxford, Parks Rd., Oxford, OX1 3PJ , UK

Summary. Recent experimental studies in the literature reveal that the electrical performance of Li ion solid state batteries is limited by the development of micron-sized voids at the interface between the Li anode and the solid state electrolyte. The voids grow by the increased rate of Li stripping adjacent to the voids, and the current mitigation strategy is the imposition of a mechanical pressure on the interface. A mechanics analysis is presented of void growth by diffusional flow of Li atoms along the void surface and then along the interface. The main non-dimensional groups are identified that dictate whether void growth or void shrinkage occurs, and the significance of the interface electrical resistance is highlighted. The results are useful for steering the development of Li ion batteries to mitigate against this degradation mode.

INTRODUCTION

There is a major worldwide demand for increasing the performance and reliability of lithium (Li) ion batteries. A promising development is the Solid State Battery (SSB), comprising a Li anode, a ceramic electrolyte and a ceramic cathode. However, cell discharge at high currents leads to the formation of voids at the interface between the Li anode and the underlying ceramic electrolyte, see Fig. 1 and [1]. The voids degrade performance and promote the formation of Li dendrites within the adjacent electrolyte, thereby short-circuiting the cell. It is thought that void growth is by surface diffusion, such that a volumetric flux j of Li atoms migrate along the surface of the void, then along the interface between Li anode and electrolyte, and thence into the electrolyte in the form of Li cations. Void formation and growth can be prevented by imposing a sufficiently high pressure p on the interface. A mechanics analysis is developed for void growth, and the dominant non-dimensional groups are identified that control the process. The significance of the interfacial electrical resistance between Li anode and electrolyte is emphasised.

ANALYSIS

Assume that a representative void exists as a spherical cap of base radius a, and contact angle ω, such that local equilibrium of the interfacial energy γ_I, surface energy γ_S of the void and surface energy of the Li/air interface γ_I demands $\gamma_I = \gamma_C + \gamma_S \cos\omega$. The voids have a spacing of $2L$ and this configuration is idealised by the axisymmetric geometry of Fig 1. Continuity demands that the volumetric flux j along the interface between the Li anode and electrolyte is a function of the radius r from the axis of symmetry; j is related to the stripping velocity $v_E(r)$ of the Li into the electrolyte and to the rate of change of thickness of Li anode H according to

$$\frac{1}{r}\frac{\partial(rj)}{\partial r} + H + v_E = 0 \qquad (1)$$

Now, the velocity $v_E(r)$ into the electrolyte is aligned with the unit normal n_i to the surface of the electrolyte and is directly related to the normal component $n_i J_i$ of the ionic current density J_i of Li+ within the electrolyte, such that $v_E = -J_i n_i \Omega / F$ where Ω is the molar volume of Li and F is Faraday's constant. The current density J_i within the electrolyte is related to the electrical potential gradient $\phi_{,i}$ and to the conductivity κ of the electrolyte according to $J_i = -\kappa\phi_{,i}$. Charge neutrality within the electrolyte demands that $\nabla^2\phi = 0$. The finite interface resistance Z at the boundary between Li anode and electrolyte is sensitive to the processing conditions of the interface and provides the necessary boundary condition at the surfaces of the electrolyte. Following common experimental practice, we assume that the discharge current I_0 from anode to cathode of the unit cell is held constant. Consequently, as the void grows or shrinks, there is a small change in the voltage drop $\phi_2 - \phi_1$ between the electrodes.

Upon solving for $\phi(x_i)$ within the electrolyte from the governing Laplace's equation $\nabla^2\phi = 0$, the stripping velocity $v_E(r)$ is known and hence the flux $j(r)$ in terms of H by integration of (1). Additionally, growth of the void provides an expression for the volumetric diffusive flux $j(r=a)$ at the edge of the void, and we can thereby obtain a in terms of H. It remains to determine H. This is achieved by invoking the Cocks-Suo variational principle [2] as follows.

First, assume that dissipation occurs only at the interface between Li anode and electrolyte as a result of diffusion of Li along the interface, and write a dissipation potential in the form

$$\Psi(H) = \frac{1}{2D_S}\int_a^L 2\pi r j^2 dr \qquad (2)$$

where D_s is an effective interface diffusivity. Second, write the free energy of the unit cell as

$$G(H) = \pi L^2 Hp + S_V\gamma_S + \pi a^2\gamma_C + \pi\left(L^2 - a^2\right)\gamma_I \qquad (3)$$

We proceed to determine $G(H)$ and determine H from the stationary condition

$$\delta\Psi + \delta G = 0$$

This delivers H and in turn the void growth rate a

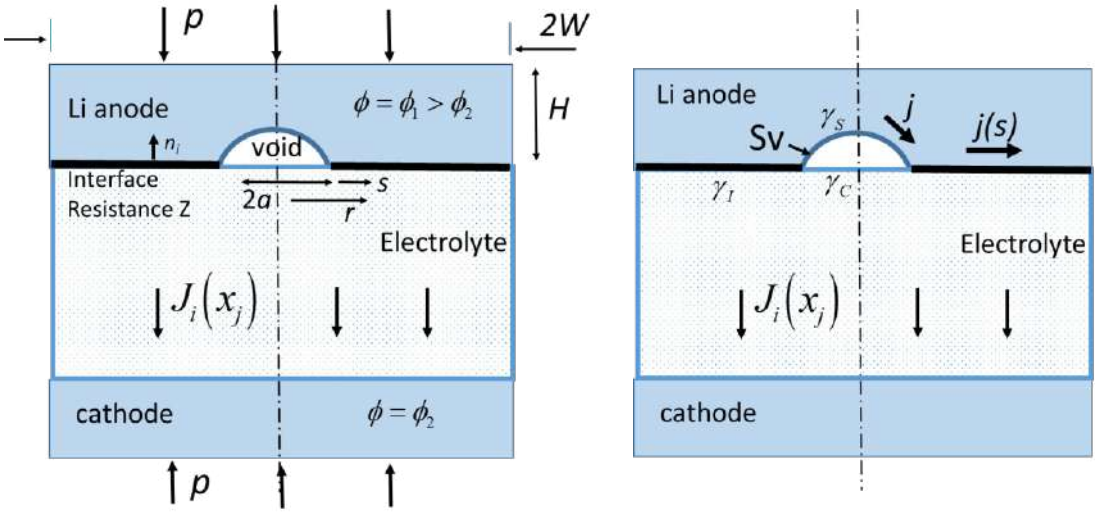

Figure 1. The voided Li anode, geometry and diffusion pathway.

RESULTS

The problem reduces to a determination of the void growth rate a due to the imposed current I_0, with void shrinkage driven by the surface energy γ_S and by the imposed pressure p. It is instructive to write the form of the solution in non-dimensional form

$$\frac{aL^3F}{aI_0\Omega} = f\left(\frac{a}{L}, \frac{Z\kappa}{a}, \frac{pa}{\gamma_S}, \frac{I_0 a}{FD_S\gamma_S}, \omega\right) \qquad (4)$$

Numerical solutions of the form (4) will be presented, and the sensitivity to parameters such as $Z\kappa/a$ will be highlighted. For example, a small value of $Z\kappa/a$ leads to an increased flux adjacent to the edge of the void and hence to enhanced void growth. The study provides insight into the sensitivity of void growth to parameters such as the pressure p on the cell: a threshold value of p is required in order to prevent void growth, which is a function of the imposed current I_0.

CONCLUSIONS

The study highlights the role of Li surface and interface diffusion in void growth within the Li anode of a solid state Li ion battery; this is an important degradation mechanism. A mechanism of void growth has been identified and the accompanying analysis quantifies the effects of imposed current and interface resistance on void growth and explains the physical basis of the mitigation pressure: the pressure required to arrest void growth. Additional deformation mechanisms remain to be analysed: bulk diffusion and power law creep within the Li anode.

COMPLIANT AND LOW-EXPANSION COMPOSITE ELECTRODES FOR A SOLID-STATE BATTERY

Ying Zhao*[1,2] and Norman Fleck[2]
[1]School of Aerospace Engineering and Applied Mechanics, Tongji University, Shanghai, China
[2]Department of Engineering, University of Cambridge, Cambridge, United Kingdom

Summary We propose a hierarchical lattice cathode for a solid-state lithium-ion battery. Due to the stiff and brittle nature of the ceramic electrolyte and ceramic active material of the cathode, the proposed composite cathode structure should ideally accommodate high actuation strains of the active material without macroscopic expansion, during lithiation and delithiation. Also, the composite cathode should have high macroscopic compliance to maintain conformal contact with other parts of the battery without stress-induced fracture. Furthermore, we optimize the structure for both electrical and mechanical performance in order to achieve: (i) high energy density, (ii) high power density, (iii) high ionic conductivity and high electronic conductivity, and (iv) minimise the risk of fracture due to cyclic charge and discharge.

INTRODUCTION

Inorganic solid electrolytes are promising alternatives to liquid electrolytes in next-generation lithium-ion batteries because they don't leak, are not flammable and are mechanically and thermally stable [1]. However, most solid electrolyte materials—stiff oxides and compliant sulfides alike—are brittle.

Recent developments of next-generation cathode materials focus mainly on the improvement of specific/volumetric energy density, but the accompanied changes of lattice parameters during cycling pose an additional challenge to be solved, especially in all-solid-state batteries. As shown in Figure 1(a), lithium nickel cobalt aluminium oxide (NCA) and lithium nickel manganese cobalt oxide (NMC) of various composition can possess a specific energy density as high as $200\,\mathrm{mA\,h\,g^{-1}}$ and their volume change reaches $5\,\%$ [3], which increases with increasing capacity. Cathode materials such as olivines, spinels and tavorites have a lower capacity but also swell significantly upon lithiation.

In order for materials of high capacity but poor mechanical properties to be used as the cathode in an all-solid-state battery, we explored various structured composite cathodes. In particular, we propose the structure shown in Figure 1(b). The solid electrolyte forms the scaffold and ionic pathways of the cathode, while the active material is embedded inside the scaffold.

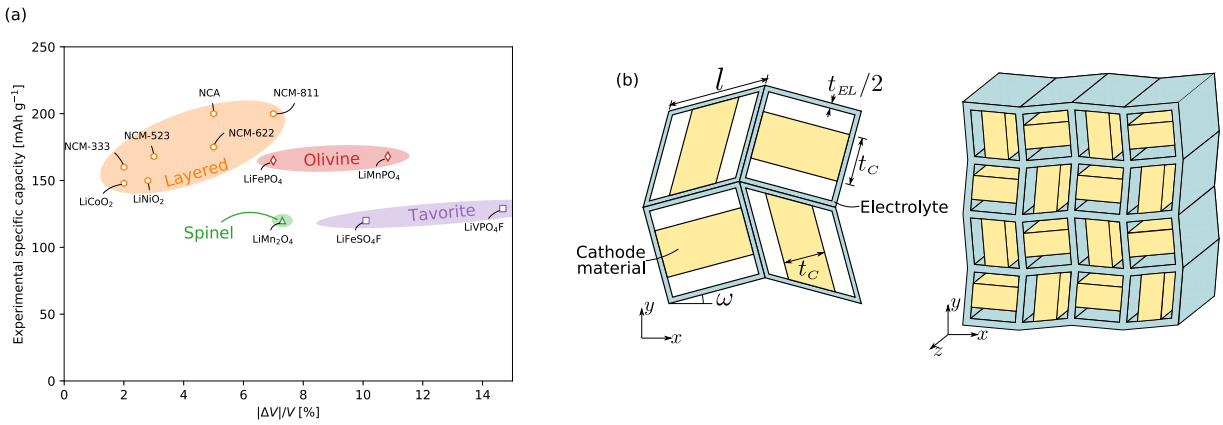

Figure 1: (a) The experimental capacity and volume change of some typical cathode materials (Refs: [6, 4, 3, 2]. NCM-333: $\mathrm{LiNi_{1/3}Co_{1/3}Mn_{1/3}O_2}$, NCM-523: $\mathrm{LiNi_{0.5}Co_{0.2}Mn_{0.3}O_2}$, NCM-622: $\mathrm{LiNi_{0.6}Co_{0.2}Mn_{0.2}O_2}$, NCM-811: $\mathrm{LiNi_{0.8}Co_{0.1}Mn_{0.1}O_2}$, NCA: $\mathrm{LiNi_{0.8}Co_{0.15}Al_{0.05}O_2}$.) (b) Proposed hierarchical composite structure.

METHOD

Electrical performance

We follow the methodology of [5], and consider a 1D model of a battery cell, which is composed of a lithium metal anode, a separator, a composite cathode and a current collector. Under galvanostatic discharge, the internal resistance of the battery cell compared with that with a traditional composite cathode is expressed as

$$R_{\mathrm{int}}^{\mathrm{rel}} = \frac{Z_a + w\chi^{-1} + W\left[2f_C\left(\chi f_{EL} + \chi_c f_C\right)\right]^{-1} + \lambda\left(\chi_c f_C\right)^{-1}}{Z_a + w\chi^{-1} + W\left(2\chi_c\right)^{-1} + \lambda\chi_c^{-1}}. \tag{1}$$

*Corresponding author. E-mail: 19531@tongji.edu.cn

In Equation (1), we denote Z_a as the interface resistance between Li-metal and electrolyte, χ as the conductivity and w as the thickness of the separator, W as the thickness of composite cathode, f_C as the volume fraction of active material and f_{EL} as the volume fraction of solid electrolyte in the structured cathode. λ is a characteristic length scale for the lithium intercalation reaction at the interface between the cathode material and the electrolyte.

Mechanical aspect

An analysis of the structure in Figure 1(b) by Euler beam theory shows that macroscopically the material is orthotropic in the xOy plane. Write E as Youngs modulus, t as the strut thickness and l as the strut length, consistent with Figure 1(b). Also, denote the electrolyte by the subscript EL and the cathode by the subscript C. Then, by making use of Euler beam theory, we may express the in-plane bulk modulus $\bar{K}$ and shear modulus $\bar{G}$ as

$$\frac{\bar{K}}{E_{EL}\bar{t}_{EL}^3} = \frac{4\,(1+2r)}{(8+3r)\sin^2\omega}, \qquad \frac{\bar{G}}{E_{EL}\bar{t}_{EL}^3} = \frac{2(2+7r)}{(8+3r)\cos^2\omega} \qquad \text{where} \qquad \bar{t}_{EL} = \frac{t_{EL}}{l}, \qquad r = \frac{E_C I_C}{E_{EL} I_{EL}}. \tag{2}$$

RESULTS

Based on the above calculations, we can plot a design map for the composite cathode for the choice $\omega = 20°$, see Figure 2. In order to achieve a high storage capacity and low internal resistance, the porosity should be minimized and the cathode volume fraction should be increased, as indicated in Figure 2(a). Mechanical failure can occur by exceeding the bend strength of the struts made from electrolyte. The degree of macroscopic swelling is minimised by the use of a small amount of active material. Two regimes can be identified on the map that deliver useful battery properties, as shown in fig. 2(b). Structures in region I exhibit a minor volumetric expansion upon lithiation of active material, and the structure also a high compliance and fracture-resistant. However, the storage capacity is low and the internal resistance is high. Structures in Region II exhibit high capacity, a low internal resistance but display a significant swell and are vulnerable to fracture. Thus, design is a compromise, and the optimal design is dependent upon the relative weighting of the above performance and failure metrics.

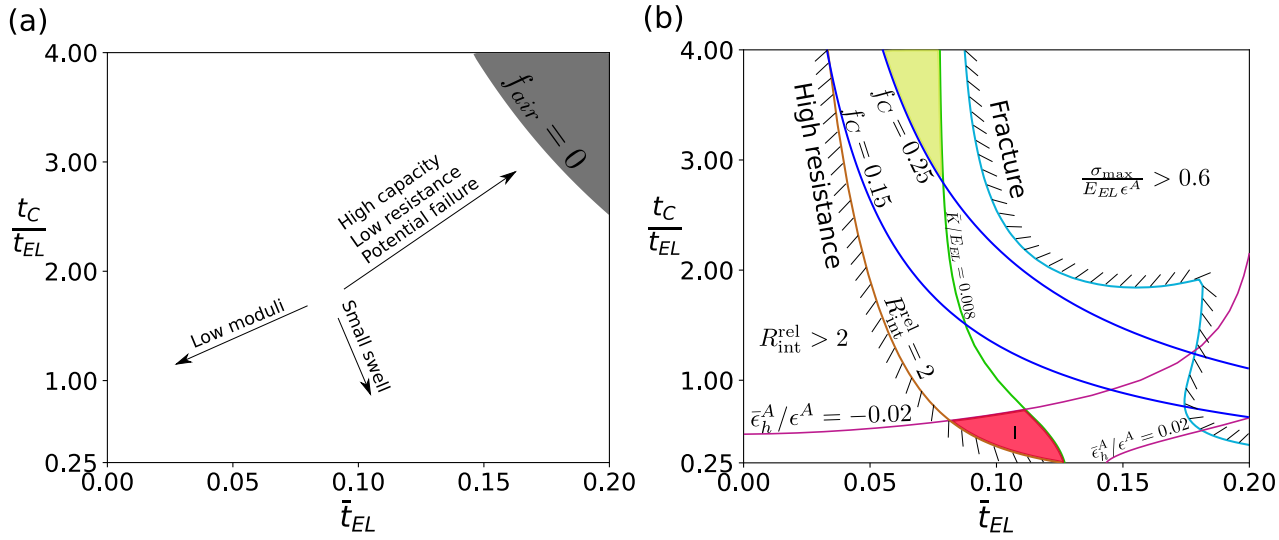

Figure 2: (a) The design map. (b) Predictions of composite cathodes for $\omega = 20°$.

CONCLUSIONS

A design map has been constructed for the composite cathode of a Li ion cell, in order to identify a geometry that delivers a satisfactory electrical and mechanical performance. The composite cathode exploits a lattice topology of high macroscopic compliance and low macroscopic volumetric strain associated with the expansion of the active material during lithiation.

PIEZORESISTIVE RESPONSE OF GRAPHENE RUBBER COMPOSITES CONSIDERING TUNNELING EFFECT

Heng Yang[1], XueFeng Yao*[2], and DaiNing Fang [1]
[1]Institute of Advanced Structure Technology, Beijing Institute of Technology, Beijing, PR China
[2]Department of Engineering Mechanics, Tsinghua University, Beijing, PR China

Summary The piezoresistive behavior of graphene polymer composites is the key performance as the smart sensing materials. In this paper, the numerical method for predicting the piezoresistive properties of graphene rubber composites is established considering the quantum tunneling effect by user subroutines. A representative volume element with randomly distributed graphene has been constructed considering the large deformation characteristics of matrix, which predicted the electrical and mechanical properties and indicated a good agreement with the experimental results. Meanwhile, the strain sensing behavior of graphene rubber composites is calculated, and the influences of the curved graphene configuration, tunneling effect and nanoparticle distributions on the piezoresistive response have been discussed. These results play an important role in evaluating and designing smart rubber composites.

INTRODUCTION

Graphene conductive rubber composites have received more and more attention due to their excellent strain sensing performance and good repeatability. The piezoresistive response (i.e. strain resistance effect) of graphene rubber composites lays a theoretical foundation for the design and application of graphene rubber composites as intelligent sensors, which are mainly concentrated on experimental investigations. Though some literatures indicate that the resistance of graphene polymer composites is approximately linear with the strain(Park et al., 2015; Yan et al., 2018), more results confirm that there are obviously nonlinear relationship (Al-solamy et al., 2012; Lin et al., 2016; Yang et al., 2019), especially in the case of large strain. The nonlinear piezoresistive relationship is mainly attributed to the influence of tunnelling (Boland et al., 2014; Zheng et al., 2017). In addition, both the content and the conductive network structure of nanofillers also affect the strain sensing behavior of conductive rubber nanocomposites(Liu et al., 2016; Yang et al., 2018b), but the mechanism of the piezoresistive response remains to be deeply investigated. On the other hand, the research on the simulation of the piezoresistive response for conductive polymer composites is mainly concentrated in the carbon nanotube composites, and it is generally assumed that the carbon nanotubes are in the one-dimensional contact condition. The contact area between two dimensional graphene sheets in the polymer composites is more complicated, and the tunneling conduction area is often three-dimensional. Meanwhile, in view of the geometrical differences of different conductive particles (zero-dimensional carbon black, one-dimensional carbon nanotubes and two-dimensional graphene), it is necessary to establish a general numerical calculation program based on user-defined material subroutine for the piezoresistive properties of conductive polymer nanocomposites suitable for different dimensional nanofillers.

PIEZORESISTIVE MODEL

Geometric representative volume element (RVE) model

The piezoresistive response of graphene rubber composites is calculated by the RVE model, which consists of a cubic rubber matrix with a side length of L_1 and two-dimensional graphene sheets with random distribution. In the RVE model of graphene rubber composites, graphene is randomly and uniformly distributed. The process for establishing periodic geometric model of the RVE is shown in Fig. 1.

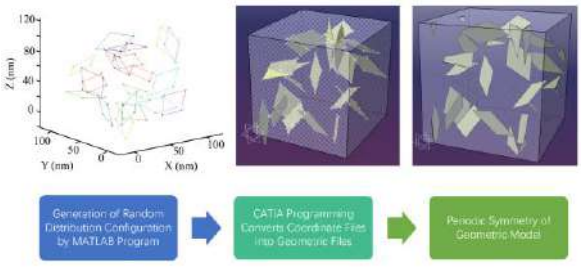

Fig. 1 The generation process of the RVE model for graphene rubber composites.

Electrical model and tunneling effect

Following the identical approach in CNT-polymer composites (Matos et al., 2018), the electrical model considering the tunneling effect is discussed here. The current of graphene and rubber in composites can be obtained according to Ohm's law, and the current density $\boldsymbol{J}$ can be written in term of homogenized values:

$$\bar{J}_i = \bar{\kappa}_{ij}\bar{E}_j = \overline{\kappa_{ij}\left(\frac{\partial V}{\partial x_j}\right)} \tag{1}$$

where κ_{ij} is the electrical conductivity tensor, $s(\boldsymbol{x})$ represents the position vector, E and V_e are the electric field and potential (voltage), respectively.

The tunneling effect should be considered in detail for conductivity calculation of conductive polymer composites. For two adjacent graphene sheets separated by polymer, the tunnel current density can be expressed as the function of the distance between graphene sheets(Simmons, 1963). Based on the distance function s, the current density model of the polymer matrix in the RVE model is calculated as follows.

$$\boldsymbol{J}=\begin{cases}\boldsymbol{k}_R\boldsymbol{E} & s>d_{cut-off}\\ J_T(\boldsymbol{E},s)\dfrac{\boldsymbol{E}}{|\boldsymbol{E}|} & s\le d_{cut-off}\end{cases} \tag{2}$$

Both the electrical constitutive model and the heat transfer constitutive model are similar(Lu et al., 2017). The ABAQUS steady-state thermo-mechanical coupling analysis module is used to analyze the mechanical and electrical properties of graphene rubber composites. The electrical model of rubber is realized by user-defined material thermal behavior subroutine UMATHT, which can calculate distance function and corresponding tunnel current density.

RESULTS AND DISCUSSIONS

Electrical and mechanical properties

The numerical model predicts a percolation thresholdof 1.76% (in Fig. 2 (a)), which is 5.9% smaller than the test result(Yang et al., 2018b), indicating a good agreement and the effectiveness of the proposed prediction method. The homogenized elastic modulus of rubber composites with different content of graphene has been presented in Fig. 2 (b). The predicted values of modulus agree with the experimental results

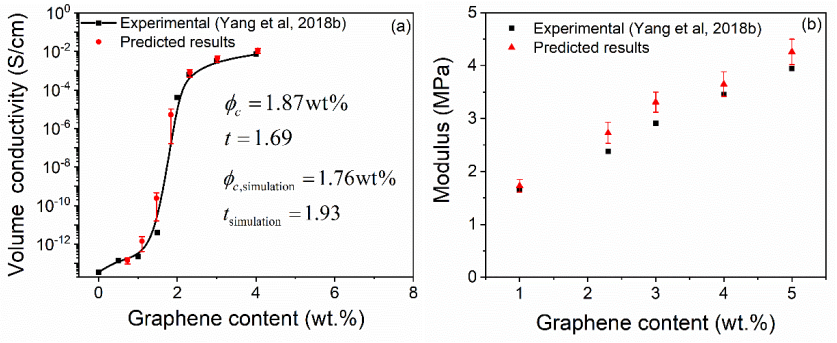

Fig. 2 Predicted conductivity (a) and elastic modulus (b) as a function of graphene content for composites.

Strain sensing behavior

The piezoresistive behaviors of the 2.3 wt.% and 3.0 wt.% graphene rubber composites are predicted. Fig. 3 (a) and (b) show that the predicted resistance response by the RVE model agrees with the test data in the previous paper(Yang et al., 2018b), which can effectively characterize the linear and nonlinear response characteristics in the experimental results.

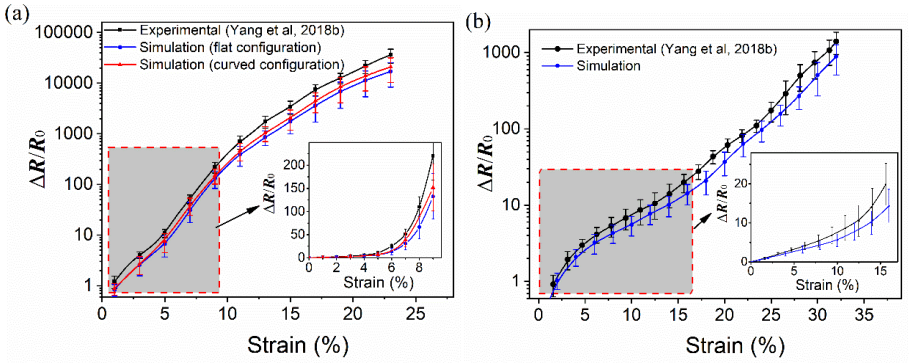

Fig. 3 Comparisons between predicted piezoresistive behavior and experimental results for the 2.3 wt.% (a) and 3.0 wt.% (b) graphene rubber composites.

In order to investigate the effect of non-planar configuration, the RVE model with the curved graphene sheet has also been established. The results indicate that there is a slight increase in conductivity for the graphene rubber composites considering the curved graphene configuration. Further, the strain sensing characteristics of the 2.3 wt.% graphene rubber composite was also predicted with the curved configuration at 15°. The resistance response between the flat and the curved configuration in the linear stage is basically consistent, but the conductivity of the curved configuration changes larger than that of the flat configuration in the nonlinear stage.

Summary This study focuses on identification and modelling of vibration characteristics of a nanocomposite; an epoxy resin as the matrix and fumed silica as the reinforcement. The resin alone is manufactured and characterised. Using the same methodology, the manufacturing and characterisation of the silica-reinforced nanocomposite are performed. Following the manufacturing and the experimental characterisation process, a nonlinear model is built to represent characterised behaviour. The model is validated by a separate test case which is also an experimental technique to extract the damping characteristics of a structure.

INTRODUCTION

In comparison to the mechanical properties of their individual components, the nanocomposites display dramatically different characteristics [1]. A significant improvement in strength and dynamic behaviour can be achieved by tailoring the right nanocomposite. Tailoring can be done by controlling the manufacturing process as well as the matrix-reinforcement combinations [2]. This study investigates the effects of addition of a small mass fraction of nano-silica particles on the damped vibration characteristics of epoxy. Using the gathered knowledge, a model is built to predict the behaviour of the structures made of that nanocomposite [3].

MATERIAL PREPARATION, CHARACTERISATION AND MODELLING

Material Preparation and Manufacturing

First, epoxy samples without any nanoparticle addition are manufactured. Therefore, laminating resin MGS® L 285 Hardener MGS® 285 from Hexion are used. Both components are mixed slowly and moulded in vacuum. After an hour in vacuum, the samples are taken to ambient pressure and temperature for 24 hours. Then, post-curing is done at 70°C for 15 hours. Next, the silica particulate reinforced epoxy samples are manufactured with a similar process to eliminate the effects of manufacturing steps on the mechanics of the materials. As nanoparticles, fumed nano-silica (HDK® N20 Pyrogenic Silica - Fumed Silica from Wacker Silicones) is used. Also, the same epoxy resin, (Laminating resin MGS® L 285 Hardener MGS® 285 from Hexion) is used. Before starting, 0.49 g silica which was held in the furnace at 60°C for 8 hours to minimise the humidity, is dispersed in 66.79 g of epoxy resin without adding the hardener with at a high speed of 2000 rpm for 3 hours. Following mixing the silica resin mixture is put into a vacuum chamber for degassing 3 hours. Later on, 26.52 g hardener is added and mixed slowly for 10 minutes. Then the blend is cast into the mould for curing at room temperature in vacuum. The same post-curing process is followed [4].

Experimental Characterisation: Dynamic Mechanical Analysis (DMA) and Vibration Test

As one of the most widely used methods, Dynamic Mechanical Analysis (DMA) is employed to characterise the dynamic behaviour of the epoxy and epoxy-silica nanocomposites [1]. For this purpose, DMA Q800 of TA Instruments is utilised to perform the necessary tests. The epoxy samples and the nanocomposite samples with the mass fraction of 0.5% silica inclusion are put through the DMA with the dual cantilever fixture. The samples are rectangular prisms. The sizes of the samples are approximately 60 mm by 14 mm by 3.5 mm. The excitation is chosen as harmonic with frequencies 1, 2, 3, 4, 5, 10, 15, 20 and 25 Hz, while the vibration amplitudes are picked so that the maximum strain values are between 0.0002 and 0.0008 with 0.0001 incrementations. The temperature is kept constant at 20°C for this first step to avoid the effect of any temperature change on mechanical properties.

A vibration test is also conducted to understand the behaviour of a beam made of the nanocomposite material. The specimen used has the dimensions of 280 mm by 24 mm by 4 mm. The experimental setup consists of the specimen with two tip masses attached and suspended from a light steel cable at the tip masses. It is crucial that only the energy dissipation contribution of the material is measured. The masses are held in place via a frictional contact, enforced by a rounded profile to reduce specimen damage whilst minimising extraneous frictional dissipation. The tip masses ensure that the system demonstrates a 'simply-supported' mode shape for the first flexural mode, placing the nodal locations of this mode at the tips of the specimen, and ensuring that the cable moves only in rotation, minimising energy dissipation of interactions between the suspension and specimen. The specimen is excited mono-harmonically to its first flexural resonance (in this case 26.9 Hz) with a shaker which attaches to the specimen using a c-bracket and contacting surface on a single side. This allows the shaker arm to be displaced from the specimen using an input signal offset initiating a free decay, allowing the calculation of the loss factor using a curve fitting method. The vibration of the specimen is measured using a Polytech LDV system.

Both, DMA and the vibration test setups are displayed in Figure 1.

Figure 1: DMA and the vibration experiment setups

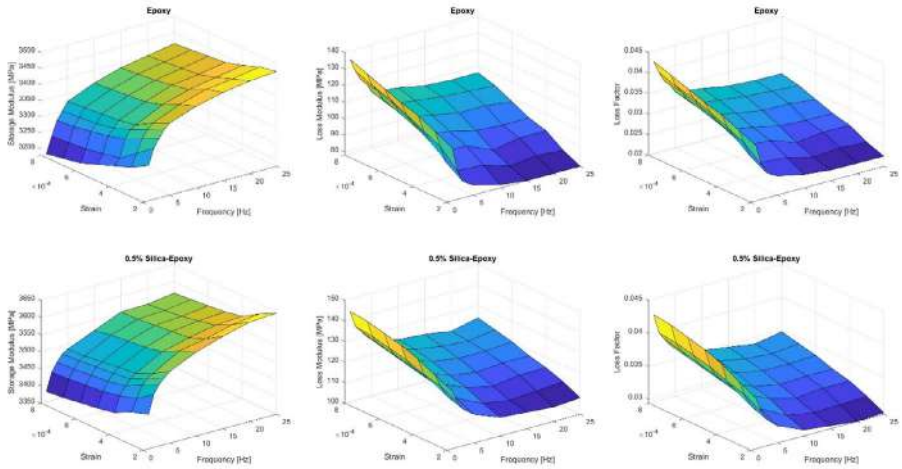

Figure 2: DMA results of epoxy and nanocomposite samples

Modelling of a Single Degree of Freedom (SDOF) System

The system, on which the vibration test is performed, is here considered as a single degree of freedom (SDOF) system. For a simply supported beam the equivalent stiffness is known as $k_{eq} = 48EI/L^3$ whereas the equivalent mass is $m_{eq} = m_{beam}/2$. The Young's modulus E is assumed to be complex. The storage and loss moduli, that are defined as functions of strain and strain rate by curve-fitting the results of DMA, are used as the real and imaginary parts respectively.

RESULTS AND CONCLUSIONS

The results of DMA are plotted in Figure 2 which display a considerable nonlinear behaviour from both materials. The variation of storage modulus of epoxy is found to be around 10% within the investigated range of amplitude and frequency. However, the damping is affected more dramatically. The change is found to be around 65%. For the nanocomposite, the storage modulus shows a similar trend by changing approximately 10%, whereas the damping is affected by around 45%. The addition of 0.5% mass of silica stiffened the material approximately by 5% whereas it increased the damping capabilities by up to 20%. This increase in damping is related to the effect of the interfaces created between the matrix and the nanoparticles. Meanwhile, in loss factor, both materials have almost the same trends as well as values. The vibration test with 0.0003 maximum strain and 26.9 Hz frequency, the loss factor is calculated as 2% whereas the SDOF model predicts the loss factor around 2.25% with an error around 12.5%. It is also important to note that the frequency of the vibration test is out of range of the DMA tests. Therefore, a direct comparison between those two tests are not done, instead, the vibration test results are compared to the results of the model which is built by using the results of the DMA.

THE ELECTROCHEMICAL AND MECHANICAL PROPERTIES OF CARBON NANOTUBE MAT-POLYANILINE COMPOSITES

Summary Composite electrodes of direct-spun carbon nanotube (CNT) mats and polyaniline (PANI) are manufactured and tested to determine their electrochemical and mechanical properties, and to investigate their degradation behaviour upon cycling and overcharging. Electrodes are manufactured by electrodeposition of a PANI layer on the CNT bundles within CNT mat. The PANI content is varied widely by suitable control of the electrodeposition time at a constant current density. The in-plane uniaxial stress-strain response and capacitance of the electrodes are determined as a function of the electrode composition, the PANI state of charge, after 1000 charge/discharge cycles, and after overcharging. The electrodes exhibit an elastic-plastic stress-strain response under uniaxial tension; their modulus and strength depend upon the volume fraction of CNT bundles. Electrode capacitance increases with increasing PANI volume fraction. A micromechanical model is proposed to relate the macroscopic modulus and yield strength of a CNT-PANI composite to the microstructure.

CARBON NANOTUBE MAT-POLYANILINE COMPOSITE ELECTRODES

The high power density, capacitance and cyclic stability of supercapacitors have attracted considerable attention from the research community [1]. A typical configuration of a supercapacitor is sketched in Fig.1a; it comprises two current collectors, each coated with an electrode material. The CNT mat microstructure comprises an interconnected network of carbon nanotube bundles. Upon coating with a suitable electrode material, the resultant porous electrode may be immersed in a liquid electrolyte, forming a psuedocapacitor. The electrode microstructure of PANI-coated CNT bundles is sketched in Fig.1b. The PANI uniformly coats the CNT bundle network, see the scanning electron microscopy (SEM) in Fig.1c. Studies of CNT-PANI composite electrodes have reported specific capacitances as high as 1030 F/g [1], much above the performance of many other capacitor materials. The reported electrode tensile strength of up to 135 MPa and Young's modulus of 5 GPa makes them promising candidate materials for structural energy storage devices. As yet, the influence of charge and discharge rate, electrode composition and state of charge upon the mechanical and electrochemical properties of these novel electrode composites remains unclear, as do the mechanisms of degradation upon cycling. These topics are the focus of this study.

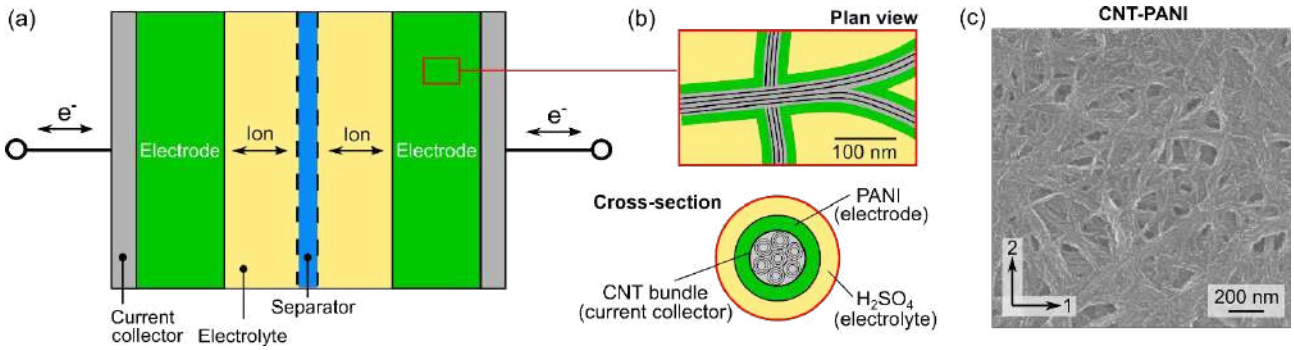

Figure 1. (a) Typical configuration of a supercapacitor. (b) Sketch and (c) SEM image of carbon nanotube-polyaniline (PANI) composite electrode microstructure.

MANUFACTURING AND CHARACTERISATION OF CNT-PANI COMPOSITE ELECTRODES

The CNT mat samples were coated with PANI through electrodeposition at a constant current of 5 mA with a potentiostat. The deposition time ranges from 5 minutes to 60 minutes. Cyclic voltammetry and linear sweep to voltage ranging from -0.2 V to 1 V were used to characterise the electrochemical properties of CNT-PANI electrodes. Tensile tests were performed on the CNT mat and CNT-PANI composites using a screw-driven machine at a strain rate of $\dot{\epsilon} = 10^{-4}\,s^{-1}$.

ELECTROCHEMICAL PROPERTIES OF CNT-PANI COMPOSITE ELECTRODES

A stable charge capacity after the application of multiple charge/discharge cycles are important property for the successful application of capacitor chemistries as energy storage devices. Consider the measured electrochemical properties of the CNT-PANI electrode after the application of 1000 charge/discharge cycles during. For these electrodes, peaks corresponding to Faradic reactions in the cyclic voltammetry response of Fig.2a are less prominent, but still present. The capacitance of a CNT-PANI-T20 electrode and CNT mat electrode absent PANI recorded over the application of 1000 charge/discharge cycles is plotted in Fig.2b, normalised to its value at the start of the test. For the CNT-PANI electrode, the rate of capacitance reduction decreases towards the end of the test, and the final measurement of capacitance

*Corresponding author. E-mail: wei.tan@qmul.ac.uk

is approximately 84% that recorded before cycling. Regardless of composition or charge/discharge history, the capacitance of these plotted CNT-PANI electrodes varies almost linearly with the ratio f_P/f_B, see Fig.2c. The PANI volume fraction is reduced by cycling or overcharging. The capacitance of the CNT-PANI-T20 samples measured after overcharging or cycling lies close to those of samples manufactured with similar ratios of f_P/f_B. Thus, the reduced PANI volume fraction is sufficient to account for the reduction in electrode capacitance upon cycling or overcharging.

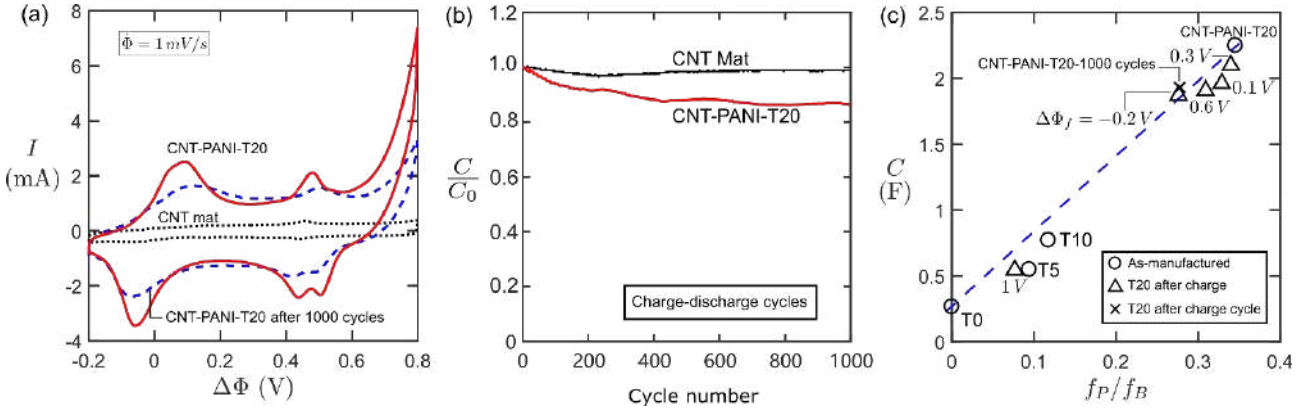

Figure 2. (a) Measured current versus voltage $\Delta\Phi$ relationship (b) The evolution of capacitance of CNT mat and CNT-PANI-T20 electrode over 1000 charge-discharge cycles. (c) Electrical capacitance versus the volume fraction ratio of PANI to CNT.

MECHANICAL PROPERTIES OF CNT-PANI COMPOSITE ELECTRODES

A micromechanical model is developed, based on the characterisation of the underlying CNT mat and CNT-PANI electrode microstructure, to predict the electrode modulus and strength. The CNT-PANI is idealized as a periodic, planar hexagonal honeycomb model, where the struts are formed from interconnected CNT bundles and PANI [2,3], as sketched in Fig.3a. Hill's anisotropic yield criterion is used here to represent the post-yield behaviour of the CNT bundles. The measured modulus and strength both lie close to values predicted by the model, see Fig.3b. The predicted modulus and strength based upon the CNT bundle honeycomb model with PANI volume fraction $f_p = 0$ and $f_p = 0.3$ is also included in Fig.3c. Note the predicted influence of the PANI content is minor compared to that of the bundle volume fraction for electrodes of the compositions studied herein. The measured modulus and strength both lie close to values predicted by the model. Hence, bundle volume fraction appears sufficient in predicting the modulus of the CNT-PANI electrodes.

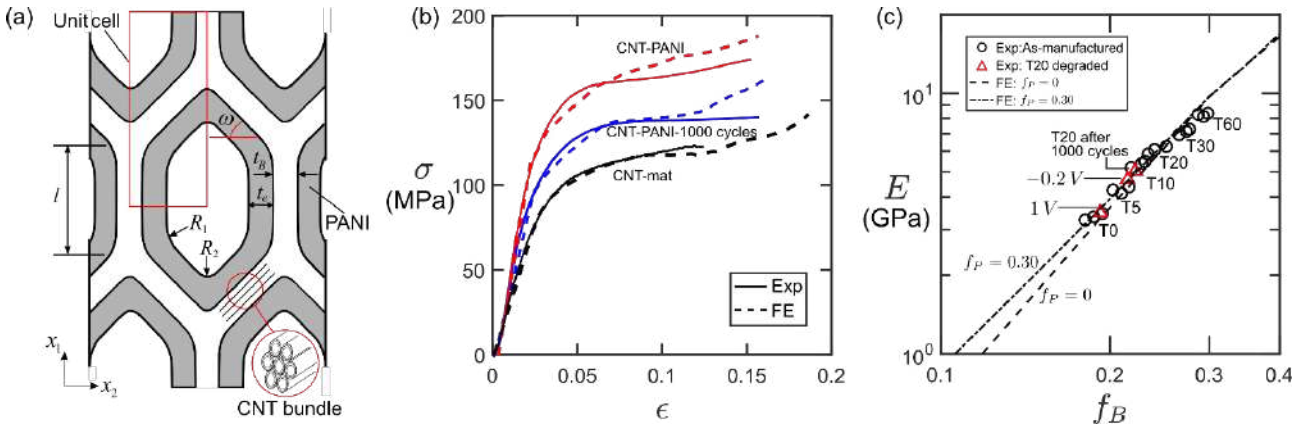

Figure 3. (a) Measured current versus voltage $\Delta\Phi$ relationship (b) The evolution of capacitance of CNT mat and CNT-PANI-T20 electrode over 1000 charge-discharge cycles. (c) Electrical capacitance versus the volume fraction ratio of PANI to CNT.

CONCLUSIONS

The electrochemical and mechanical properties of CNT-PANI were characterised. The reduction in capacitance after repeated cycling or overcharging is attributed to a decreases in PANI volume fraction. The decrease in modulus and strength is attributed to the reduction in CNT volume fraction, which is also captured by the micromechanical model.

CUF-BASED FINITE ELEMENTS FOR THE FREE-EDGE STRESS CONCENTRATION ANALYSIS OF COMPOSITE COUPONS AND STRUCTURES

Alfonso Pagani*[1], Tommaso Cavallo[1], Enrico Zappino[1], and Erasmo Carrera[1]
[1]Mul2, Department of Mechanical and Aerospace Engineering, Politecnico di Torino, Turin, Italy

Summary Based on the Carrera Unified Formulation (CUF), the present study proposes refined finite elements for the free-edge stress concentration analysis of composite structures. CUF makes use of a hierarchical and scalar procedure to approximate the 3D elasticity problem with 1D or 2D theories. In detail, the displacements are expressed as an arbitrary expansions of the generalized unknowns by using generic expansion functions, which determines the theory approximation. In this manner, the theory accuracy can be refined with ease close to critical regions, e.g. at the free-edge, which remains an unresolved problem and for which analytical solutions are limited to a few cases. We demonstrate the high versatility of this approach, which can be indistinctly used at the coupon scale up to the size of a final composite assembly, such as a composite wing or a tape spring for space applications.

INTRODUCTION

Free-edge effects arise in laminates at the interfaces between dissimilar layers in the vicinity of discontinuities in the structure. This phenomenon has been demonstrated to be a crucial actor in damage initiation in composite structures. Nevertheless, current numerical methodologies for the analysis of composites lack in accuracy and efficiency, and the evaluation of stress fields close to free edges may be prohibitive in industrial practise. As a matter of fact, classical laminate theories cannot provide any useful information of the free-edge effects and active interest is still focused nowadays in the development of accurate tools for their evaluation in real composite applications [1].

This work introduces a numerical approach based on higher-order models for the free edge analysis of composite laminates. The Carrera Unified Formulation (CUF) [2] is employed to generate a theory of structure which makes use of displacements as only variables and Lagrangian polynomials as cross-sectional assumptions, named as Lagrange expansion (LE). This theory of structures was first introduced by Carrera and Petrolo [3] and has proven to be a powerful tool for the accurate stress analysis of composite structures in many works, see [4, 5, 6]. The use of a distribution of mathematical expansion domains to assume the deformation of the cross-section of the laminated beam enables the model to capture 3D-like stress distributions at the ply level. Moreover, it also allows the user to refine the cross-section domain in the zones of interest, such as the free-edges. The accuracy and robustness of the proposed method to represent the free-edge effects in generic composite beams is presented in the present work and particular emphasis is given to the scalable nature of CUF, which allows to study indistinctly composite coupon samples under traction/compression and complex assemblies under general loadings and boundary conditions.

LAYERWISE LAMINATED THEORIES BASED ON CUF

Many displacement-based theories of structure have been introduced in the past decades for the study of the mechanical response of laminated structures. Among the others, the layerwise (LW) models make use of independent assumptions for each layer and provide more information of the meso-scale effects by accounting for the deformation of each ply independently. Furthermore, by taking displacement assumptions at the ply-level, LW models are able to capture the zig-zag effect of the displacements in the thickness direction, which is strongly related to the complex distribution of transverse stresses in composite laminates.

In the framework of CUF for beam theories, the LW displacement field of the composite beam is written as:

$$\mathbf{u}(x,y,z) = F_\tau(x,z)\mathbf{u}_\tau^k(y) \quad \tau = 1,2,...,M \tag{1}$$

where $\mathbf{u}(x,y,z)$ is the three-dimensional displacement field, $\mathbf{u}_\tau(y)$ is the vector of generalized displacements that depends on the longitudinal coordinate y and $F_\tau(x,z)$ are the expansion functions of the cross-sectional domain. The class and number of expansion functions is arbitrary, being M the maximum number of expansions, which is a user defined parameter. Repeating indexes denote summation.

The LE beam theory, introduced by Carrera and Petrolo [3], is based on the use of interpolating Lagrange polynomials as expansion functions F_τ of the cross-sectional coordinates. In this manner, the cross-section of the composite beam can be discretized with an arbitrary number of Lagrangian domains, which are used to represent the surfaces of each layer. Since LE beam models make use of displacement unknowns as degrees of freedom, they represent a useful tool for the efficient stress analysis of beam-like structural components. Moreover, LE are in particular interesting to generate LW models since the displacement compatibility at the interfaces between plies is automatically satisfied with no need of numerical artifacts.

COMPOSITE COUPON UNDER TRACTION

For representative purpose, we propose here the free-edge analysis of a composite coupon subjected to unitary axial strain, $\varepsilon_0 = 1$. The material and geometry are equivalent to that of the pioneering work of Pipes and Pagano [7], who considered a symmetric cross-ply with four layers of equal thickness, $t = h/4$.

The model generated for the present assessment consists of 6 cubic 1D elements along the beam axis and a distribution of quadratic LE over the cross-section domain which in all cases consists of 10 LE in the x-axis with a graded distribution towards both the free edges. A convergence study regarding the number of mathematical layers in the direction of the stacking sequence is perform, accounting from one LE per layer up to eight LE per layer. The total number of degrees of freedom goes from 10,431 for the coarsest model, to 77,805 for the finest. All the stress solutions reported in the following are obtained at half-length of the beam, $y = L/2$.

Fig. 1 shows the transverse normal stresses, σ_{zz}, across the thickness at the free-edge for an increasing number of mathematical layers per ply, from one (CUF - 1LE) to eight (CUF - 8LE). The convergence study proves that highly refined kinematics are required to compute accurate free-edge stresses by means of LW theories. Since the only unknowns are displacements and no recovery of the 3D stress fields is performed, the trasnverse stress solutions may show some discontinuities between the expansion domains (corresponding to the vertical lines in the graphs), which are more pronounced in the vicinities of the interfaces between layers due to the high stress gradients. By increasing the number of mathematical layers in the beam model, the stress distributions tend to those obtained from the exact theories, approximating well both the stress-free boundary conditions and the interlaminar continuity.

CONCLUSIONS

This paper has introduced the use of CUF to study free-edge stress concentrations of composite structures. Preliminary results demonstrate that LW models may provide accurate and efficient results at coupon scale. Further analyses will show that the method can be successfully employed for the study of complex composite structural assemblies, in a global/local sense. Particular attention will be given to, but not limited to, the analysis of composite wings and composite truss structures for space applications.

Summary Non-linear structural responses present the opportunity for a paradigm change in the design of transformative (meta)-materials. Designers are presented with the opportunity to create truly bespoke elastic responses. However, design complexity, such as complex topological forms, is often a consequence, which leads to a reliance on non-intuitive computational simulation. Alternatively, through judicious selection of structural architecture, it is possible to harness structural non-linearity robustly to produce an algorithmic tailoring method that retains insight. Herein we extend this physical insight-driven approach to analysis to explore the behaviour of space-filling lattices constructed of bistable elements. By embedding non-linearity within each element we are able to produce highly adaptive multi-stable lattice frameworks with a simple topology.

INTRODUCTION

The increased use of compliant structures to facilitate adaptivity is indicative of the paradigm shift away from the purely-linear design philosophy. These structures oftentimes exploit large deformations facilitated by snapping between stable configurations to achieve desirable performance. Although structural topology can be tailored to obtain desirable transfomative properties, see, e.g. [1–3], it often relies upon costly computational analysis. Indeed, harnessing structural instabilities alone is not without its own challenges, see e.g. Champneys et al. [4] who outline recent advances in the field. In particular these limitations affect the (meta)-material community that is actively developing novel material systems constructed from multi-scale arrangements of mechanically multi-stable snapping components, e.g. [5]. As the size of the system increases, so the number of possible equilibrium states scales geometrically, making analysis challenging [6].

To avoid the difficulty of complex topology, non-linearity can be subsumed into a well understood 1D non-linear spring whose behaviour may be readily tuned [7]. By employing these structural response mechanisms at sufficiently small length scales, a desirable macroscopic continuum response can be achieved [8, 9]. When used in combination, they permit an algorithmic tuning process that can match, to an arbitrary precision, any energetic function up to a constant [10]. This approach permits an analytical exploration of the behaviour, retaining physical insight. Herein, we propose a new approach for creating novel material behaviour from a hierarchy of non-linear elements; namely, rather than utilising complex topologies to achieve the desired non-linear behaviour, we can subsume this complexity into well understood non-linear "springs" acting as base-units of a hierarchical design.

ANALYSIS APPROACH

Following the approach of Dixon et al. [10] we are able to construct a 1D bistable element that is tuned to possess two energetic minima at lengths l_0 and 1, and one maximum at the midpoint, see figure 1a. We are able to construct the first hierarchical form, the triangular lattice, from three identical elements, see Figure 1b. The lattice's total energy is described by specifying the lengths of each element permitting an analytical exploration of transitions between stable configurations using a parametric sweep of the cubic design space, see Figure 1c. In doing so we are able to identify the stability diagram and the energetic barrier to actuation.

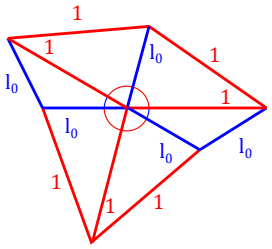
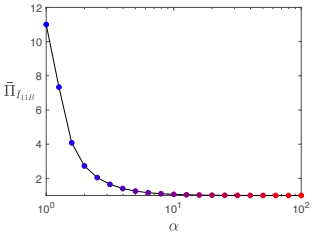
(a) Example of a regular hexagonal lattice composed of 12 bistable elements.



(b) Example of a non-regular hexagonal lattice in a stable configuration. The side lengths of each sub-triangle determines the interior angles which governs the existence of stable configuration for given lengths l_0.



(c) Exploration of the energetic barrier to actuation between stable configurations obtained via a parametric path sweep.

Figure 2: Representative analysis of a hexagonal lattice framework.

The analysis is subsequently extended to the second hierarchy, the hexagonal lattice, see Figure 2a. In doing so we identify the geometric constraints, arising from the inability to independently modify all elements' length. We present constraints on the relative lengths of the stable configuration, i.e. permissible l_0, that determine the existence of non-regular hexagonal configurations that are also global energetic minima, see Figure 2b. A parametric sweep of the hypercube that defines the design space is used to identify the energetic barrier to actuation Figure 2c. Using our approach we are able to characterise the transition behaviour of hexagonal lattices and in doing so identified that sequential activation sequences minimise the energetic barrier.

CONCLUSIONS

We present the analysis of multi-stable space-filling lattices composed of bistable one-dimensional elements as an initial foray into the analysis of generalised space-filling lattices. We utilise an analytical description of the system's energy in order to characterise the behaviour of triangular and hexagonal lattices. In particular we identify the actuation path that minimises the energetic barrier, indicating the structures' preferred response mode, and explore the geometric constraints that govern the existence of global minima of hexagonal systems. Using our semi-analytical approach we retain physical insight into the system's behaviour and avoid the use of computationally-expensive analysis.

EFFECT OF BOUNDARY CONDITIONS, CONSTRAINTS AND IMPERFECTIONS ON THE SNAP-THROUGH PERFORMANCE OF BISTABLE LAMINATES

Aghna Mukherjee*[1], Shaikh Faruque Ali[1], and A Arockiarajan[1]
[1]Department of Applied Mechanics, Indian Institute of Technology Madras, India

Summary In this work, an analytical model is developed to predict the equilibrium shapes and the snap-through load for a class of hybrid symmetric bistable laminates (HBSL) with cantilever boundary conditions. Additionally, the snap-through behavior of HBSL is analyzed in detail to understand the effects of different loading conditions, clamp conditions, and imperfections using FEA (ABAQUS) and experiments. It has been shown that the snap-through behavior is highly complex and extremely sensitive to the parameters as mentioned above. The observations from the analysis are subsequently used to design an actuation system using a solid-state actuator.

INTRODUCTION

Bistable laminates are a class of composite structures exhibiting two stable equilibrium configurations. Since their discovery, there have been many attempts to understand the mechanics of bistability and snap-through (1). Several analytical models exist in the literature that predicts the equilibrium shapes and the snap-through loads of such laminates. However, all these attempts have been restricted to a free-free boundary condition. In this work, a model is developed that predicts the stable configurations and the snap-through loads for a class of HBSL with cantilever boundary conditions. It is possible to use FEA to study the behavior of these laminates in boundary conditions other than free-free; however, the FE models are computationally expensive and hence not suitable for the design space analysis. The developed model has been used to analyze the design space. Subsequently, a detailed numerical (using ABAQUS) and experimental study have been carried out to understand the effect of clamping, load configurations, and imperfections.

Analytical Model

To model the curing process, the total potential energy of the laminate system is written in terms of the assumed displacement field. The total potential energy function is then minimized with respect to the assumed coefficients to obtain the equilibrium shapes of the laminate. The potential energy function of the laminate is given as:

$$U_{tot} = \int_V \left(\begin{bmatrix} \epsilon^o \\ \kappa^o \end{bmatrix}^T \begin{bmatrix} A & B \\ B & D \end{bmatrix} \begin{bmatrix} \epsilon^o \\ \kappa^o \end{bmatrix} - \begin{bmatrix} \epsilon^o \\ \kappa^o \end{bmatrix}^T \begin{bmatrix} N_T \\ M_T \end{bmatrix} \right) dV - W_{ext} \tag{1}$$

In the formulation, von Karman nonlinear strains have been assumed (2). The novelty of the model is that the continuity requirements of multi-sectioned layup (shown in Fig. 1 (a)) and the boundary conditions are satisfied within the approximated displacement fields using the following constraints:

$$u^o_{in}(x,y^{ab}) = u^o_{out}(x,y^{ab}); \quad u^o_{in}(x,y^{cd}) = u^o_{out}(x,y^{cd}); \quad v^o_{in}(x,y^{ab}) = v^o_{out}(x,y^{ab}); \quad v^o_{in}(x,y^{cd}) = v^o_{out}(x,y^{cd})$$

$$w^o_{inner}(x,y^{ab}) = w^o_{outer}(x,y^{ab}); \quad w^o_{inner}(x,y^{cd}) = w^o_{outer}(x,y^{cd}); \quad \frac{\partial w^o_{in}}{\partial x}(x,y^{ab}) = \frac{\partial w^o_{out}}{\partial x}(x,y^{ab})$$

$$\frac{\partial w^o_{in}}{\partial x}(x,y^{cd}) = \frac{\partial w^o_{out}}{\partial x}(x,y^{cd}); \quad \frac{\partial w^o_{in}}{\partial y}(x,y^{ab}) = \frac{\partial w^o_{out}}{\partial y}(x,y^{ab}); \quad \frac{\partial w^o_{in}}{\partial y}(x,y^{cd}) = \frac{\partial w^o_{out}}{\partial y}(x,y^{cd})$$

Effect of point of application of load and clamping configurations

The equilibrium shapes obtained using the analytical model, FEA, and experiments are shown in Fig. 1(b). To understand the behavior of these laminates subjected to different clamping configurations and loading, two sets of numerical and experimental studies are done: a) The snap-through is obtained by applying the load at different distances from the clamped edge. b) The laminate is clamped at different lengths at the cantilevered edge. It is seen from the numerical simulations and experiments that, on loading the bistable laminate at different distances from the free edge, the laminate snaps to an intermediate state, as shown in Fig. 1(c). However, on the application of a small perturbation at the free end, the laminate snaps to the cylindrical shape initially predicted by the analytical scheme. In the second study, the load-displacement diagrams are plotted for the laminate clamped at different distances at the cantilever edge, while a concentrated load is applied at the center of the free edge. It can be seen from Fig. 1(d) that for an increase in the clamping distance, the area under the load-displacement hysteresis plot decreases, while the snapping load remains almost the same.

Effect of imperfections

To study the effect of imperfections, the relative thickness of the aluminum layers and the central $[0]$ laminae are varied. Using FE simulations in ABAQUS and experiments, it is observed that introducing an imperfection by changing the thickness of the $[0]$ laminae, from 0.3 mm to 0.25 mm while keeping the thickness of aluminum layer 0.3 mm, the load-displacement characteristics changes substantially, as shown in Fig.1(e). Introducing an asymmetry in the structure leads to an asymmetry in the load-displacement plot i.e., the load-displacement plot loses its symmetry about the x-axis.

(c) Intermediate equilibrium states obtained against the position of application of load. (d) Load-displacement plots of the laminate clamped at different distances. (e) Effect of imperfections. (f) Snap through of the HBSL using SMA wire actuator.

Actuation by solid state actuator

The solid-state actuators available currently have certain limitations. For instance, SMA wires can be actuated at a maximum strain of 5-7%. From the analysis, it has been shown that for a complete snap-through, a continuous force over a large displacement is required. To analyze the efficacy of actuation, an SMA wire is attached to the bistable laminate at an eccentricity, as shown in Fig.1(f). The eccentricity has been kept at minimum, and the SMA wire is actuated at its full capacity. From the experiments, it is observed that a complete snap-through occurs only when the distance of clamping is more than 90 mm. The same set of experiments are repeated for a laminate with imperfection. It was observed that by virtue of imperfection, the forward snapping could be achieved with a clamping distance of 35 mm.

CONCLUSIONS

In conclusion, the developed analytical model accurately predicts the behavior of HBSL with cantilever boundary conditions, thus extending state of the art. From the numerical and experimental study, it is concluded that to achieve a complete snap-through, the position of application of load is critical. A force constraint, in addition to a boundary condition, can lead to an intermediate stable state which has higher energy than the configurations predicted by the analytical model. Furthermore, it is observed that clamping at different distances substantially reduces the area under the load-displacement hysteresis curve. This information has been subsequently used to design an actuation system using SMA wire. It is shown that SMA wire strained at 3% achieves complete snap-through when the laminate is clamped at 80 mm distance at the fixed end. Finally, the effect of imperfection has been analyzed, and it is shown that, while a small imperfection with respect to the relative thicknesses of the individual laminae does not have much effect on the equilibrium shapes, it substantially alters the load-displacement behavior.

PERIODIC MATERIALS WITH RESONANT CAVITIES FOR ENERGY LOCALIZATION

Marco Moscatelli*[1,2], Claudia Comi[1], and Jean-Jacques Marigo[2]
[2]Laboratoire de Mécanique des Solides, École Polytechnique, Palaiseau, France
[1]Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy

Summary Composite periodic materials, made by a regular repetition of a unit cell with two or more components, can exhibit an "unusual" dynamic behavior. In particular, the propagation of elastic and/or acoustic waves of frequency within specific intervals can be attenuated. This peculiarity makes them feasible for controlling the mechanical energy flow carried by the traveling waves, guiding it into some demarcated regions where it can be localized.

RESONANT CAVITY IN THREE COMPONENT PERIODIC MATERIALS

In this contribution, we consider periodic continua whose unit cell contains an heavy and stiff inclusion with a soft coating, embedded in a stiff matrix, see Figure 1a . This particular internal structure is typical of the so-called "Locally Resonant Materials" (LRMs): the very compliant material used for the coating allows for the presence of local resonances inside each cell generating the so-called band-gaps, i.e. intervals of frequencies in the dispersion plot corresponding to a complex wavenumber and, thus, to attenuated propagating waves, as shown for instance in [1]. Here we analyze the possibility of focusing the mechanical energy of anti-plane elastic waves inside an homogeneous cavity (part Ω_3 in Figure 1a) placed between two barriers (Ω_2 and Ω_4) made of three-components LRMs. The described system resembles a Fabry-Pérot interferometer [2]; the dimensions along axis x_2 and x_3 (out-of-plane axis) are comparable and both very large with respect to the size of the unit cells composing the LRMs. The incoming wave, traveling through the homogeneous part Ω_1 with a fixed angular frequency ω inside a band-gap of the LRM and a wave front perpendicular to the x_1 axis, reaches the first barrier Ω_2 where it experiences both reflection and attenuation; once inside the cavity Ω_3, due to the presence of the two barriers, the wave is rebounded back and forward several times before leaving that region and reaching part Ω_5. The propagating elastic wave can hence be trapped inside the cavity, obtaining an accumulation and a focusing of its mechanical energy in that specific region.

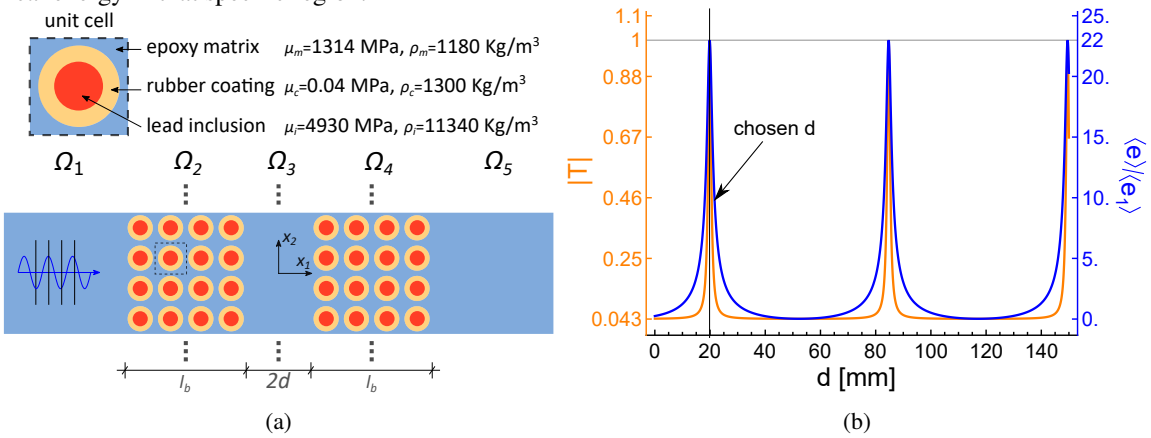

Figure 1: (a) Unit cell of the LRM with material properties and general scheme of the analyzed system: composite with resonant cavity; (b) modulus of wave amplitude $|\mathrm{T}| = 1$ (Orange, left axis) and cavity energy density $\langle e_3 \rangle$ normalized with input energy density $\langle e_1 \rangle$ (Blue, right axis) versus cavity width d.

Homogenized properties and bandgaps of LRM

The problem is characterized by two different length scales: a scale corresponding to the size a of the unit cell of the LRM and a scale L of the wave length of the considered wave propagating in the matrix. When $a/L = \epsilon << 1$, a two-scale asymptotic analysis could be applied for obtaining a macroscopic equivalent description of the behavior of the heterogeneous medium (see e.g. [3]). The unknown displacement field u can be expressed by asymptotic expansion, in powers of ϵ. By approximating the solution at the first order of the expansion, both an effective shear modulus μ_{eff} and an effective mass density ρ_{eff} can be derived. More in details, μ_{eff} is a function only of the elastic properties and the geometry of the LRM unit cells, whereas ρ_{eff} depends also on the frequency and can become negative. This latter peculiarity may occur only if $\mu_c/\mu_m = \mathcal{O}\left(\epsilon^2\right)$, where μ_c and μ_m are the shear moduli respectively of the coating and of the matrix materials. As shown in [4], the effective mass is negative for frequencies corresponding to a band-gap and becomes unbounded at the resonance frequencies of the internal inclusions. Considering the geometry of the unit cell shown in figure 1a, ρ_{eff} can be analytically derived, hence the effective motion of the two barriers becomes completely known in closed form, with the only exception of μ_{eff}, which can be computed numerically and remains constant for all the frequencies.

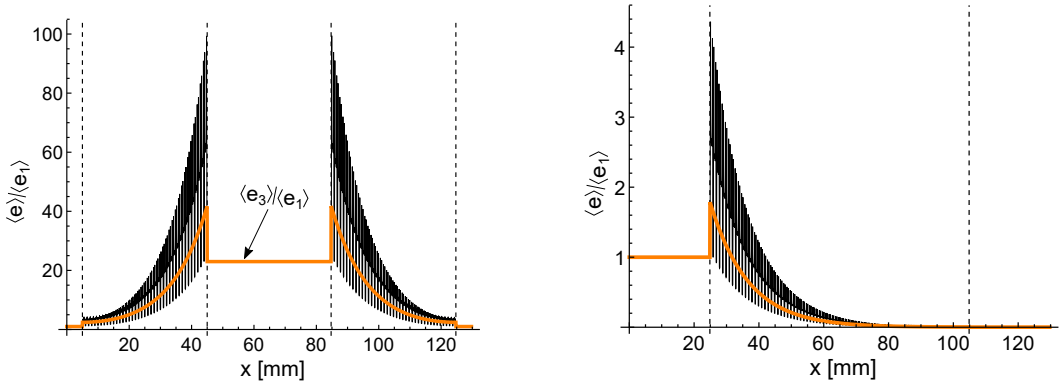
Optimization of the cavity

For a specific chosen LRM, the wave motion in the system of Figure 1a depends only on 3 parameters, namely the frequency (ω), the width of the barriers (l_b) and the width of the internal cavity ($2d$). For any fixed value of ω inside the band-gap and any fixed number of unit cells (i.e. for any l_b) the mechanical energy which is trapped inside the cavity is averaged in time over the period and optimized with respect to d. The problem can be entirely solved analytically and a sequence of optimal dimensions of the cavity are obtained. The maximization of $\langle e_3 \rangle$ (average energy density inside part Ω_3) provides the same optimal d of the maximization of the amplitude T of the transmitted wave propagating in part Ω_5. When $|\mathrm{T}| = 1$ (complete transmission), the energy reaches its maximum value, see Figure 1b.

ANALYTICAL AND NUMERICAL RESULTS

We have applied the analytical procedure previously described to an example problem, comparing the results with a finite element analysis. The analyzed composite is constituted by square unit cells,1mm×1mm, as specified in Figure 1a. Notice that the ratio $\mu_c/\mu_m << 1$, respecting the condition which guarantees the presence of band-gaps. The two barriers are made up of forty unit cells in the x_1 direction. The energy $\langle e_3 \rangle$ has been maximized considering a traveling wave with a frequency of $\omega = 4068$ Hz (value taken in the middle of the lowest band-gap). From the set of optimal cavity widths, the first value $d = 19.9$mm has been chosen, see Figure 1b. Note that a change of the frequency or a scaling of the unit cells geometry would imply a new optimal set of d.



(a) (b)

Figure 2: Normalized mechanical energy density for ω=4087 Hz in the different parts of the analysed systems: (a) system with the optimal cavity (d = 19.9 mm), (b) system without the cavity. Orange curves: analytical results, black curves: numerical results.

In Figure 2a we report the average mechanical energy density generated by the motion caused by the propagating wave, normalized with respect to the energy of the incoming wave $\langle e_1 \rangle$. The analytical results (in orange) are in good agreement with the numerical one (in black), attaining for both cases a value of energy $\langle e_3 \rangle$ inside the cavity twenty-two times bigger than the value of the incoming wave in part Ω_1. In the LRM barriers the analytical solution, based on the homogenized material, does not describe the oscillations due to the inclusions which are evidenced by the numerical analysis. For comparison, Figure 2b shows the results obtained in a system without a resonant cavity (i.e. with d=0). One can see that in this latter case the LRM as expected attenuates the energy of the incoming wave and no energy localization occurs.

CONCLUSIONS

With the aim of focusing the vibration mechanical energy in a confined region, we analysed a system made with a composite material with a resonant cavity. By applying a two-scale asymptotic technique we computed the band-gap of the composite material and we derived the optimized cavity dimension to maximize the energy localization. Since $|\mathrm{T}| = 1$ when the energy inside the cavity is maximum, the system could also be employed for selecting some specific frequencies within a packet of waves which are traveling at a frequency situated inside a band-gap.

DAMPING OF VIBRATIONS OF SMART-STRUCTURES BASED ON PIEZOELECTRIC ELEMENTS AND GRAPHENE COMPOSITES

Valerii Matveenko*[1], Dmitrii Oshmarin[1], and Nataliia Iurlova [1]
[1]Institute of Continuous Media Mechanics Ural Branch of RAS, Perm, Russia

Summary In this paper a variant of a smart-structure, which is piecewise-homogeneous body composed of elastic and viscoelastic materials and also piezoelectric elements connected to shunting electric circuits with the aid of its electrodes, is considered. The content of the paper is connected with an option of a shunting circuit where a graphene composite is used as a resistor instead of classic one. In this case a graphene composite in smart-structure is not only a deformable solid but also acts as a resistor. The results of numerical experiments show the applicability of graphene-based composites for additional damping of vibrations in smart structures based on piezoelectric elements.

In general case smart-materials fix their parameters and change their properties taking into account information about their condition. Realization of these problems is reached when smart-materials or, to be more precise, smart-structures contain elements which serve a function of sensors, actuators and processors, which set up specified connections between sensors and actuators. Among the manifold of smart-structures there are a lot of possible variants where these elements are combined in different ways and partially perform the functions mentioned above.

In this paper smart-structures based on application of piezoelectric elements are considered. It should be noted that hardware basis for such smart-structures develops rapidly. Nowadays there are known more than fifteen hundred materials having a property of piezoelectric effect. An additional possibility of structural behavior control emerges for piezoelectric-based smart-structures, is in connection of shunting electric circuits, comprised of resistive, inductive and capacitive elements, across the electrodes of piezoelectric elements.

Analysis of the information about graphene composites allows concluding that elements made of these materials may acts as resistive elements simultaneously with realizing their mechanical properties. The main content of the current paper is devoted to proposition of application of graphene composites as resistors in piezoelectric-based smart-structures and mathematical modeling of dissipative properties of such systems.

The variational equation of motion of deformable solid having the elements which exhibit piezoelectric effect is used for mathematical formulation of a problem of vibrations of deformable solids with elements made of piezoelectric materials and resistors [1-4]. A piecewise-homogeneous body occupying the volume $V = V_1 + V_2$ is considered as the object under study. Here the volume V_1 is made of homogeneous elastic or viscoelastic elements and the volume V_2 is the volume of the element with piezoelectric properties.

Within the frameworks of the problem under consideration specific elements of the volume V_1 can be performed of graphene composites which have the property of electric conductivity along with conventional mechanical properties, and consequently they can additionally act as a resistor. In this case if piezoelectric element (V_2) and graphene-based element have electrodes, the latter will perform functions of resistor in addition to deformable properties. And if a conductor is placed across the electrodes of piezoelectric element and graphene composite such a system can be treated as electrodeformable body made of elastic and viscoelastic elements with a resistor.

An assessment of dissipative properties for the systems under study is carried out on the basis of quantities of amplitude values of displacements in resonant modes in case of steady-state vibrations or on the basis of decay rate of a corresponding mode in case of free vibrations. The procedures of finite element method are used for numerical realization of problems on natural vibrations and steady-state vibrations formulated for electro-viscoelastic body with electric circuits comprised of resistor, inductors and capacitors.

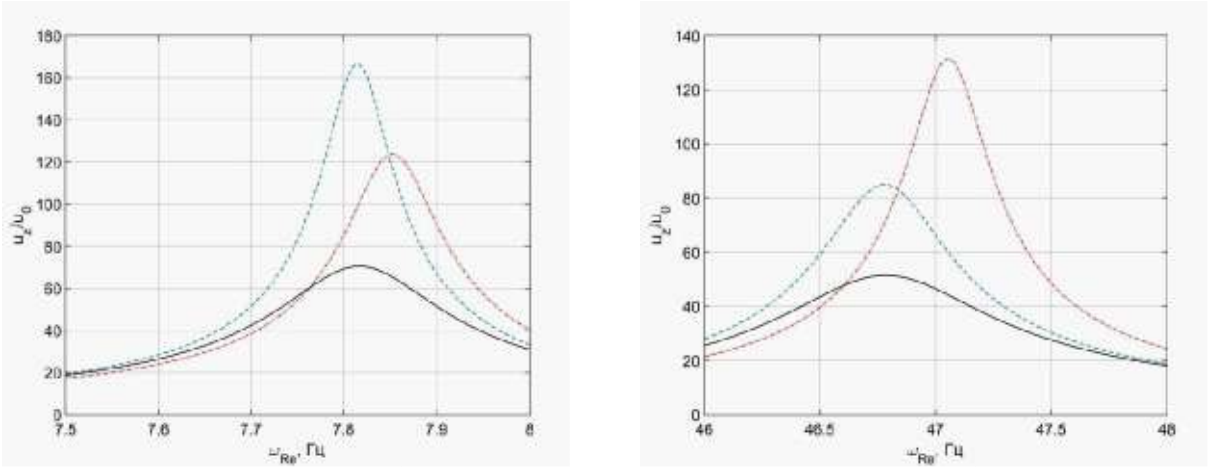
plated and element made of graphene composite is attached to another side. The material of the plate is aluminum. Piezoelectric element (dimensions are 60x90x1.3 mm) is made of PKR7 piezoelectric ceramics. In the performed numerical calculations there was considered a variant of a graphene composite on the basis of PMMA. In the case when this element was modeled within the frameworks of the elastic model the following material properties was settled: shear modulus G=2.29·10^8 Pa, bulk modulus B=5.96·10^8 Pa, specific density ρ=1190 kg/m^3. For the case when viscoelastic model was used the complex shear modulus $G = G^R + iG^I$ and elastic bulk modulus was established as follows $G^R = 2.29 \cdot 10^8$ Pa, $G^I = 5.73 \cdot 10^7$ Pa, $B = 5.96 \cdot 10^8$ Pa.

For the problem of steady-state vibrations it is accepted that the clamped end of the plate performs the vibrations which can be described using the following relations: $x = 0$, $u_x = u_y = 0$, $u_z = U_0 e^{ipt}$. Figure 2 shows the frequency response plots of the component u_z of the displacement vector for the free end of the plate in the vicinity of the first and the second resonances for the following calculation cases:

1. Only elastic properties of the element made of graphene composite are taken into account (dashed line);
2. Graphene composite material is elastic and performs functions of a resistor (dot-dashed line);
3. Graphene composite material is viscoelastic and performs functions of a resistor (solid line).

The values of complex natural vibration frequencies for all these cases were also obtained and presented in table 1.



(a) (b)

Figure 2. Frequency response plots for the u_z component in the vicinity of the first resonance (a) and in the vicinity of the second resonance (b).

Table 1. The values of complex natural vibration frequencies for the first and the second vibration mode

Calculation case	$\omega = \omega_R + i\omega_I$	
	The first vibration mode	The second vibration mode
1	7.81597 – i 0.04401	46.33836 – i 0.16603
2	7.78116 – i 0.03360	46.10908 – i 0.22177
3	7.78344 – i 0.07784	46.11665 – i 0.38729

The analysis of the results presented at figure 2 and obtained values of complex natural vibration frequencies presented in table 1 shows that exploitation of property of electric conductivity of graphene composite in smart materials based on the application of piezoelectric elements gives additional possibilities for damping of vibrations.

The work was supported by RFBR (project № 19-51-10003-KO_a).

TEMPERATURE DEPENDENT PAYNE EFFECT OF FILLED RUBBER

Wenbo Luo*[1,2], Youjian Huang [2], Xiaoling Hu [2], and Boyuan Yin [3]

Summary The focus of this paper lies on the modelling of the temperature dependent complex modulus of filled rubber. The strain amplitude sweep DMA tests were conducted at various temperatures ranging from -30℃ to 50℃ on carbon-black filled rubber samples to obtain the variations of the storage and loss moduli with the dynamic strain amplitude, which swept from 0.1% to 5% by steps of 0.1%. A quantitative description of the Payne effect is presented by the Kraus model at a reference temperature of 20℃, and the effect of temperature on the Payne effect is evaluated by a reduced factor, by which the logarithmic storage and logarithmic loss modulus vs. strain amplitude curves at different temperatures can be overlapped by a vertical shift.

INTRODUCTION

The Payne effect is known to be a particular nonlinear characteristic of the mechanical behaviour of carbon black filled rubbers. It is manifested as a strain amplitude dependence of the dynamic viscoelasticity. Above approximately 0.1% strain amplitude, the dynamic storage modulus decreases gradually with the increase of strain amplitude and approaches to an asymptotic value, while the dynamic loss modulus increases first and then decreases, showing a maximum in the region where the storage modulus decreases[1]. The Payne effect and its frequency and temperature dependence are closely related to the damping characteristics of filled rubbers when they are used as vibration absorption and seismic isolation components. Therefore, modelling the temperature and frequency dependence of the Payne effect has attracted much attention in the last decades.

DYNAMIC VISCOELASTICITY MEASUREMENTS

Material

The material for Dynamic Mechanical Analysis (DMA) is carbon black filled natural rubber, and was generously provided by the Zhuzhou Times New Material Technology Co., Ltd. in China. The main formulation of the rubber compound was as follows: 100 phr NR (Thailand RSS3), 56 phr carbon black (N330), 5 phr ZnO, 2 phr antioxidant, 2.2 phr sulfur, 2 phr stearic acid, 0.8 phr vulcanization activator. Rubber sheet samples were prepared by platen vulcanizing press in according to the ASTM D3182.

Strain sweep DMA tests

In order to investigate the dynamic viscoelasticity and the Payne effect of the CB filled rubber, the DMA tests were conducted with a *Gabo Eplexor 500N* working in the tensile mode at a frequency of 5Hz and at various temperatures ranging from -30℃ to 50℃. All specimens were mechanically preconditioned to eliminate the Mullins effect. Afterward isothermal strain sweep measurements for a given prestrain of 0.1 were performed to obtain the variations of the storage and loss moduli with the dynamic strain amplitude, which swept from 0.001 to 0.05 by steps of 0.001. The test results are shown in Fig.1. It is indicated that when the strain amplitude (Δ) increases, the storage modulus (E') decreases with the increasing Δ, while the loss modulus (E'') shows a maximum in the region where the storage modulus decreases rapidly. This is referred as the Payne effect.

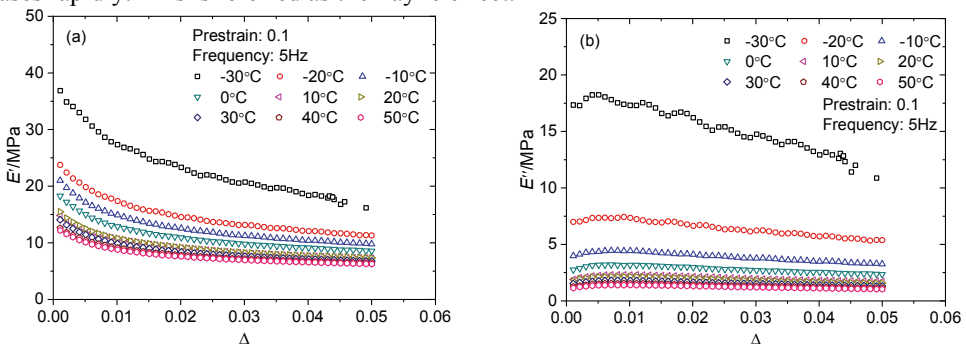

Fig.1 Variation of storage modulus (E') and loss modulus (E'') with strain amplitude at various temperatures

MODELLING OF THE PAYNE EFFECT

The Payne effect can be attributed to the deformation-induced breakage and reforming of the weak physical bonds between the filler aggregates in filled rubber. The Kraus model is the first phenomenological model to represent the Payne effect based on the mechanism of de-agglomeration and re-agglomeration of the filler clusters, it describes rather

*Corresponding author. E-mail: luowenbo@xtu.edu.cn.

well the experimental data using the following equations [2]:

$$E'(\Delta) = E'_{\infty} + \frac{E'_0 - E'_{\infty}}{1+(\Delta/\Delta_c)^{2m}} \tag{1}$$

$$E''(\Delta) = E''_{\infty} + \frac{2(E''_{\mathrm{m}} - E''_{\infty})(\Delta/\Delta_c)^{m}}{1+(\Delta/\Delta_c)^{2m}} \tag{2}$$

Δ_c is the characteristic value of the strain amplitude, at which the loss modulus reaches its maximum value E''_{m}, E'_0 is the storage modulus for small strain amplitudes (usually < 0.0001), E'_{∞} and E''_{∞} are the asymptotic plateau values of the storage and loss moduli at large strain amplitudes respectively, m is a non-negative phenomenological exponent to fit the experimental data. It was reported in the literatures that the exponent m is nearly independent of temperature and carbon black loading [3], but decreases slightly with increasing frequency [4]. In many cases $E''_{\infty} = 0$, thus Eq.(2) reduces to $E''(\Delta) = 2E''_{\mathrm{m}}(\Delta/\Delta_c)^{m}/1+(\Delta/\Delta_c)^{2m}$, the model parameters can be determined by fitting the test data in Fig. 1(b) with Eq.(3). Fig.2 shows the model fit curves in log-log scale. $\Delta_c = 0.006$, m=0.4, only the parameter E''_{m} is temperature dependent. Setting $E''_{\mathrm{m}}(T) = \phi(T)\cdot E''_{\mathrm{m}}(T_0)$, then the temperature dependent loss modulus can be written by

$$E''(\Delta,T) = \phi(T)\cdot E''(\Delta,T_0) \tag{3}$$

It is revealed that the $\log E''(\Delta,T) \sim \Delta$ curves at different temperatures are parallel to each other and can be overlapped by a vertical shift. The resultant shift factors with a reference temperature of 20°C are given in Fig.3, and are fitted by a WLF equation with C_1=-0.55 and C_2=80°C. A similar analysis can also be performed for the storage modulus in Fig.1(a), and the Kraus model fit and the corresponding temperature shift factors for storage modulus are shown in Fig.4 and Fig.5.

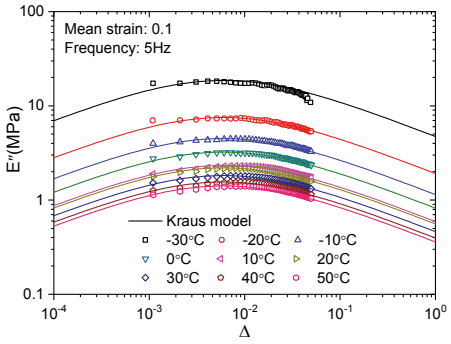

Fig.2 Kraus model fit vs. test data for loss modulus

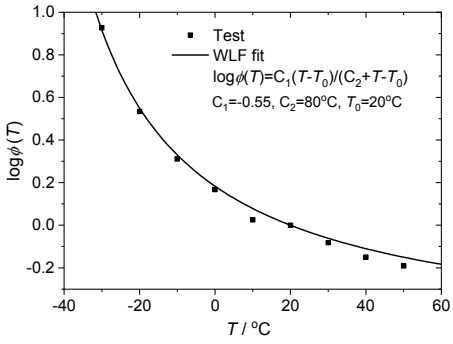

Fig.3 Temperature shift factors of loss modulus for T_0=20°C

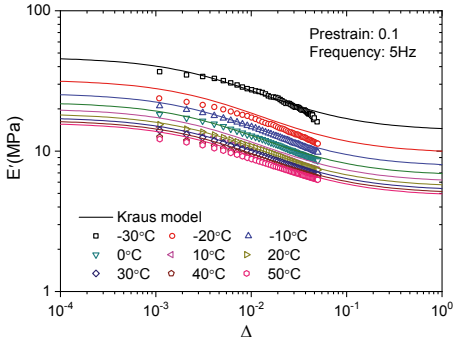

Fig.4 Kraus model fit vs. test data for storage modulus

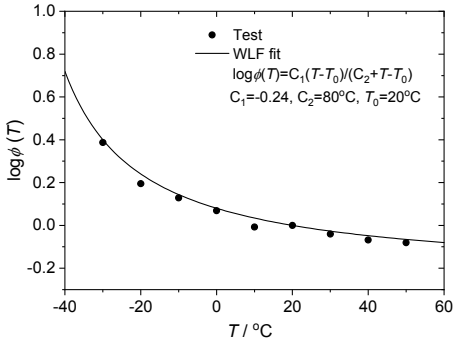

Fig.5 Temperature shift factors of storage modulus for T_0=20°C

CONCLUSIONS

The temperature dependent Payne effect of the carbon-black filled rubber is experimentally investigated and described by the Kraus model with a temperature shift factor. The logarithmic loss modulus vs. strain amplitude curves at various temperatures can be shifted vertically to overlap, and the temperature shift factor satisfies the WLF equation.

THE INTERFACIAL THERMAL RESISTANCE IN COMPOSITES ACCOUNTED BY THE REITERATED HOMOGENIZATION AND FINITE ELEMENT METHODS

Summary The reiterated homogenization method is applied to investigate macroscopic behavior of fibrous and particulates conductive composites with a thermal barrier at the interface. Two micro-structural levels (nano- and micro- scales) are considered. The homogenization method provides a methodology for obtaining the effective coefficients through the solution of local problems corresponding to each level. Such problems involve partial differential equations on the periodic cells with imperfect conditions at the interfaces. The combination of finite element and domain decomposition methods is implemented to solve the local problems. The numerical results is calibrated by comparisons with known analytical formulas. This contribution could be useful for nanofibers and nanofluids applications.

INTRODUCTION

The Reiterated Homogenization Method (RHM) is a rigorous mathematical technique for investigating the macroscopic behavior of periodic composites with different microstructural levels. The application of RHM to the partial differential equations modeling such media leads to new PDE for each microscopic scale, called local problems. The macroscopic or effective coefficients in each higher scale can be calculated solving the local problem in the previous one.

Analytical solution of such problems can only be achieved for composites with specific geometries, and it is necessary to apply numerical methods, e.g. Finite Element Method (FEM). For instance, in [1] FEM is combined with RHM to investigate macroscopic behavior of heat transfer problems in 2D composites considering perfect thermal contact though the interfaces. In [2] an Ad-hoc homogenization model was developed to analyze the role of aggregation processes and interfacial thermal resistance on the effective thermal conductivity of nanofluids and nanocomposites. Aggregation relates directly with multiple spatial scales, and a significantly enhancement of the overall thermal conductivity was founded.

There is an increasing interest in the influence of imperfect contact, [3, 4] find variational bounds and analytical solutions for simple geometries respectively, but this feature adds difficulties in the implementation of numerical methods. The Domain Decomposition Method (DDM) developed in [5] showed to be efficient in the case of imperfect contact due to the natural characterization of the domains and its ability to manage several conditions in said interface. The combination of FEM and DDM [6] was used to obtain the effective coefficients in simple homogenization with imperfect contact.

METHODOLOGY AND RESULTS

The RHM is applied to a strong-form Fourier heat conduction problem on a composite formed by a matrix and an inclusion (fiber or particulate). With this asymptotic method we obtain a local problem for each microscopic scale consisting in to find the Ω^α-periodic local function u^α such that:

$$\begin{cases} \nabla \cdot (K^\alpha(\nabla u^\alpha + x)) &= 0, & \text{in} \quad \Omega^\alpha, \\ [\![K^\alpha(\nabla u^\alpha + x)]\!] \cdot n^\alpha &= 0, & \text{on} \quad \Gamma^\alpha, \\ K^\alpha(\nabla u^\alpha + x) \cdot n^\alpha &= \beta\,[\![u^\alpha]\!], & \text{on} \quad \Gamma^\alpha. \end{cases} \tag{1}$$

The supra-index α represent the micro-structural level for which the local problem was stated. Ω^α is the periodic cell, $x \in \Omega^\alpha$ is the local (fast) variable, and Γ^α is the interface, which determines the inner and outer region in Ω^α filled with the inclusion and the matrix, respectively. Here n^α is a normal unit vector to Γ^α and $[\![u^\alpha]\!]$ is the jump of the function u^α across the interface. The effective coefficients in each scale can be calculated by solving the local problem in the previous scale according to

$$K^1 = \left\langle K^2(\nabla u^2 + x) \right\rangle, \qquad \text{and} \qquad \hat{K} = \left\langle K^1(\nabla u^1 + x) \right\rangle, \tag{2}$$

where the angular brackets denotes the average over a periodic cell.

To solve (1) numerically we will apply the Schwarz scheme of DDM in a FEM framework [7], i.e. solving in the inner and outer region alternatively and using it in the boundaries condition. Applying this methodology twice we obtain the macroscopic effective coefficient (2). Finally, we compare the result for spherical cross section fibers and spherical particles with the analytical known results [8]. We compare also with [7] for circular fibers obtaining the same solutions.

1	0.3	0.679	0.7721	0.843996	0.696063	0.9
10^3	0.3	1.2194	1.221	1.24359	1.27085	1.2988
10^{-3}	0.75	0.0702	0.0793	*0.0413238*	0.205932	0.2507
1	0.75	0.4908	0.5003	0.674059	0.533934	0.75
10^3	0.75	1.624	1.6715	*1.86681*	1.71103	1.747

CONCLUSIONS

We combine DDM and FEM to solve numerically the local problems, for fibers and spherical inclusions arising from the RHM. This allow us to address the problem for a composite considering a thermal barrier at the interface and to obtain the effective conductive properties of composites with these feature. The novelty of the present work lies in the shapes considered for calculations, and in the fact that two micro level were taken in account to calculate the effective conductivities in a medium with two scales (it is justified via reiterated homogenization). In this way, the effective properties obtained on one scale are used to find these same properties on the next one. The results obtained are in agreement with analytical ones appearing in the literature.

ANISOTROPIC VISCOELASTIC MODELS FOR CREEP OF CONTINUOUSLY AND DISCONTINUOUSLY FIBER REINFORCED THERMOPLASTICS

Sascha Fliegener [1], and Jörg Hohe [*1]
[1]Fraunhofer Institute for Mechanics of Materials IWM, Freiburg, Germany

Summary The present contribution is concerned with the definition of anisotropic creep material models for different types of fiber reinforced plastics, considering both, continuous and discontinuous (chopped) fibers. For these materials, anisotropic three-term Kelvin-Voigt models are developed. The parameters are determined in tensile creep experiments at different temperatures and load levels. The formulation is validated in a structural experiment concerning a fastener support structure for a sandwich plate consisting of face sheets made from unidirectionally fiber reinforced thermoplastic tape laminates with a foam core. The load point support structure is made from a discontinuously long fiber reinforced thermoplastic, also forming an additional ply to the face sheets. The numerical prediction is found in a rather good agreement with experimental data obtained in breadboard tests.

INTRODUCTION

In lightweight construction, fiber reinforced materials with thermoplastic matrix become increasingly popular, especially in technological fields characterized by industrial scale mass production such as the automotive sector. Both, continuous and discontinuous (chopped) fiber reinforcements are used. Their advantages are their high load carrying capacity and especially the short manufacturing cycle times. On the other hand, neat thermoplastic materials - due to the missing crosslinking of the molecules - are subject to distinct creep deformation under long term loads. For fiber reinforced materials less extreme but still pronounced creep effects are encountered. Due to the anisotropy of the fiber reinforcement, anisotropic creep models are requires for the assessment of structures consisting of such materials.

MATERIAL MODEL AND NUMERICAL IMPLEMENTATION

Starting point of the development of the anisotropic creep models presented in the present contribution is the isotropic three-parameter Kelvin-Voigt formulation. Thus, the stress increments are defined by

$$\mathrm{d}\sigma_{ij} = 2\bar{G}(t)\left(\mathrm{d}\varepsilon'_{ij} - \sum_{q=1}^{3}\left(1-e^{-\frac{dt}{\tau^{(q)}}}\right)\varepsilon_{ij}^{is(q)}(t-dt)\right) + 3\bar{\kappa}(t)\left(\mathrm{d}\varepsilon^{v} - \sum_{q=1}^{3}\left(1-e^{-\frac{dt}{\tau^{(q)}}}\right)\varepsilon_{ij}^{iv(q)}(t-dt)\right)\delta_{ij}$$

with the time-dependent shear and bulk stiffness functions:

$$\bar{G}(t) = \left(\frac{1}{G^{(0)}} + \sum_{q=1}^{3}\frac{1}{G^{(q)}}\left(1-\frac{\tau^{(q)}}{dt}\left(1-e^{-\frac{dt}{\tau^{(q)}}}\right)\right)\right)^{-1}, \qquad G^{(q)} = \frac{E^{(q)}}{2(1+\upsilon)}, \qquad q = 0,1,2,3$$

$$\bar{\kappa}(t) = \left(\frac{1}{\kappa^{(0)}} + \sum_{q=1}^{3}\frac{1}{\kappa^{(q)}}\left(1-\frac{\tau^{(q)}}{dt}\left(1-e^{-\frac{dt}{\tau^{(q)}}}\right)\right)\right)^{-1}, \qquad \kappa^{(q)} = \frac{E^{(q)}}{3(1-2\upsilon)}, \qquad q = 0,1,2,3$$

The model is generalized to nonlinear viscoelasticity in the Schapery [3] sense by substituting the elastic moduli $E^{(q)}$ with stress dependent functions. In order to account for the anisotropy of fiber reinforced materials, two routes are employed. For moderately anisotropic materials as discontinuously long fiber reinforced thermoplastics (LFT) with a single, flow dependent preference orientation, anisotropic weight parameters for the individual stress components are introduced. For highly anisotropic unidirectionally (UD) fiber reinforced materials, the isotropic viscoelastic model is superimposed with the anisotropic Hooke's law. In this context, the isotropic viscoelastic part represents the response of the polymeric matrix whereas the anisotropic linear elastic part represents the response of the fibers. The anisotropic viscoelastic models are implemented as material subroutines into a finite element program.

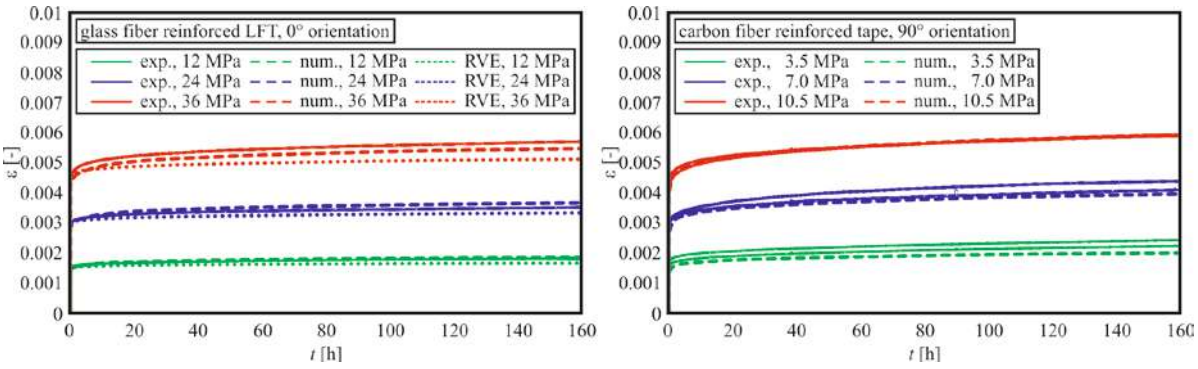

Figure 1: Coupon experiments for parameter identification and validation.

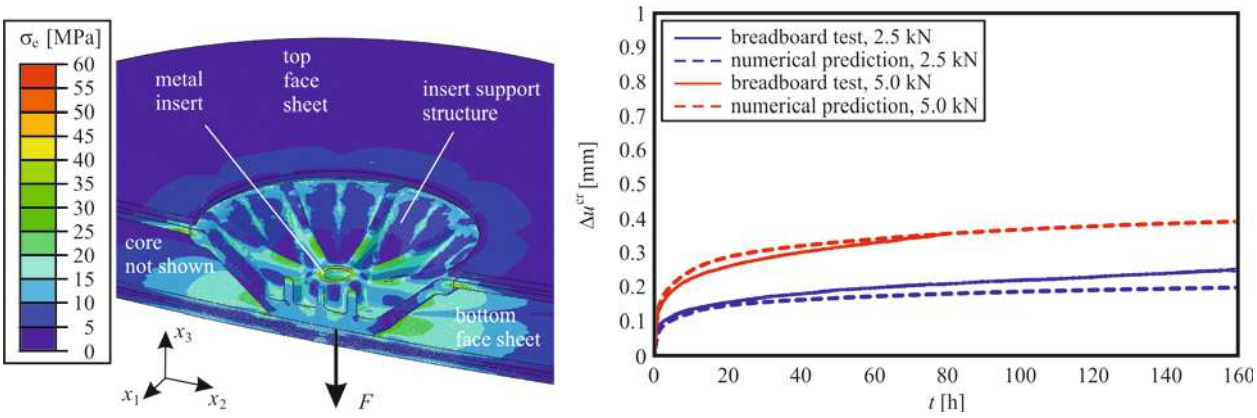

Figure 2: Breadboard test and simulation.

PARAMETER IDENTIFICATION

For determination of the material parameters and for a first validation of the proposed anisotropic creep models, an experimental study on coupon level is performed, considering continuously (UD) and discontinuously fiber reinforced thermoplastics (LFT) as well as neat matrix material. In all cases, PA6 is employed as matrix material Standard specimens are machined from plane plates. Creep experiments are performed at different constant load levels applied for 160 h. For the LFT materials, both carbon and glass fiber reinforced materials are tested within (0°) and perpendicular (90°) to the flow direction. The unidirectionally carbon fiber reinforced material is tested within and perpendicular as well as under 45° to the fiber direction.

As an example for the variety of experiments and simulation, the creep curves for glass fiber reinforced LFT and carbon fiber reinforced UD material, both tested at ambient temperature, are presented in Figure 1. For the LFT material, creep curves obtained in a microstructural analysis considering a representative volume element (RVE) for the LFT microstructure using the creep model and parameters for the neat matrix material are presented in addition to the experimental curves and the numerical prediction based on the model proposed in the previous section. In all cases, the experimental results and the numerical prediction as well as the prediction based on the microstructural (RVE) analysis are found in a good agreement. Similar results are obtained for the other test directions and temperatures.

BREADBOARD EXPERIMENTS AND VALIDATION

For a further validation, the creep modes together with the parameters determined in the previous section are applied to the numerical simulation of breadboard experiments on the long-term response of sandwich fastener support structures designed and tested in a previous contribution [2]. The breadboards consist of two circular laminated face sheets of unidirectionally carbon fiber reinforced plies with an additional co-moulded LFT ply, separated by a 20 mm thick PU foam core. In the centre of the sandwich plate, a fastener with a ribbed LFT support structure according to Figure 2 is positioned. The breadboards are loaded by a constant normal force of 2.5 kN and 5.0 kN applied to the metal insert for 160 h to 80 h. The creep experimental creep curves are presented in Figure 2 together with the numerical predictions. For both load levels, a rather good agreement is obtained.

CONCLUSIONS

Within the present study, an anisotropic creep model for different kinds of fiber reinforced polymers has been formulated and implemented. In a validation against an experimental data base of coupon experiments as well as more complex breadboard structures involving different types of FRP materials, the model provides accurate predictions.

GAUSSIAN PROCESS HOMOGENISATION AND DESIGN OF TECHNICAL TEXTILES

Sumudu Herath Mudiyanselage[1] and Fehmi Cirak *[1]
[1]Department of Engineering, University of Cambridge, Trumpington Street, Cambridge CB2 1PZ, U.K.

Summary A method for computational homogenisation of thin membranes is proposed to assist in the mechanical analysis of technical textiles. Conventional computational homogenisation schemes have a limited scope in analysing the complex nonlinear behaviour of textiles where the interlooped or interlaced fibres undergo large deformations. Also, the higher computational cost of the existing homogenisation schemes inspires the inception of a data-driven multiscale computational homogenisation scheme. In this paper, the efficient integration of statistical learning in computational homogenisation is proved not only to result in the efficient mechanical analysis but also to open avenues in material design of knitted and woven technical textiles.

MICROSCALE ANALYSIS

Finite deformation rod analysis

An isogeometric finite deformation rod model is developed to simulate the large deformations of interlooped and interlaced yarns of knitted and woven textiles, respectively. Base vectors of the rod centrelines ($\boldsymbol{X}$ and $\boldsymbol{x}$) are given by[1],

$$\boldsymbol{A}_1 = \frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}\theta^1}\,, \quad \boldsymbol{a}_1 = \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}\theta^1} \qquad \text{and} \qquad \boldsymbol{a}_\omega = \boldsymbol{\Lambda}\boldsymbol{A}_\omega\,. \tag{1}$$

where θ^1 is a convected parameter and $\omega = 2, 3$. Base vectors $\boldsymbol{A}_\omega$ and $\boldsymbol{a}_\omega$ are chosen as unit vectors and are aligned with the principal directions of the rod cross-section. The rotation map $\boldsymbol{\Lambda}$ in Equation (1) is composed by two distinct rotations, $\boldsymbol{\Lambda}_1$ and $\boldsymbol{\Lambda}_2$, given by,

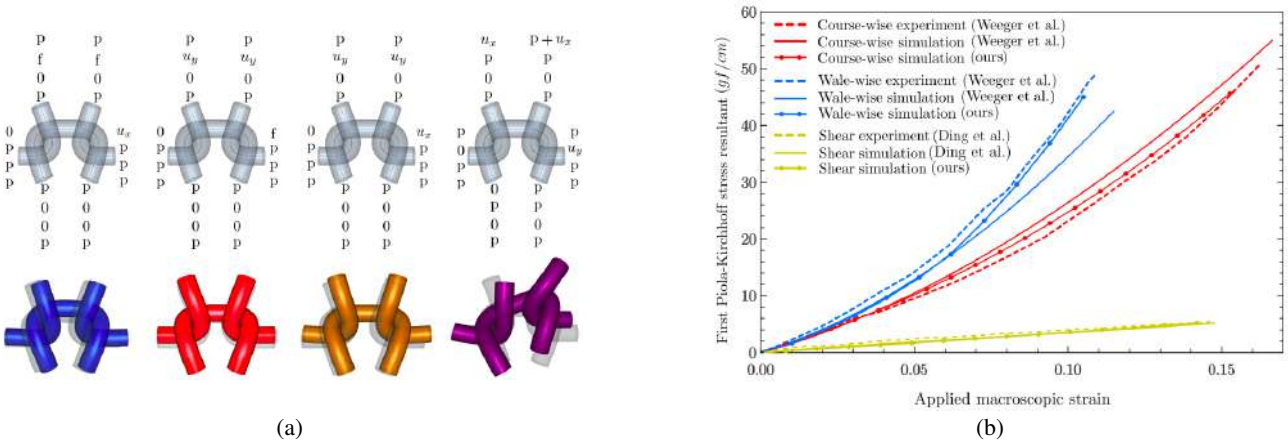
$$\boldsymbol{a}_\omega = \boldsymbol{\Lambda}_2(\boldsymbol{a}_1)\boldsymbol{\Lambda}_1(\vartheta)\boldsymbol{A}_\omega\,. \tag{2}$$

We use Rodrigues' rotation formula [2] for the rotation $\boldsymbol{\Lambda}_1$ where rotation axis is given by the undeformed normalised tangent vector $\boldsymbol{A}_1/||\boldsymbol{A}_1||$ and torsional rotation ϑ. Also, we use the smallest rotation formula [3] for the rotation $\boldsymbol{\Lambda}_2$.

$$\boldsymbol{\Lambda}_1(\vartheta) = \mathbf{I} + \sin\vartheta\mathbf{K} + (1-\cos\vartheta)\mathbf{K}\mathbf{K}\,, \quad \boldsymbol{\Lambda}_2(\boldsymbol{a}_1) = \mathbf{I} - \frac{(\boldsymbol{A}_{1u}+\boldsymbol{a}_{1u})\otimes\boldsymbol{a}_{1u}}{1+\boldsymbol{a}_{1u}\cdot\boldsymbol{A}_{1u}} \qquad \text{where} \qquad \boldsymbol{a}_{1u} = \frac{\boldsymbol{a}_1}{||\boldsymbol{a}_1||}. \tag{3}$$

Rod internal forces are formulated based on a St. Venant-Kirchhoff hyperelastic rod model and discretised using cubic B-spline basis functions. Also, the linearised algebraic system is solved iteratively using a Newton-Raphson scheme [2, 3].

Homogenised response validation



(a) (b)

Figure 1: Boundary value problem definitions for (a) weft-knitted textiles using periodic boundary conditions. At every boundary node, four characters denote the constraint enforcement to each degree of freedom at the respective boundary node. u_i refers to the applied displacements in the i direction. Moreover, $p, f, 0$ refer to *p*eriodic, *f*ree and *zero*-displacement constraints respectively. (b) Microscale homogenised response validation.

We formulate boundary value problems on characteristic weft-knitted and plain-woven textile RVEs. Homogenised responses of RVEs are validated against similar results from the literature to verify our microscale simulations [4, 5]. Figure 1 illustrates the boundary value definitions and result validation for weft-knitted textile RVEs. Though not presented, plain-woven textile RVEs are analysed and validated following a similar manner.

[1]Quantities in the reference and deformed configurations are denoted using uppercase and lowercase letters, respectively.

DATA-DRIVEN COMPUTATIONAL HOMOGENISATION

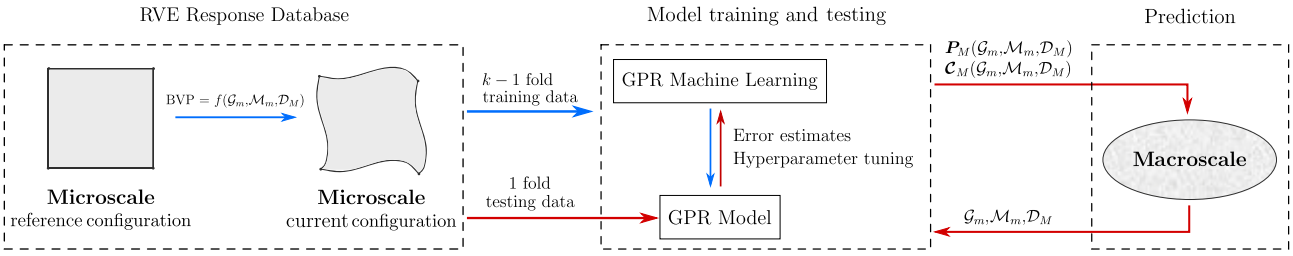

Figure 2: Data-driven computational homogenisation and textile material designing framework using GPR.

Homogenised responses of RVEs are stored in a response database with inputs: Green-Lagrange strains ($\mathcal{D}_M$), material ($\mathcal{M}_m$) and geometric ($\mathcal{G}_m$) parameters. Also, strain energy densities (ψ) are taken as outputs and stored in the same response database. Hence, the i^{th} data point in the response database is succinctly written as $(\mathbf{Z}_i, y_i)$. We also distinguish the test data points using subscript $(\bullet)_*$. The proposed data-driven homogenisation framework is presented in Figure 2.

Gaussian process regression (GPR)

The joint distribution of training and test outputs are written as a zero mean multivariate Gaussian distribution [1],

$$\begin{bmatrix} \boldsymbol{y} \\ \boldsymbol{y}_* \end{bmatrix} \sim \mathcal{N}\left(\mathbf{0}, \begin{bmatrix} \mathbf{K}(\mathbf{Z},\mathbf{Z}) & \mathbf{K}(\mathbf{Z},\mathbf{Z}_*) \\ \mathbf{K}(\mathbf{Z}_*,\mathbf{Z}) & \mathbf{K}(\mathbf{Z}_*,\mathbf{Z}_*) \end{bmatrix}\right) . \tag{4}$$

Predictions based on the conditioning of the joint Gaussian distribution on the observations and test inputs takes the form,

$$\boldsymbol{y}_*|\mathbf{Z}_*,\mathbf{Z},\boldsymbol{y} \sim \mathcal{N}(\mathbf{K}(\mathbf{Z}_*,\mathbf{Z})\mathbf{K}(\mathbf{Z},\mathbf{Z})^{-1}\boldsymbol{y}, \mathbf{K}(\mathbf{Z}_*,\mathbf{Z}_*) - \mathbf{K}(\mathbf{Z}_*,\mathbf{Z})\mathbf{K}(\mathbf{Z},\mathbf{Z})^{-1}\mathbf{K}(\mathbf{Z},\mathbf{Z}_*)) . \tag{5}$$

Gaussian process homogenisation

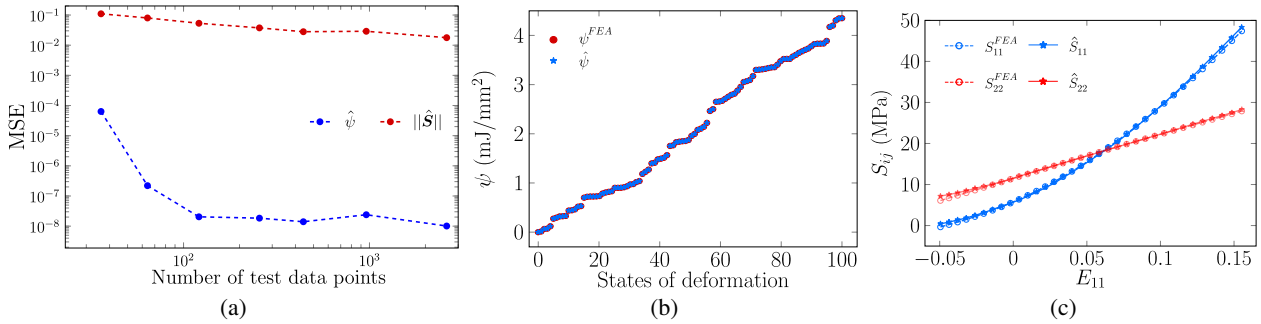

Figure 3: (a) GPR prediction mean squared errors. GPR predictions of (b) strain energy density (sorted by ascending potential) and (c) stress components for a biaxial strain state of $E_{11} = [0.\%, 15\%]$, $E_{22} = 8\%$ and $E_{12} = 0\%$.

CONCLUSIONS

Large deformations prevalent in technical textiles are accurately captured by the finite deformable rod model and validated against experimental and numerical results. Incorporating GPR in computational homogenisation circumvents the need for element-wise microscale simulations, thus yields significant computational savings. Also, the inclusion of design parameters were shown to open avenues for textile material designs.

DAMAGE PROGRESSION IN CURVED CFRP LAMINATES UNDER STATIC AND FATIGUE LOADING

Ahmet Çevik[1], Burcu Taşdemir[2], and Demirkan Çöker*[1,3]

[2]Dept. of Engineering Science, University of Oxford, Oxford, United Kingdom
[3]METU Center for Wind Energy, Middle East Technical University, Ankara, Turkey

Summary In this paper, experimentally investigation of the progression of fatigue and static damage in L-shaped CFRP laminates is presented. Curved beam specimens having lay-up configurations $[0_3/90_3/0_3/90_3/0_3]_s$ were manufactured. To observe the fatigue and static damage progression, in-situ strain field of the specimens was obtained with Digital Image Correlation (DIC) method. In static experiments, deformed states of the specimens were taken at 3 Hz frequency while in fatigue experiments, those were taken at peak load of each cycle. Our results show that main failure mode of the specimens is delamination driven by the interlaminar stresses in the curved region [1-3]. It is shown that the static test specimens failed from the first 0/90 interface while fatigue test specimens failed from the second 0/90 interface.

INTRODUCTION

Advances in composite manufacturing technologies enable to produce complex parts such as curved beam section. These curved composite parts are used in aerospace industry, especially in spar flanges, shear webs and ribs. During their life time, these parts are experienced both static and fatigue loading. Due to applied loadings, interlaminar tensile and shear stresses develop in the curved region of that parts, and delamination type failure which is driven by these interlaminar stresses occurs [1-3]. This study is carried out to understand the damage mechanism in these L-shaped composite part under static and fatigue loading. Static and fatigue experiments were carried out on specimens having stacking sequence $[0_3/90_3/0_3/90_3/0_3]_s$.

EXPERIMENTAL METHOD

Static and fatigue experiments were conducted with the setup shown in Figure 1. Curved specimens were mounted to MTS servo-hydraulic test machine with test fixture. In static experiments, test speed was chosen as 1 mm/min. By using results of the static experiments, the load condition applied to specimens in fatigue experiment was determined as 2 Hz cycling load under displacement control with a displacement range 2 - 4 mm. ARAMIS DIC test setup is used to obtain in-situ strain field. In addition to experiment which were conducted with DIC method, some static tests were recorded at 100000 fps with Photron high speed camera to investigate the initiation and propagation of the delamination in detail.

Figure 1: Test setup used in the experiments.

*Corresponding author. E-mail: coker@metu.edu.tr.

RESULTS

High speed camera pictures show the sequence of dynamic damage progression under static loading. The damage progression under fatigue loading is shown with DIC pictures taken at specified number of cycles. These pictures show a difference between fatigue & static loading in terms of sequence and location of damage. Load displacement curve which was obtained from static test specimen is shown in Figure 2a. Mises strain field obtained at the half failure load and just before the failure load is shown in Figure 2b and Figure 2c, respectively.

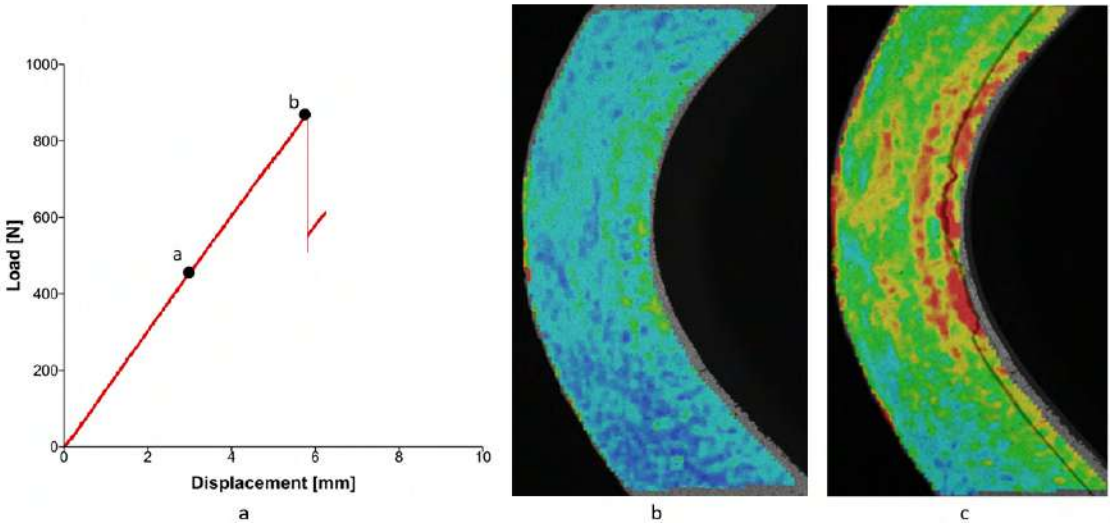

Figure 2: (a) Load - displacement curve of static test specimen, mises strain field (b) at point a (c) at point b on load displacement curve.

Under static loading, matrix cracks initiate in the first 90° grouped plies, then these cracks propagate to the 0/90 interface by making 45 - 50° kink as shown in Figure 3a. Under fatigue loading, microcracks in second 90° grouped plies grow, and connection of these microcracks leads to failure of the specimens shown in Figure 3b.

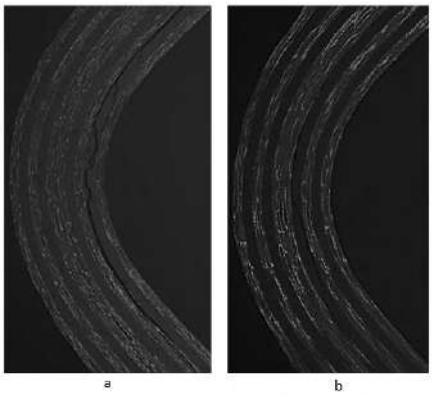

Figure 3: Failure location of curved beam specimens under (a) static loading and (b) fatigue loading.

CONCLUSIONS

In this study, fatigue and static experiments were conducted on curved beam specimens. These experiments show that failure mechanism and location of curved beam specimen under fatigue loading are different than that under static loading. In fatigue failure, growing microcracks under cyclic loading leads to failure so fatigue life of the curved beam specimens highly depends on manufacturing quality.

NONLOCAL MICROMECHANICS OF COMPOSITES OF BOTH RANDOM AND PERIODIC STRUCTURES

Valeriy A. Buryachenko*
Micromechanics & Composites LLC, Cincinnati, OH 45202, USA

Summary The basic concepts and directions of locally elastic micromechanics of composites materials are generalized to the nonlocal micromechanics (so-called strongly nonlocal ones by Eringen and peridynamics by Silling). It was established formal similarity of the operator forms of the new general integral equations (forming the second background of micromechanics) for both locally elastic CMs and nonlocal ones that opens the opportunities for straightforward generalization of their solutions for locally elastic CMs to their nonlocal counterparts. Background principles for CMs with both random and periodic structures are proposed. New notions of both the micropolarization tensor and the average local polarization tensor as well as the volumetric periodic boundary conditions are introduced. Variational principle and generalized Hill's bounds of peristatic composites are proposed.

In locally elastic theory, the numerous methods of micromechanicsof random structure composite materials (CMs), inspired by Eshelby, can be classified, according to Willis, into four broad categories (see for Refs. [1]): perturbation methods, self-consistent methods of truncation of a hierarchy, variational methods, and the model methods among which there are no rigorous boundaries. In parallel with micromechanics of random structures, conceptually different methods of micromechanics of periodic structure composites can be subdivided on two-scale expansion methods (apparently coined by Babuska) and the methods of computational homogenization inspired by Suquet. We will demonstrate that the mentioned basic directions of locally elastic micromechanics are generalized to the nonlocal micromechanics (so-called strongly nonlocal ones by Eringen and peridynamics by Silling [2]).

In contrast to these classical local and nonlocal theories, the peridynamic equation of motion introduced by Silling [2] is free of any spatial derivatives of displacements. Wide expansion of the methods of locally elastic micromechanics into nonlocal phenomena [3, 4] was supported by a critical generalization of micromechanics. Namely, the author (see for Refs. [5, 6]) proposed the general integral equation GIE of microinhomogeneous media forming the second background of micromechanics (the first one is based on the effective field hypothesis, EFH, proposed by Faraday, Poisson, Mossotti, Clausius, and Maxwell (1830-1880), see for Refs. [1]). The critical features of the new GIE [5, 6] are the absent of a direct dependence of GIE on both the Green function and the constitutive law (either local or nonlocal) without restrictions of the conventional micromechanics (such as, e.g., acceptance of the EFH and ellipsoidal symmetry of microtopology) that offers opportunities for a fundamental jump in multiscale and multiphysics researches with drastically improved accuracy of local field estimations (even to the point of correction of a sign, see [6]). It was established formal similarity of the operator forms of GIEs for both locally elastic CMs and nonlocal ones (in the senses of either Eringen [7, 8] or Silling [9-12]) that opens the opportunities to straightforward generalization of their solutions for locally elastic CMs [1] to their nonlocal counterparts.

For statistically homogeneous thermoperistatic media subjected to homogeneous volumetric macro boundary loading, one proposed the background principles [10, 12] in the framework of the bond-based approach considered. The general results establishing the links between the effective properties (effective elastic moduli, effective thermal expansion) and the corresponding mechanical and transformation influence functions (do not miss with the influence functions in peridynamics) are obtained by the use of both the decomposition of local fields into the load and residual fields as well as extraction from the material properties a constituent of the matrix properties. The energetic definition of effective elastic moduli is proposed. A detected similarity of results for both the locally elastic (and so-called strongly nonlocal) and peristaltic composites is explained by the fundamental reasons because the methods used for obtaining of the mentioned results widely exploit the Hill's condition proved and the self-adjointness of the peristatic operator.

Effective moduli are expressed through the introduced new notions of both the micropolarization tensor and the average local polarization tensor (although the local polarization tensor is not defined) [10, 12]. The average is accomplished over the surface of the extended inclusion phase (that was performed by a straightforward generalization of interphase integral technique proposed by the author in locally elastic micromechanics [13-15]) rather than over an entire space. Any spatial derivatives of local displacement fields are not required. The basic hypotheses of locally elastic micromechanics (in the version of the second background of micromechanics [5, 6]) are generalized to their peristatic counterparts [16-18] as the generalized dilute approximation, Mori-Tanaka, and the effective field methods. In so doing, the classical EFH is relaxed, and the hypothesis of the ellipsoidal symmetry of the random structure of CMs is not used. Effective nonlocal properties of statistically homogeneous peristatic CMs subjected to arbitrary self-equilibrated strongly inhomogeneous body-force density are estimated as a straightforward generalization of locally elastic micromechanics (see Chapter 12 in [1]).

The variational methods proposed are based on introduction of the admissible displacement and force fields are defined in [19]. The theorem of work and energy, Betti's reciprocal theorem, and the theorem of virtual work are proved. Principles of minimum of both potential energy and complimentary energy are generalized. The strain energy bounds are estimated for both the displacement and force homogeneous volumetric boundary conditions. Generalized Hill's bounds

*Corresponding author. E-mail: buryach@yahoo.com.

on the effective elastic moduli of peridynamic random structure composites are obtained. In contrast to the classical Hill's bounds, in the new bounds, comparable scales of the inclusion size and horizon are taken into account that lead to dependance of the bounds on both the size and shape of the inclusions. Generalized Hashin-Shtrikman variational principle and bounds can be obtained as a straightforward combination of variational principles proposed and the new version of Hashin-Shtrikman bounds [20] obtained by the author in locally elastic micromechanics of CM with noncanonical shape of inclusions in the framework of the EFH.

The background principles of computational homogenization (initiated by Suquet for locally elastic micromechanics) of micromechanics of periodic structure CMs with the peristatic mechanical properties of constituents are proposed [21-23]. One introduces new volumetric periodic boundary conditions (PBC, [21, 23]) at the interaction boundary of a representative unite cell (UC) whose local limit implies the known locally elastic periodic boundary conditions. The classical representations of effective elastic moduli through the mechanical influence functions for elastic CM are generalized to the case of peristatics, and the energetic definition of effective elastic moduli is proposed. A generalization of the Hill's equality to peristatic composites is proved analogously to the theory for the peristatic random structure CM. Due to the volumetric displacement periodicity the special traction boundary condition is not required for establishment of the micro-to-macro displacement relationship although this classical antiperiodic traction condition at the geometrical boundary of the UC is needed for estimations of both the overall stresses and effective moduli. The discretization of the equilibrium equation acts as a macro-to-micro transition of the deformation-driven type, where the overall deformation is controlled. One shows numerically the convergence of the effective moduli estimations by the peristatic model to their locally elastic counterpart. Estimation of effective moduli of the medium with periodically distributed damage (i.e. with the broken bonds) is considered [22]. Asymptotic exactness of Kachanov formula is proved for uniformly damaged peridynamic medium. Proposal of the new volumetric Bloch conditions opens the opportunities for analyses of a wide class of wave propagation in periodic peridynamic composites (e.g. metamaterials and phononic crystals).

CONCLUSIONS

Background, opportunities, and prospective on nonlocal micromechanics are presented. The mentioned problems are considered for the bond-based approaches, which can be easy generalized to the linear state-based approaches in a straightforward manner. Linear solutions are used as the basic elements in analyses of wide classes of dynamic, nonlinear, and coupled problems in the framework of the second background micromechanics proposed by the author (see for Refs. [5, 6]).

FINITE-ELEMENT MODELLING OF ACTIVE COMPOSITE MATERIALS TAKING INTO ACCOUNT INTERNAL STRUCTURE AND INTERFACE EFFECTS IN ANSYS AND ACELAN–COMPOS PACKAGES

Andrey Nasedkin*
Institute of Mathematics, Mechanics and Computer Science, Southern Federal University, Rostov-on-Don, Russia

Summary This research deals with computer modelling in finite element software ANSYS and ACELAN-COMPOS of multiscale two-phase piezoelectric or magnetoelectric (piezomagnetoelectric) bulk composites of irregular structures. The proposed technique is based on the models of micro- and nanoscale materials with interface or surface effects, the effective moduli method, the modelling of representative volumes, and the use of finite element technologies for solving the problems in the representative volumes.

In this short article, as active materials we will understand the materials in which sufficiently noticeable deformations can be caused by external nonmechanical influences. Such materials are piezoelectric, magnetoelectric, pyroelectric and other materials with coupling between mechanical fields and fields of a different nature: electric, magnetic or thermal. These materials are widely used in modern engineering as active elements of transducers, sensors, actuators and other devices. Recently, new materials with improved characteristics are being intensively developed to improve the efficiency of these devices. Especially important are the problems of developing active composite materials consisting of materials of different phases. Methods of mathematical and computer modelling help us to predict the effective properties of composite materials depending on the characteristics of the initial phases, their percentage ratio and the peculiarities of the internal structure.

The problems of determining effective properties, also called homogenization problems, can be solved on the basis of various approaches known in the mechanics of composite materials. For active materials whose behavior is described by a sufficiently complicated system of differential equations, it is convenient to use the method of effective moduli. For example, for piezoelectric composites according to this method, it is necessary to solve a set of boundary-value problems of piezoelectricity (electroelasticity) with special boundary conditions providing for homogeneous materials the exact solutions with constant field gradients (strains, stresses, electric field and electrical induction). In a non-uniform representative volume, these gradients, naturally, will not be constant, but their averaged integral characteristics will permit to determine the effective moduli of the composite material [1, 2].

For nanostructured composites, in which inclusions or pores have nanodimensions, the nanoscale effect can be taken into account in the framework of the Gurtin–Murdoch theory of surface stresses and its generalizations to the problems with coupling fields. In the theory of surface stresses for the interfaces of materials with different phases, the special equations are written that relate stress jumps in volumes with fields for surface stresses. Finally, in recent years, the technologies have been proposed for creating the new materials composed of piezoelectric matrix and of inclusions from other materials or pores, on which interface boundaries the particles of third type materials are deposited.

To solve the homogenization problems for all active composites described in this article, the specialized software was developed, which is based on the finite element solution of boundary problems in representative volumes and takes into account the main features of the internal structure of composites.

Namely, the program systems written in the APDL ANSYS language were created, which allow in the automated mode to solve in the ANSYS package the homogenization problems for active composites of various types and determining their effective moduli. To generate the structures of representative volumes in addition to the simple random ANSYS algorithm, external programs that implement various algorithms were created [1, 2, 3]: 3–x algorithm, supporting the connectivity of finite elements of the first phase, up to 90 % of inclusions of the second phase; 3–0 algorithm with a regular structure of connectivity of the first phase in three axial directions and with a closed structure of the elements of the second phase; cluster algorithms (Witten-Sander method, cluster of the second phase method; method of ”growth out of the plane”; method of initial concentration, etc.)

For the case of porous piezoceramic materials with metalized pore surfaces and nonuniform polarization we used the following approaches. The metallization of the pores we modelled by the boundary conditions of free electrodes and elastic shells [4]. Next, we simulated nonuniform by intensity and direction polarization field around the pores. For this we previously solved the electrostatic problem for the dielectric composite by finite element method. Further, according to founded electric field, the polarization field have been finding. After that every volumetric finite element of a representative volume was associated with a new coordinate system so that the third axis was chosen codirectional to the element polarization vector. The material properties for each finite element were also recalculated in accordance with the found intensities of the polarization field. As a result, we had a representative volume with inhomogeneous properties of piezoceramic matrix [5].

However, in the ANSYS package there were no basic means for solving the problems of magnetoelectricity and there were no piezoelectric and magnetoelectric shell finite elements. In this regard, at the Department of Mathematical

*E-mail: nasedkin@math.sfedu.ru.

Modelling of Southern Federal University, a specialized finite element package ACELAN–COMPOS was developed. The ACELAN–COMPOS package is focused on solving the homogenization problems with coupled mechanical and electromagnetic fields. In this package, implemented new algorithms 3–3 connectivity [6, 9], supporting the connectivity of the two phases; algorithm 3–0 connectivity, creating the granular structures [7, 9]; and algorithm 1–3 connectivity, creating the structures with rod elements in a matrix [8, 9].

For all these models of representative volumes, the algorithms have been developed for the automated search for finite elements located at the interphase boundaries and placing shell elements on them that simulate the presence of surface effects for nanoscale inclusions or pores. For transversely isotropic materials, an algorithm was additionally implemented for the plate surface elements, parallel to the coordinate axes, with the material properties that inherit the anisotropy structure of the neighboring volume elements.

Other means of ACELAN-COMPOS and a more detailed presentation of models, algorithms and results are presented in [4, 5, 6, 7, 8, 9, 10], et al.

Author acknowledges the support of the Government of the Russian Federation (contract No. 075-15-2019-1928).

COMPRESSIVE STRENGTH OF SOIL ECO-BLOCKS REINFORCED WITH PET FLAKES AND TREATED *LUFFA CYLINDRICA* PARTICLES

Maria-Belen Martinez-Pavetti*[1,2] and Magna Monteiro[1]
[1]Polytechnic Faculty, National University of Asuncion, San Lorenzo, Paraguay
[2]Research Center in Mathematics, Asuncion, Paraguay

Summary Influence of the addition of *Luffa cylindrica* (LC) particles in the compressive strength (CS) of eco-friendly soil blocks reinforced with PET flakes was studied. Samples of the composite blocks were manufactured; their matrix was a mixture of red soil, cement and water, in constant volume fractions. Volume fractions of total aggregate (PET+LC) were kept constant, but different PET:LC ratios were tried. The addition of LC to the composite was done in three conditions: natural, surface-treated with a boiling solution of sodium hydroxide, and with boiling water. Aiming to evaluate CS of the blocks, Paraguayan standards were applied, NP 131 for the compressive test conditions, and NP 17 027 077 to define the minimum CS of traditional ceramic bricks which is 5 MPa. No one of the samples reinforced with LC accomplished this requirement. Causes for low performance are still under discussion.

INTRODUCTION

The development of viable options to introduce alternative materials, as recycled waste and natural fibers, in the construction industry is one of the targets of eco-building. Since a very basic form of construction material is a brick, this work focuses on blocks, whose main structural function is to bear compressive stress (CS). As aggregate material, recycled PET is attractive for being inexpensive, lightweight, durable, and for having good mechanical properties. Regarding natural materials, one exhibiting good potential to be used as an aggregate in blocks is the sponge gourd *luffa cylindrica* (LC) [1].

Beneficial behavior when introducing reinforcements into a matrix can be achieved only if the interface between matrix and reinforcement has a good contact area [2]. This induces to considerate treatments to increase the surface area of the reinforcement. In this work, there were manufactured PET-LC reinforced soil bricks. In order to study the CS of the PET-LC soil b composite, apart from trying various dosifications, we added LC in three different states. It was intended to determine the influence of surface-treated LC in the CS of PET-reinforced soil blocks. These LC states were chosen for the low cost of acquisition of treating agents and ease of treatment application.

MATERIALS AND METHODS

The eco-blocks studied were composites, with a matrix of red soil (RS), Portland cement (PC) and water (W), and aggregates of PET flakes and LC particles. Raw materials underwent through different processes, in order to be prepared for the composite mixture. Red soil was processed with a grinder and then sieved. Portland cement was sieved. PET flakes were obtained from PET bottles, which were cleaned, got their labels and caps removed, were grinded into flakes and sieved. Flakes of 2,4 mm^2 approximately were used. LC particles were obtained by cutting the LC sponge with scissors into cubes of 1 cm^3, approximately. Skin and seeds were removed. Figure 1 shows the aggregate materials after conditioning.

(a) (b)

Figure 1. Reinforcement of the composite studied: (a) PET flakes, (b) LC particles.

Surface treatments on *Luffa cylindrica*

Luffa cylindrica particles in three states were used as aggregates, in order to produce different matrix-LC interfaces. One of these states consists of untreated LC particles, referred to as natural LC (LN). The other two states correspond to the treated LC, applying two surface modifying media, as explained as follows.

On one side, LC was treated with a basic solution of sodium hydroxide, in concentration 0,1 mol/L, dissolved in deionized water. Conversely, LC was treated with tap water. LC treated with sodium hydroxide is referred to as LS, and LC treated with tap water as LW. In both cases, LC was introduced to the vessel containing the treatment solution, and heat was supplied by a burner until boiling point, where LC was kept for 20 min. The mixture was constantly stirred throughout this process. LS was then washed with deionized water and LW with tap water. Right after, both of them were dried in a stove at 50°C until they reached a constant weight. The treatment procedures were adapted from [1;3].

Composite dosification

Seven kinds of composite soil eco-blocks, were manufactured, keeping the matrix materials ratio constant. The volume fractions of the matrix components RS:PC:W were 0,7:0,1:0,1, respectively. Volume fractions of aggregates, on the other hand, were considered in three different ratios, but

Table I. Identification code of different samples and their volume composition.

Sample Code(*)	RS (%)	PC (%)	W (%)	PET (%)	LC (%)

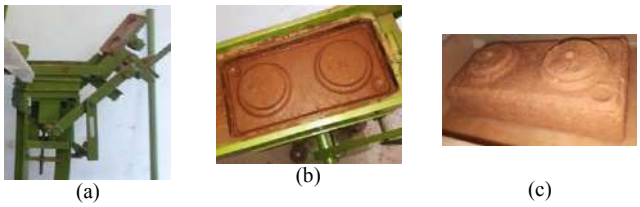
total aggregate volume fraction (PET+LC) was kept constant in 0,1. The identification code of the different samples and their respective volume composition relation and are summarized in Table I.

Composite manufacturing

Manufacturing of bricks was done in volume fractions according to Table I. Samples were produced in triplicate. After conditioning of raw materials, and treatment of LC, matrix materials and aggregates were mixed homogeneously. The mixture was molded into blocks by a manual press, as shown in Figure 2 (a) and (b). The resulting dimensions of the bricks are, on average, 24cm x 12cm x 5,5 cm. After unmolding, soft bricks underwent the curing process, by manual spray wetting twice a day, for seven days. After 28 days from manufacturing, the final product was ready, as shown in Figure 2 (c), and compressive strength tests were performed.



(a) (b) (c)

Figure 2. Moulding of blocks: (a) manual press, (b) molded soft block, (c) finished product.

Compressive strength test

The performance of samples manufactured with aggregates of PET and LC, in different volume fractions, was compared with that of samples manufactured with PET as only aggregate. Samples for the compressive tests were prepared according to Paraguayan standard NP 131 [4]. The minimum CS requirement for solid blocks in Paraguay is established by the standard NP 17 027 77 [5]; CS shall at least be 5 MPa.

(a) (b)

Figure 3. Compressive test: (a) specimens, (b) failure due to uniform compressive load.

The specimens for the compressive tests were prepared as described next. First, blocks were cut in halves, perpendicularly to their longest dimension, and the biggest faces were joined with a mortar layer, and mortar layers were also added at upper and lower faces, as shown in Figure 3 (a). Once mortar was hard, specimens were submitted to uniform compression through a universal testing machine, until failure, as shown in Figure 3 (b).

RESULTS

The results of the compressive tests are presented in Figure 4.

For the sample 10P0LC containing only PET, a good performance was observed, with CS = 7,12 MPa > 5 MPa, meeting the Paraguayan standard, which was reported on previous work.

Conversely, for all the samples containing LC, it can be observed that, CS < 5 MPa. The best performance was obtained for the sample 3P7LN, with 3% v/v PET and 7% v/v of LC as natural, exhibiting a CS = 3,56 MPa. However, this value is not enough to meet the requirement of the applicable Paraguayan standard.

The unexpected low CS values reached could be due to an inappropriate specimen manufacture, an excessive degradation of the LC fibers during the surface treatments, or a non-beneficial interface between the soil matrix and the LC fibers.

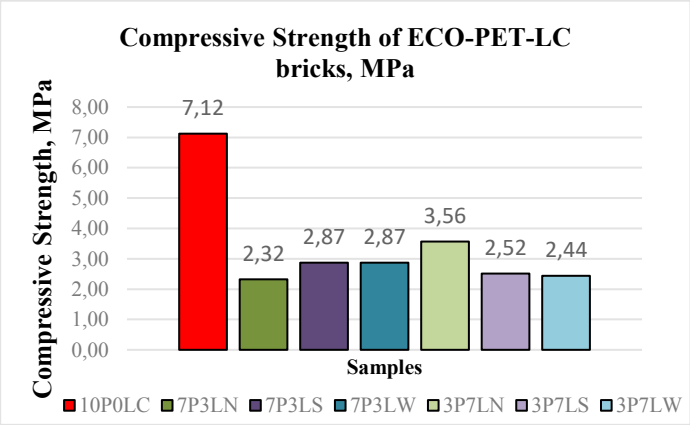


Figure 4. Results of compressive test.

CONCLUSIONS

Apparently, the inclusion of LC as aggregate in a PET reinforced soil composite reduced its CS for the conditions applied. Even worse, LC reinforced blocks do not meet the minimum requirement of 5 MPa of the Paraguayan standard. In order to determine if LC truly weakens the PET-soil composite studied, the same tests shall be performed again.

Summary The present study aims to develop a methodology to calibrate ultrasound devices for medical purposes. As a first step, a simple sandwich composite made of agar at different densities is modeled to estimate which thickness values of each layer produce a macroscopic response that guarantees a low acoustic impedance and an average attenuation coefficient. Each layer is considered homogeneous, isotropic, and with a complex elastic modulus. Analytical expressions for the corresponding effective properties such as the real and imaginary parts of the elastic modulus, and the mass density, which depends on the thickness, densities and elastic properties of each sheet, are derived. Next, the acoustic impedance and acoustic attenuation effective properties are obtained as a function of effective properties and, consequently, of the thickness of each sheet. Numerical experiments are performed using data reported in recent literature and it is shown how the proposed mathematical model could contribute to the design of a suitable prototype for the calibration of ultrasound devices. Model feedback is planned through experimental tests.

INTRODUCTION

The authors form a multidisciplinary research group interested in studies related to biomedical applications. One of the problems of its interest is to calibrate ultrasound equipments. For this purpose, it is necessary to design prototypes represented by composite materials in which the dimensions and geometric characteristics of their constituents are known. The components of these materials must be durable and have properties that allow waves to travel and return; additive manufacturing is being considered as a versatile and low-cost alternative to produce these prototypes. A first step in the mathematical modeling of these prototypes is to find which parameters should be optimized. For example, they must have a macroscopic behavior such that their acoustic impedance is low to avoid loss of energy at the transducer-prototype interface; as well as an attenuation coefficient of the average wave that allows the wave travels and not fade; and preferably a curvilinear shape to decrease dispersion effects and simulate geometric shapes similar to those of real organs. In this work, a methodology is described for modeling a simple sandwich composite made of Agar with different densities. The methodology is based on homogenization results reported in [1]. Each layer of the sandwich is assumed linear elastic, isotropic and homogeneous material. The problem is to estimate a variation range for the layers thickness to obtain a macroscopic response guarantying a low acoustic impedance and an intermediate wave attenuation. The procedure is presented by an example that suggests the best combination according to the parameters selected for the design.

METHODOLOGY AND RESULTS

We consider a simple sandwich composite wherein the top and the bottom layers has a shear elastic modulus $E^T = E^T_{Re} + iE^T_{Im}$, a mass density ρ^T, and a thickness l. The properties corresponding to the core layer are $E^C = E^C_{Re} + iE^C_{Im}$, ρ^C and $1-2l$, respectively, where $i^2 = -1$ and the sub-indexes Re and Im mean the real and imaginary parts of the elastic moduli. The elastic effective coefficients can be calculate by using the formulas (41) and (42) of [1], whereas the effective mass density is obtained by the mixtures rule, as follows

$$\overline{E}_{Re} = \left\langle \frac{E_{Re}(x)}{\tau(x)} \right\rangle \left(\left\langle \frac{E_{Re}(x)}{\tau(x)} \right\rangle^2 + \left\langle \frac{E_{Im}(x)}{\tau(x)} \right\rangle^2 \right)^{-1}, \tag{1}$$

$$\overline{E}_{Im} = \left\langle \frac{E_{Im}(x)}{\tau(x)} \right\rangle \left\langle \frac{E_{Re}(x)}{\tau(x)} \right\rangle^{-1} \overline{E}_{Re}, \tag{2}$$

$$\overline{\rho} = \langle \rho \rangle, \tag{3}$$

where $\langle P \rangle = 2lP^T + (1-2l)P^C$, with $l \in (0, 0.5)$, is the average on $[0,1]$ of a property P, $\tau(x) = E^2_{Re}(x) + E^2_{Im}(x)$, $E_{Re}(x) = E^T_{Re}\chi_T(x) + E^C_{Re}\chi_C(x)$ with χ_T and χ_C denote the characteristic function of the top layers and the core

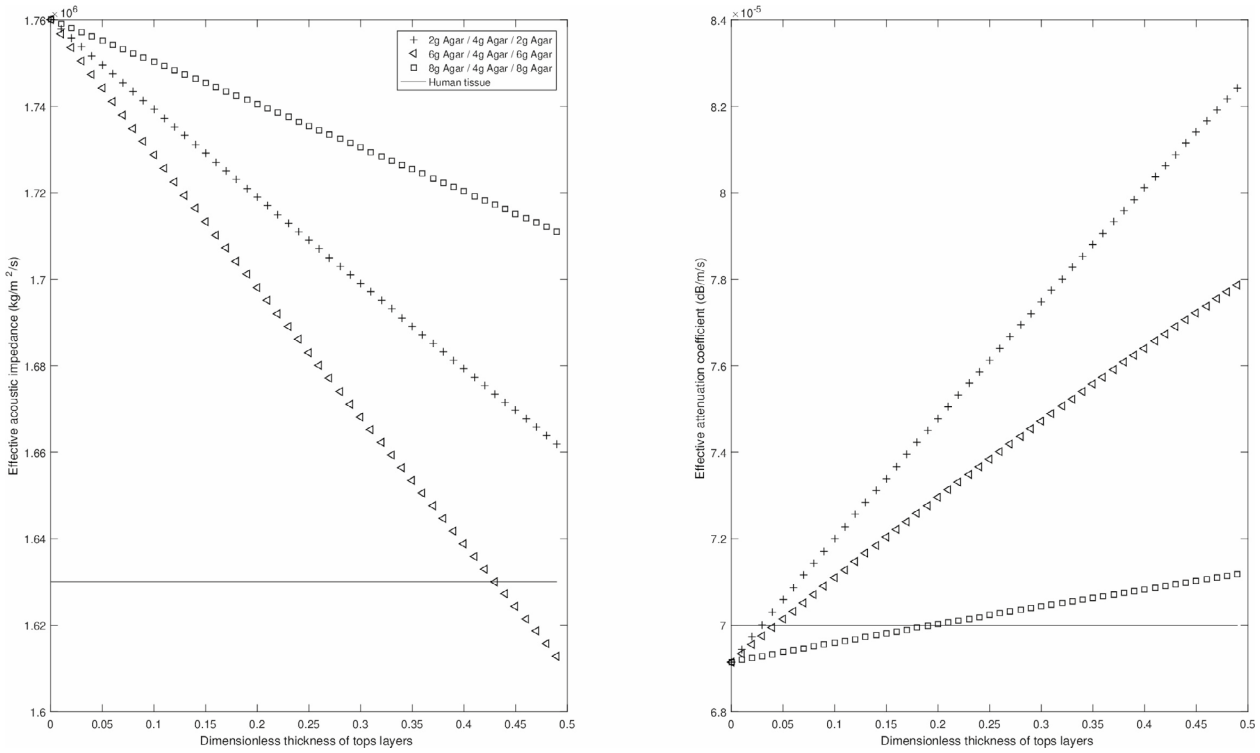

Figure 1: Effective acoustic impedance (left) and effective attenuation coefficient (right) as a function of dimensionless thickness of the top layers. Three simple sandwich composites made of Agar with different densities were considered.

layer, respectively. Using (1)-(3) it is possible to compute the effective acoustic impedance $\overline{Z}$ and the effective attenuation coefficient $\overline{\alpha}$ by means of the following formulas:

$$\overline{Z} = \sqrt{\overline{\rho}\overline{E}_{Re}}, \qquad \overline{\alpha} = 8.686\pi \frac{\overline{\rho}\overline{E}_{Im}\overline{f}}{\overline{Z}\overline{E}_{Re}}, \tag{4}$$

where $\overline{f} = \langle f \rangle$ is the average of the frequency. Formula for $\overline{\alpha}$ is a valid approximation for small loss factor $\frac{\overline{E}_{Im}}{\overline{E}_{Re}}$ [2]. The data used in the calculations, shown in Figure 1, were taken from Table 1 of [3]. As can be seen from the Figure, the sandwich "$6gAgar/4gAgar/6gAgar$" has the lowest acoustic impedance and an attenuation intermediate for all the variation range of the dimensionless thickness of top layers. Therefore, among the composites studied this would be the recommended combination for a dimensionless thickness l about 0.45.

CONCLUSIONS

A simple example is analyzed in order to show a modeling methodology for composite materials that could be used as prototypes for calibration of ultrasound devices. Sandwich models are useful for calibrating ultrasound equipment for imaging diagnosis. The current plan is to have model feedback by means of experiments to improve it. Mathematical and computational modeling of laminated media in curvilinear coordinates and composite materials with more complex geometries is envisaged. The manufacture of prototypes for the calibration of ultrasound equipment is of great social relevance and as far as we know the methodology proposed here is new.

THEORETICAL PREDICTION FOR THE STRAIN HARDENING OF ARTIFICIAL NACRE

Yi Yan[1], Zi-Long Zhao, and Xi-Qiao Feng*[1]
[1]Department of Engineering Mechanics, Tsinghua University, Beijing, China

Strain-hardening contributes to the high strength and toughness of nacre. Understanding the inner mechanisms of strain-hardening is vital to design biomimetic nacre-like composites. In this study, we provide a unit-cell theoretical model to predict the stress–strain response of nacre. We give two thresholds to predict the occurrence of strain-hardening and platelet failure. The analytical expressions of the strength of nacre are given based on three failure modes. Two parametric studies with regard to the aspect ratio and interfacial stiffness are presented.

Introduction

Owing to the simple mortar–brick microstructure and the outstanding strength and toughness, nacre becomes an important biomimetic resource of artificial composites [1]. To guide such biomimetic designation, we need to understand the inner relationships between the macroscopic properties of nacre and the microscopic properties of the mortar–brick structure. Strain-hardening is an important phenomenon that contributes to the high strength and toughness of materials. However, the designation of nacre-like composites with strain-hardening, thus, still lacks a theoretical guidance. In this study, we provide a unit-cell theoretical model to predict the stress–strain response of nacre. We give two thresholds to predict the occurrence of strain-hardening and platelet failure. Two parametric studies with respect to the aspect ratio and interfacial stiffness are presented.

Theoretical Model

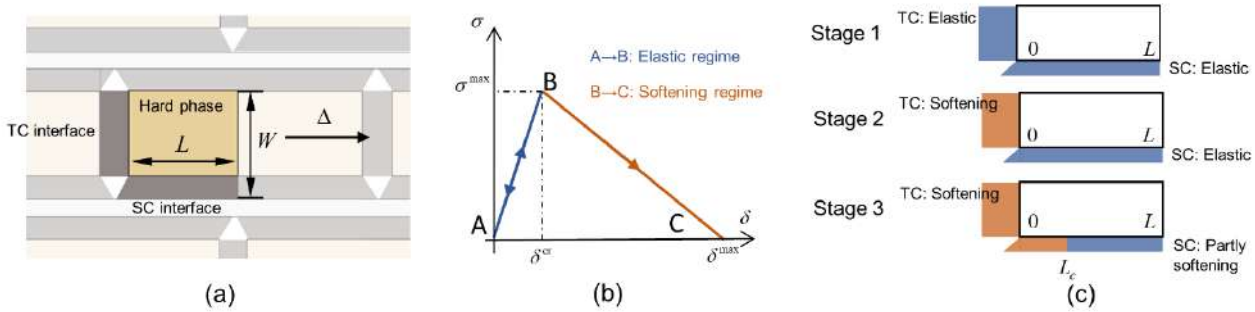

Figure 1. Schematic of the theoretical model. (a) A one-dimensional unit cell. (b) Bilinear cohesive law on the TC and SC interfaces. (c) Gradual softening of the TC and SC interfaces during the tensile deformation [4].

This study follows the classic Tensile–Shear–Chain (TSC) model developed by [2]. A uniaxial tensile displacement load Δ is imposed on the unit-cell model (Fig.1a). The unit-cell comprises three parts: the hard phase, tensile cohesive (TC) interface, and shear cohesive (SC) interface.

The tensile stress of the hard phase is write as the integrate from the tractions on the TC and SC interfaces

$$\sigma_{\text{hard}}(x_1)=\sigma_{\text{TC}}+\frac{1}{W}\int_0^{x_1}\sigma_{\text{SC}}(\xi)\,\mathrm{d}\xi,\ 0\le x_1\le L. \tag{1}$$

where W is the width of the hard phase platelet, and L denote the half length of the platelet.

The tangential moduli corresponding to the three stages are expressed as

$$E_1=\frac{\sigma_{\text{TC}}^{\max}L}{\delta_{\text{TC}}^{\text{cr}}}+\frac{L^2\sigma_{\text{SC}}^{\max}}{12W\delta_{\text{SC}}^{\text{cr}}},\quad E_2=\frac{\sigma_{\text{TC}}^{\max}L}{\delta_{\text{TC}}^{\text{cr}}-\delta_{\text{TC}}^{\max}}+\frac{L^2\sigma_{\text{SC}}^{\max}}{12W\delta_{\text{SC}}^{\text{cr}}},\quad E_3=\frac{\sigma_{\text{TC}}^{\max}L}{\delta_{\text{TC}}^{\text{cr}}-\delta_{\text{TC}}^{\max}}+\frac{L^2\sigma_{\text{SC}}^{\max}L_c}{12W\delta_{\text{SC}}^{\text{cr}}L}+\frac{L^2\sigma_{\text{SC}}^{\max}(L-L_c)}{12W\left(\delta_{\text{SC}}^{\text{cr}}-\delta_{\text{SC}}^{\max}\right)L}. \tag{2}$$

The critical strain can be solved based on the ellipticity condition of instability $E(\varepsilon_{\text{cr}})=0$.

Threshold 1: Occurrence of strain-hardening

When the TC interface steps into the softening stage, the SC interface still provides a positive modulus to the unit-cell, thus forming the strain-hardening stage. Accordingly, the occurrence of the strain-hardening stage is given as $E_2>0$.

Threshold 2: Failure of the platelet

We give the condition of platelet failure as $\sigma_{\text{norm}}>\sigma_{\text{platelet}}$, where σ_{platelet} is a material parameter of the fracture strength of the hard phase.

According to the two thresholds, we give the analytical prediction of the strength of nacre σ_{th} as: Mode 1: Platelet failure, Mode 2: Interface failure, with strain hardening, and Mode 3: Interface failure, without strain hardening.

Result

Figure 2 shows the stress–strain curves calculated from the unit-cell theoretical model and the finite element model in a larger representative volume element. In Fig. 2a, we can observe the TC interface softening first, and a gradual softening on the SC interface. In Fig. 2b, the softening of TC interface introduces crack initiation immediately. The contribution of the SC interface cannot be observed.

The effect of aspect ratio on the mechanical response of nacre is shown in Fig. 3. Our result reveals a preferred zone

*Corresponding author. E-mail: fengxq@mail.tsinghua.edu.cn

(green) of aspect ratio in which the model fails in Mode 2. It is shown that natural nacre chooses the strategy of high strength, which is coherent with its biological function (protect the shell from impact load) [4].

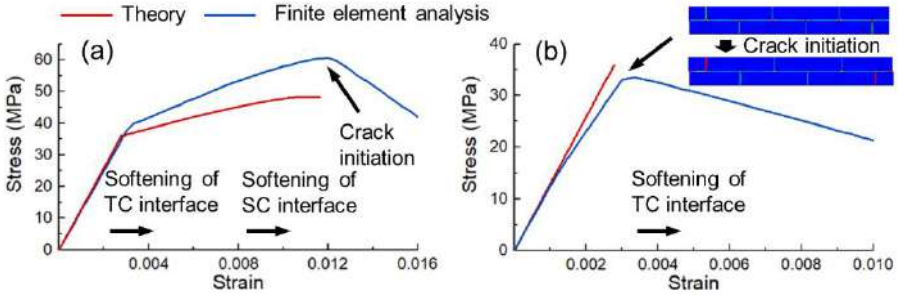

Figure 2. Theoretical prediction of the stress strain curve compared to finite element simulation result. (a) Interfacial failure with strain hardening (Mode 2), $\sigma_{SC}^{max} = 30$ MPa. (b) Interfacial failure without strain hardening (Mode 3), $\sigma_{SC}^{max} = 3$ MPa.

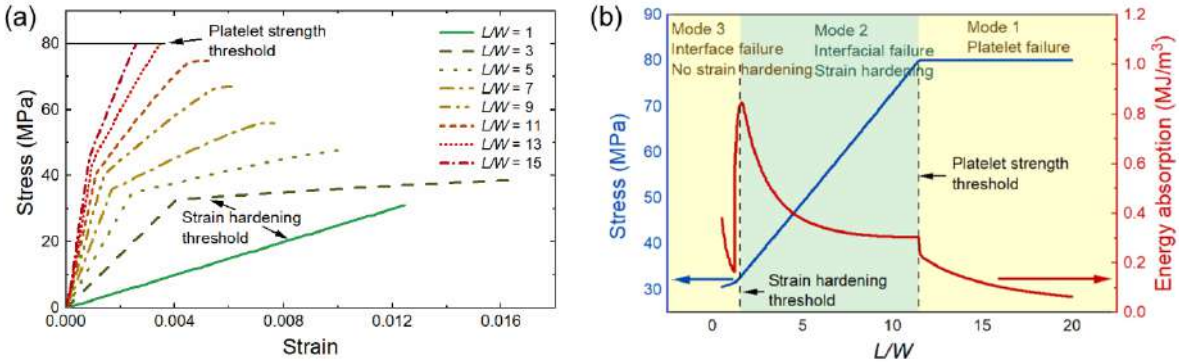

Figure 3. Effect of aspect ratio on the stress strain curve (a), strength, and toughness (b).

The interfacial stiffness is another important design parameter. There are variety of polymers as the candidate of the soft phase in artificial nacre. A basic but vital problem is to choose whether a stiff polymer such as PMMA, or a softer material like PLMA [5]. Our result shows that a softer interface is benefit to the toughness, which is consistent with the earlier analytical result [6]. However, if the interface is too soft, we can observe the occurrence of failure Mode 3 (no strain-hardening).

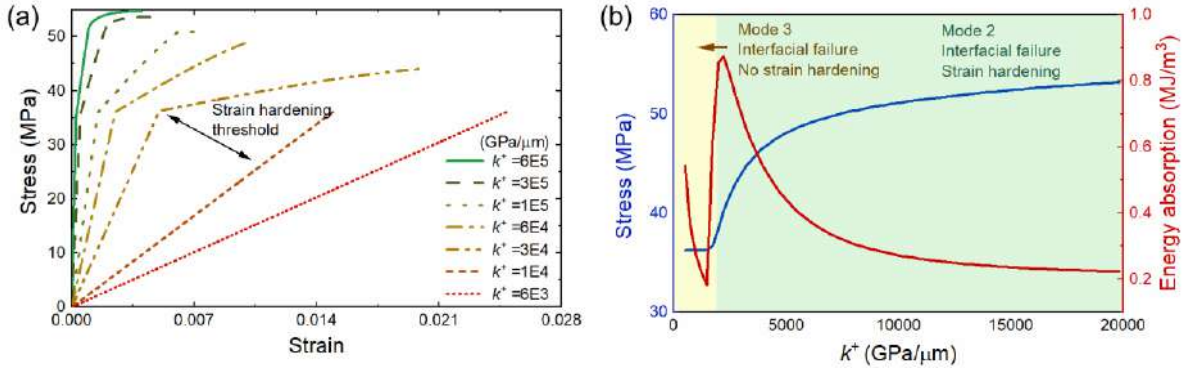

Figure 4. Effect of interfacial stiffness on the stress strain curve (a), strength, and toughness (b).

CONCLUSIONS

In this study we developed a unit-cell theoretical model to calculate the mechanical response of nacre. Two important thresholds are presented to predict the occurrence of strain-hardening and platelet failure. The results give a preferred range of aspect ratio and interfacial stiffness to achieve high strength and toughness. The strategy of structural design of natural nacre can be well explained, indicating the potential of this model as the guidance of the designation of artificial nacre.

MECHANICAL PROPERTIES OF FIBERBOARD COMPOSITE BONDED WITH POLYMER MATRIX COMPUTED BY MEAN-FIELD HOMOGENIZATION METHODS

Janka Kovacikova[*1], Martin Kroon[1], Sheikh Ali Ahmed [2], Reza Hosseinpourpia[2], and Stergios Adamopoulos[2,3]
[1]Department of Mechanical Engineering, Faculty of Technology, Linnaeus University, Växjö, Sweden
[2]Department of Forestry and Wood Technology, Faculty of Technology, Linnaeus University, Växjö, Sweden
[3]Department of Forest Biomaterials and Technology, Swedish University of Agricultural Sciences, Uppsala, Sweden

Summary Nowadays, the design of composite materials considering sustainability and the environmental impact of the production is conspicuous. Therefore, in this work, we focus on investigating the mechanical behaviour and structure of a new green wood-based fibrous composite material bonded with a novel polymer matrix. The constitutive prediction models employing the material and structure design approaches simultaneously are proposed here to describe the material's microstructure. The goal is speeding up trials and reducing experiments expenses by replacing tests with computer simulations. Additionally, the relationship between material behaviour and structure is established and will be later used to generate Representative Volume Elements (RVEs) for finite element analysis (FEA).

INTRODUCTION

Employment of a multiscale concurrent design approach while developing a new composite material compared to a conventional material and structural design executed separately has multiple advantages (from saving resources needed for conducting experiments to easing the environmental impact of production). Therefore, in this work, we focus on developing mean-field homogenization models of a composite material predicting a material's performance. Ultimately, we will couple these models with the macro-scale models to perform the complex structural analysis. The studied composite material is wood fibre-reinforced composite with a polymer matrix. We used *Digimat 2020.0* modelling platform and the mean-field homogenization (MFH) methods. The results are the homogenized micro-mechanical material models that consider the heterogeneous nature of component materials and predict the composite material properties and performance under uniaxial loading.

MATERIAL AND METHODS

Studied composite material belongs to the category of polymer-matrix composites (PMC) [1, 2] with short fibres. We consider that material is homogeneous, and it consists of two constituents: inclusion and matrix. The inclusion is wood fibres from Pinus sylvestris, and the matrix is polyurethane from isocyanates and dextrin. Both the inclusion and the matrix are products obtained from biomass; thus, they are biodegradable. The values used to describe the mechanical properties of constituents in the micromechanical models are in table 1 and compiled from [3-6].

Table 1. Input material parameters of constituents

Phase (compound)	Density [kg/mm^3]	Young's Modulus [MPa]	Ultimate Stress [MPa]	Ultimate Strain [%]	Poisson's ratio [-]
Matrix (PU)	9.88E-007	1554	46	5	0.4
Fibres (*Pinus Sylvestris*)	4.2E-007	9000	49	2	0.3

We executed a static analysis of elastoplastic brittle material with monotonic uniaxial loading applied and with no failure indicator. The microstructure consists of a mass fraction of 40% and an aspect ratio of 22. It is a single generic type microstructure.

We employed the mean-field homogenization (MFH) models to estimate the stress and stains regions, both at the macro scale level as well as microscale level. Namely, Mori-Tanaka (M-T) [7] using two available techniques: first and second-order homogenization. Material for each compound is calculated assuming an accurate material model of the phase and volume average of the strain field is computed in the phase, in first-order homogenization. To define comparison materials using second-order homogenization, we also employ second statistical moments of the strain field [8]: Double Inclusion (D-I) models [9]. Ultimately, we create a representative volume element (RVE) using the mentioned methods. Moreover, in our models, we assume that the composite is the RVE of composite consists of a matrix of uniform stiffness C0 in which the many inclusions (I) of uniform stiffness C1 are nested. At the same time, strain ε is constrained on the boundary.

In the Mori-Tanaka model, the strain concentration tensor expressing the strains' volume average over all inclusion to the mean matrix is presumed ad follows:

$$\mathbf{B}^{\varepsilon} = \mathbf{H}^{\varepsilon}(I, C_0, C_1) \quad (1)$$

*Janka Kovacikova. E-mail: janka.kovacikova@lnu.se.

Where $\mathbf{B}^{\varepsilon}$ is mean strain matrix, $\mathbf{H}^{\varepsilon}$ is the single inclusion's concentration tensor.

In the Double inclusion (D-I) model, each inclusion (I) of C_I stiffness assumes to be encircled by the material matrix of stiffness C_0. Additionally, a reference medium of stiffness C_r is introduced in the close area between inclusion and matrix.

In this case, the strain concentration tensor to the mean matrix is defined as follows:

$$\mathbf{B}^{\varepsilon} = \left[(1-\xi(v_1))(\mathbf{B}_l^{\varepsilon})^{-1} + \xi(v_1)(\mathbf{B}_u^{\varepsilon})^{-1}\right]^{-1} \quad (2)$$

Where v_1 is volume fraction and $\xi(v_1) = \frac{1}{2}\, v_1(1+v_1)$ is a smooth quadratic interpolation function.

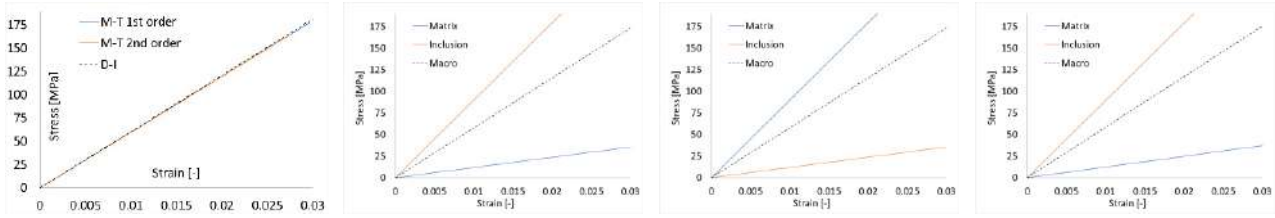
RESULTS AND DISCUSSION

The engineering constants computed via M-T and D-I models for the macroscopic representation of RVE are in Table 2. Here, E_{11} (x-axis) is an axial modulus of elasticity, E_{22} (y-axis), E_{33} (z-axis) are transverse moduli of elasticity; υ_{12}, υ_{21}, υ_{13}, υ_{31}, υ_{23}, υ_{32} are macroscopic Poisson's ratios; G_{12}, G_{13}, G_{23}: macroscopic shear moduli.

Table 2. The engineering constants computed using MFH methods

Constant Model	E_{11} [MPa]	E_{22} [MPa]	E_{33} [MPa]	υ_{12} [-]	υ_{21} [-]	υ_{13} [-]	υ_{31} [-]	υ_{23} [-]	υ_{32} [-]	G_{12} [MPa]	G_{13} [MPa]	G^{23} [MPa]	Global Density [kg/mm^3]
M-T	5991	3953	3953	0.338	0.223	0.338	0.223	0.446	0.446	1438	1438	1367	6.41E-07
D-I	6043	4330	4330	0.334	0.239	0.334	0.239	0.418	0.418	1631	1631	1527	6.41E-07

The macroscopic stress-strain diagrams for M-T 1st order, M-T 2nd order and D-I models are shown in Figure 1 (a). Additionally, stress-strain diagrams for matrices, inclusions and macro are shown in Figure 1 (b-d).



(a) (b) (c) (d)

Figure 1. Stress-strain diagrams: (a) comparison of all used models; matrix vs inclusion vs macro for (b) Mori-Tanaka 1st order, (c) Mori-Tanaka 2nd order, (d) Double inclusion models

We can see that there is no significant difference between the obtained engineering constants and stress-strain diagrams comparing the used methods. Thus, all methods are employable in the case of the studied composite.

CONCLUSIONS

The used methods are suitable to solve the studied problem and will be further developed into more sophisticated models. Specifically, we will consider mechano-sorptive creep models that will be described via the material's viscoelastic properties. The additional model using the direct finite element method (FEM) at the microscopical level will also be developed. These will be later compared to the experimental work submitted for publishing and the work presented in [10].

SELF-ASSEMBLY OF GRANULAR PARTICLES FOR INVERSE OPAL MANUFACTURE

Ivan Grega*, Angkur Shaikeea, and Vikram S. Deshpande
Department of Engineering, Cambridge University, Cambridge CB2 1PZ, UK

Summary Self-assembly is a scalable and cheaper method for the manufacture of certain architected solids compared to additive manufacturing methods. Here, via a combination of large-scale numerical simulations of granular assemblies and associated experiments, we investigate the use of vibration schemes to promote crystalline assemblies. The effect of vibrations type, seeding layer and height of assembly on both the kinetics and equilibrium of the assemblies is investigated.

INTRODUCTION

The motivation of this work is to improve the manufacture of inverse opal metamaterials, which exhibit superior mechanical properties [1]. Self-assembly of opal template followed by deposition of main material should bring improvements over additive manufacturing in terms of scalability, speed, and cost. The first step is to assemble opaline crystal without stacking defects such as vacancies, grain boundaries, dislocations, regions of low packing density, and misorientations of grains. Traditionally, inverse opal crystals were manufactured on a microscopic scale for their optical properties (photonic bandgap) [2]. Constituent spheres of diameters below 2 μm were often synthesised in a solution [3]. It was discovered that it is possible to achieve dense crystalline packing by slow evaporation of the solvent. The disadvantages of this approach are the limited thickness of opaline layers which can be produced, low control over the process, and the presence of numerous stacking defects [4]. On solvent drying, stresses can develop in the assembly which are high enough to initiate cracking of the sample [5]. In this work we take a top-down approach. Starting on a macroscale, we investigate the potential for achieving a defect-free crystalline granular assembly from random packing without resorting to colloidal solution.

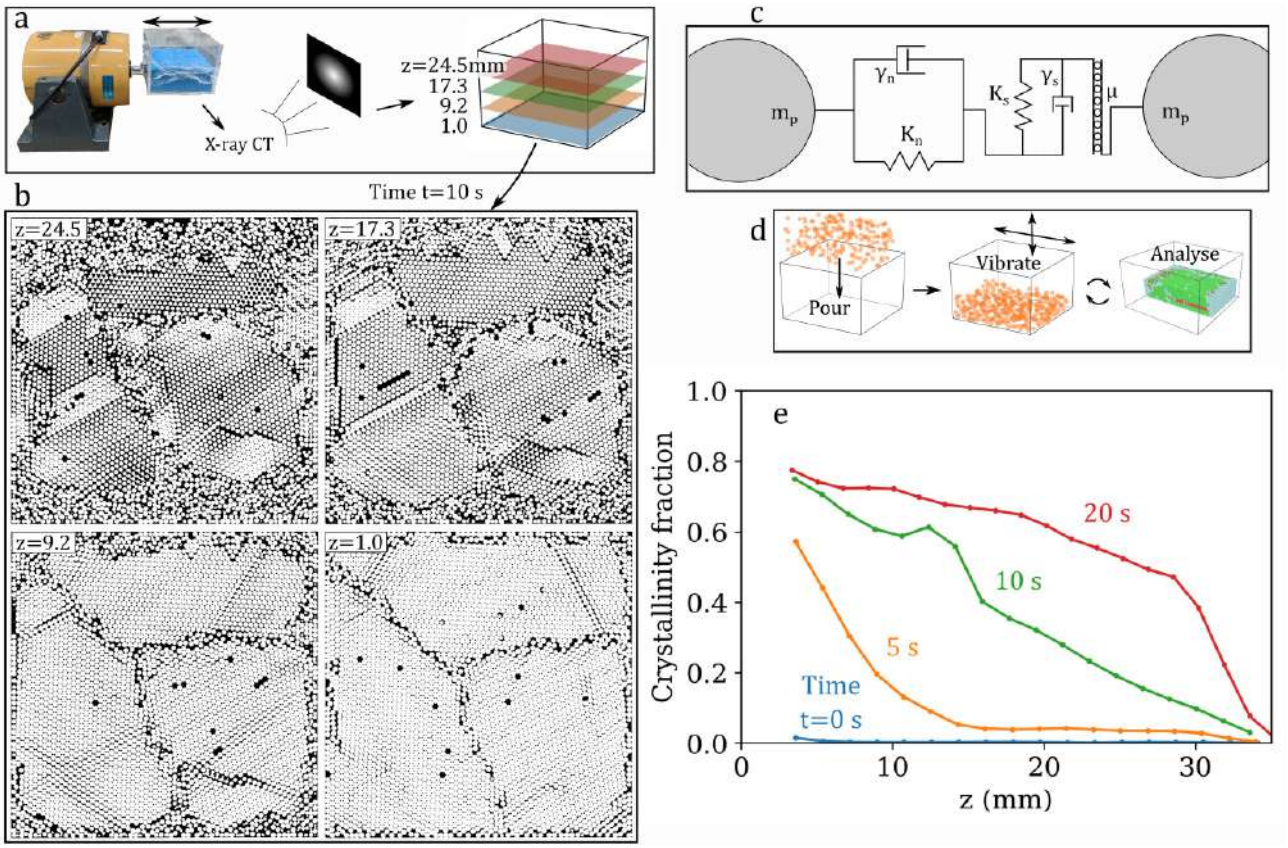

Figure 1 Development of crystallinity is captured by soft-sphere model
a) Experimental setup: enclosed box with cellulose acetate spheres (⌀2mm) connected to linear shaker. After vibration phase, sample is analysed using X-ray CT. b) Cross-sectional slices at representative heights *z* after 10s of horizontal vibration: lower layers have denser packing. c) Soft-sphere model is used to model particle interactions. d) Conceptual workflow in simulations: spherical particles are poured into simulation box, horizontal or vertical vibration is applied, and resulting packing is analysed using PTM [6]. e) Crystallinity varies with time *t* and height *z*, increasing from the bottom upwards.

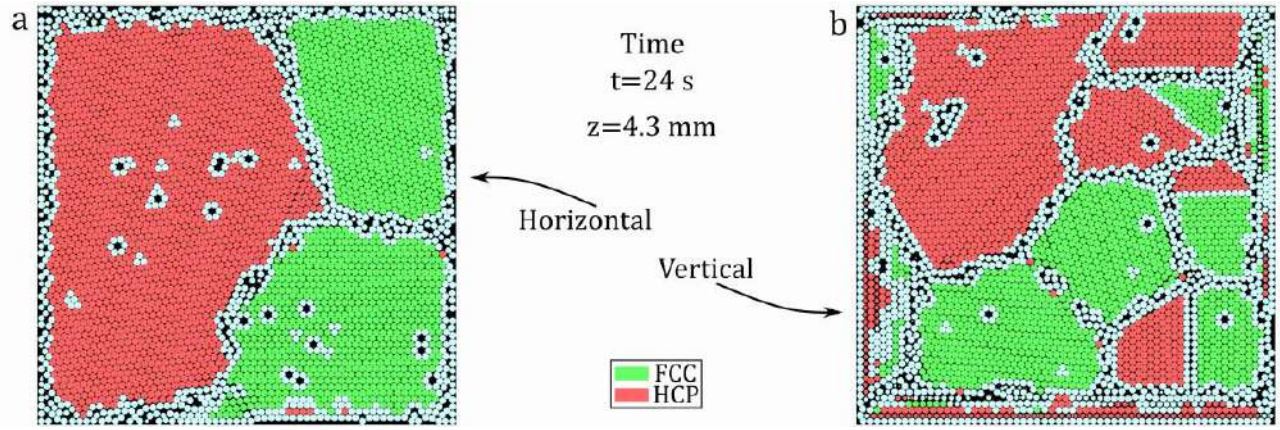

Figure 2 Horizontal vibration improves growth of single grain over vertical vibration
Cross-sections at *z=4.3mm* after *t=24s* of vibration at *16Hz*. Increased shearing motion resulting from horizontal vibration improves merging of grains

METHODOLOGY

In our experiments, the granular assembly was comprised of 75'000 precision cellulose acetate spheres with 2 mm diameter inside a transparent acrylic box with 120x120 mm planform. The box was placed on rollers and attached to a linear shaker to induce horizontal vibrations. Positions of particles were measured from X-ray CT cross-sectional images (Fig 1a). Numerical simulations were carried out using LAMMPS and its package *granular*. To model particle interactions, we used soft-sphere model (Fig. 1c) with parameters determined from experiments. Information about crystallinity of packing was obtained using polyhedral template matching (PTM) algorithm [6].

RESULTS

Agreement between results of numerical simulations and experiments was established. The soft-sphere model can capture the behaviour exhibited by experiments (Fig. 1). We found it possible to convert the bulk of granular assembly from random packing to grains of close-packed FCC and HCP by various vibration schemes.

- Horizontal vibration and associated shearing motion are more efficient at dissipating grain boundaries than vertical vibration. In vertical vibration it takes more time for various grains to coalesce (Fig. 2)
- The rate at which crystallinity is established and the quality of packing can be strongly influenced by the introduction of a *seeding* layer (with packing corresponding to FCC 100- or 111-planes). Seeding layer accelerates crystal growth and imposes matching lattice orientations to all grains.
- The total height of random assembly influences kinetics of crystal growth. When sample height is bigger, overall crystallinity increases more slowly. Secondly, while for smaller height crystal growth always starts from the bottom and propagates upwards, nucleation for taller samples initiates mainly at the vertical walls.

CONCLUSIONS

In the presented study, we show that granular assembly of spheres in random packing can be transformed to crystalline assembly using vibrations. We also demonstrate the rate and quality of this process can be largely influenced by several factors such as directionality of applied vibrations, presence of ordered seeding layer and total height of the granular assembly. It has been experimentally shown that line defects can be eliminated with sufficient time of vibration. By improving quality and eliminating the need for colloidal dispersant, this process has a potential to improve the manufacture of inverse opals.

SELF-ASSEMBLY BEHAVIOR OF BLOCK COPOLYMER BLEND THIN FILMS

Suwon Bae[1] and Kevin G. Yager *[1]
[1]Center for Functional Nanomaterials, Brookhaven National Laboratory, Upton, NY, USA 11973

Summary Block copolymer blend thin films have potential as patterning materials. Here, a molecular dynamics approach is used to investigate the variation in morphologies formed by block copolymer blends in a thin film geometry. It is shown that blends of cylinder- and lamella-forming block copolymers in a thin film geometry form patterns of dots and lines coexisting in separate regions, which is not observed in single component block copolymer thin films. Blending one with another block copolymer diversifies nanostructure registry and facilitates the use of block copolymer as patterning materials.

INTRODUCTION

Block copolymers (BCPs) are a class of self-assembling material that segregates on nanometer length scale. BCPs are as the name indicates are composed of two or more blocks which are chemically distinct and incompatible with each other. This chemical incompatibility drives BCPs to phase separation and self-assembly. Having a covalent bond between blocks prevents macrophase separation of otherwise free, distinct homopolymers. BCPs therefore microphase separate and self-assemble into nanoperiodic structure. The nanostructure shape and size can be controlled by the underlying BCP chain architecture such as molecular weight, chemical incompatibility, and relative fraction of blocks. BCPs in thin film geometries include applications in nanopatterning, nanoporous membranes, nanorods, etc. The patterns formed by BCP thin films can be diversified through blending, which further facilitates the use of block copolymer as patterning materials. We study the morphologies formed by blends of cylinder- and lamella-forming diblock copolymes in a thin film geometry by means of molecular dynamics simulations.

METHODS

We use a Kremer-Grest bead-spring model to describe our representative A-d-B diblock copolymer chain. For both cylinder- and lamella-forming BCP chains, denoted by C and L chains, the number of beads per chain is set to 20. f_A is set to 0.25 and 0.5 for C and L chains, respectively, meaning a C chain is composed of 5 A beads and 15 B beads. Mass of each bead is $1.0m$ regardless of type, where m is Lennard-Jones (LJ) unit for mass. The interactions between beads are governed by FENE and LJ potentials, widely used to describe the behavior of polymer melts. The LJ potential is responsible for non-bonded interactions and it normally describes repulsive interaction alone. We choose $r_c = 2.5\sigma$, where $sigma$ is LJ unit for distance, which enables attractive interactions between BCP chain beads. Thin films of representative BCP chains are constructed by using a self-avoiding random walk algorithm. The total number of chains is 2400, which yields $0.7L_0^*$ thin films, where L_0^* is the domain/repeat spacing of line patterns formed by pure L chains, which will be discussed in results. The films is placed on top of a substrate, which is located on the bottom surface of a simulation bocs. The substrate is modeled with a single layer of beads (type S) aligned and fixed on the 111 plane of an FCC lattice. The substrate beads interact only with BCP chain beads in the pairwise (non-bonded) manner. The pairwise interactions are captured by an LJ potential, enabling the BCP film to stand on the substrate with attractive interactions between the BCP chain beads and the substrate beads. The substrate interfacial energies are precisely tailored so that the substrate can behave as a "neutral" substrate, which promotes morphologies aligned perpendicular to it. With periodic boundary conditions imposed along the plane, MD simulations are performed using LAMMPS. Individual films are subjected to annealing and cooling, which are carried out using *NVT* ensemble with Nosé-Hoover thermostat. We define $f_C = n^C/(n^C + n^L)$, which is fractional number of C chains of individual blend thin films, and use it to quantify blending ratio.

RESULTS AND DISCUSSION

BCP blend thin films are studied as a function of f_C. At $f_C = 0$, pure L chains form vertical lamellae, visualized as a line pattern in a SEM-like top-down view image (Figure 1-a) generated by using BCP chain trajectories. The morphologies formed in the films studied here span the whole thickness. At $f_C = 1.0$, pure C chains self-assemble into vertical cylinders, visualized as a dot pattern in Figures 1-c and 2. We applied a Fast Fourier Transform (FFT) to determine domain spacing. Pure L and C chains exhibit $16\sigma(= L_0^*)$ and 13σ, respectively. Dual component thin films created by blending L chains with C chains show a pattern of dots and lines coexisting in separate regions (Figure 1-b). The dots are aligned as if each one has a guided line extended from the lines, which is confirmed by the domain spacing analysis of the pattern that the dots and lines share a single characteristic domain spacing. This provides more favorable environments to C and L chains at the boundaries between regions. The response of individual BCP chains is also studied by identifying which chain constructs which object. L chains in the blends does not nearly change in terms of R_g, radius of gyration, compared to the state at $f_C = 0$ while C chains in the blends experience chain stretching when blended with L chains to form line patterns.

*Corresponding author. E-mail: kyager@bnl.gov.

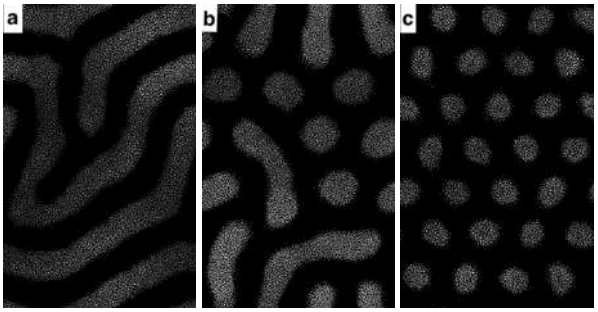

Figure 1: SEM-like top-down view images of patterns formed by (a) pure L chains at $f_C = 0$, (b) blends of C and L chains at $f_C = 0.55$, and (c) pure C chains at $f_C = 1$. Minority blocks (A blocks) remain with majority blocks (B blocks) removed.

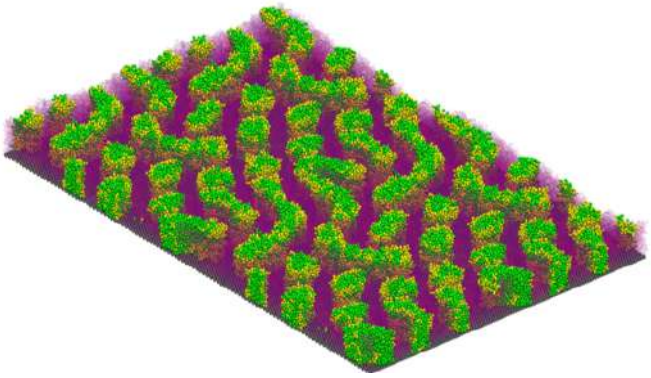

Figure 2: Perspective view image of patterns formed by blends of C and L chains at $f_C = 0.55$. Periodic images were copied and pasted in order to clearly show patterns over periodic boundary conditions. Yellow and green beads are A blocks constructing C and L chains, respectively, and purple and magenta beads are B blocks constructing C and L chains, respectively. B blocks, majority blocks, are slightly transparent to highlight vertical morphologies.

CONCLUSIONS

We built MD simulation models of BCPs in a thin film geometry with attractive interactions included. The neutral substrate was implemented in MD simulation and used to form vertical morphologies in BCP thin films. Since we focus on BCPs as patterning materials, films are thin (thickness of about $0.7L_0$) and all morphologies span the whole thickness. Pure L and C chains form undulating lines and an array of dots, respectively, and the dual component BCP thin films exhibit patterns of lines and dots coexisting in separate regions in a single film. Blending diversifies nanostructure registry and can further facilitates the use of BCPs as patterning materials.

A GUI-ASSISTED COMPUTATION OF LATH MARTENSITE VARIANTS

Thomas Antretter*, Manuel Petersmann, and Alexander Sannikov
Institute of Mechanics, Montanuniversitaet Leoben, Leoben, Austria

Summary Industrially relevant martensitic steels exhibit a complex morphology of martensite variants appearing as laths grouped into blocks and packets. The martensite is typically highly dislocated in order to ensure compatibility with the parent austenite matrix during formation. A graphical user interface is presented that predicts those variants that are most likely to appear in lath martensite. Knowledge of the deformation gradients accompanying the mechanisms of martensitic phase transformation in combination with shear along well defined slip planes is crucial for micromechanical full field models as illustrated by an example provided in the current work.

INTRODUCTION

In most industrially relevant martensitic steels the martensite forms at sufficiently high temperatures to make dislocation glide energetically favourable in comparison to twinning mechanisms. As has thoroughly been discussed in [1] the martensite morphology is hierarchical, with individual variants forming laths grouped in blocks, which, in turn, form packets. The position of those variants relative to the lattice of the parent phase is dictated by crystallographic compatibility conditions expressed in terms of an Invariant Plane Strain (IPS) condition. From a continuum-mechanical point of view martensite is commonly described by the classical phenomenolocial theory of martensite crystallography (PTMC). It allows calculating the deformation gradients accompanying the formation of individual martensite variants. Compatibility of those variants or ensembles thereof with the parent lattice requires $\lambda_2 = 1$ where λ_2 is the middle eigenvalue of the deformation gradient mathematically representing a transformed domain. In steels this can usually only be accomplished by applying an additional lattice invariant shear, which - on the atomic scale – is bound to discrete slip planes determined by the lattice. The latter rotates in the course of progressing deformation – a fact that is neglected by the classical PTMC. In [2] Petersmann et al. propose a concept that (i) accounts for the lattice rotation and updates it incrementally, (ii) applies an incremental amount of shear that guarantees the validity of the compatibility conditions at any time and any stage of transformation. As expected, the solution is not unique, i.e., there is a large number of eligible slip systems all ensuring the IPS condition. The number of solutions can be narrowed down by providing physically reasonable bounds dictated by crystallography-microstructure relationships reported in the literature, see e.g. [1,3,4].
The mathematical description of martensite variants is highly valuable in materials science. E.g., it is useful for inversely determining the morphology of prior austenite grains if only the martensite morphology is available from electron backscatter diffraction (EBSD) characterization, see also [5]. As another example any micromechanical model that resolves individual variants can take advantage of the presented algorithm.

THE GRAPHICAL USER INTERFACE

The theory described above has been coded into a graphical user interface (GUI) that allows computing a selection of most probable martensite variants along with their associated deformation gradients given the crystallographic features of the parent and the product lattice. Aside from lattice parameters and the lattice correspondence (defined by the Bain strain) the user must also specify the slip system families in the austenite and, if applicable, in the martensite. By default the algorithm then computes all possible deformation gradients satisfying the IPS condition. Without any additional constraint this would yield a large number of solutions where some are more likely to appear than others.

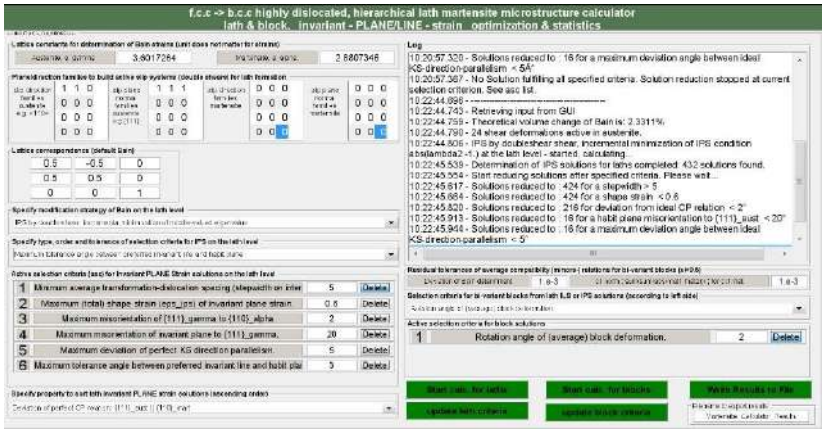

Figure 1. Graphical User Interface for calculating variants in lath martensite

The user may decide to prune the solution space by prescribing physically reasonable constraints of crystallography-microstructure relations entered in the lower left section of the GUI, see the example shown in Figure 1. In the particular case shown in this figure, the maximum misorientation angle between the {111} γ-plane and the {110} α'-plane has been set to 2°. The other constraints shown in the figure follow reasonable bounds found in the literature. Given these constraints the algorithm eventually reduces the number of solutions to a mere 16, see the upper right log window of the GUI. The so-determined solutions constitute bi-variant blocks which, in turn, are subject to selection criteria and constraints that can be defined in the lower right section of the GUI. The deformation gradients passing all filters set by the user are written to a results file for further use. The GUI is freely available at [6].

APPLICATION TO MICROMECHANICAL MODELS

The phenomena ensuing phase transformations in solids are frequently studied by means of representative volume elements (RVE), where the evolution of the morphology is monitored by phase field approaches, see e.g. [7]. The focus of this work is on studying the evolution of internal stresses and strains under the influence of an external stress. By contrast, here the thermodynamics of the phase formation is not considered. Therefore, it is admissible to prescribe the volume fraction of the product phase as a function of temperature without having to solve the phase field equations. The information of the transformation strains is obtainable from the deformation gradients calculated by the GUI presented above. The RVE is discretized by 32 x 32 x 32 finite elements, see Figure 2. Starting from a randomly chosen nucleation site an element is toggled from austenite to martensite by imposing the transformation strains from the list generated by the GUI. The direction of further growth of the variant is governed by the same arguments of austenite to martensite compatibility that defines the eligible transformation strains. The shape of the growing martensite domain is assumed ellipsoidal. It is further assumed that a martensite lath grows rapidly until it hits an obstacle such as an already existing variant or the domain boundary as represented by the faces of the RVE, see Figure 2. Such models can subsequently be used to calibrate mean-field models accounting for the consequences of martensitic transformation in industrially relevant steels.

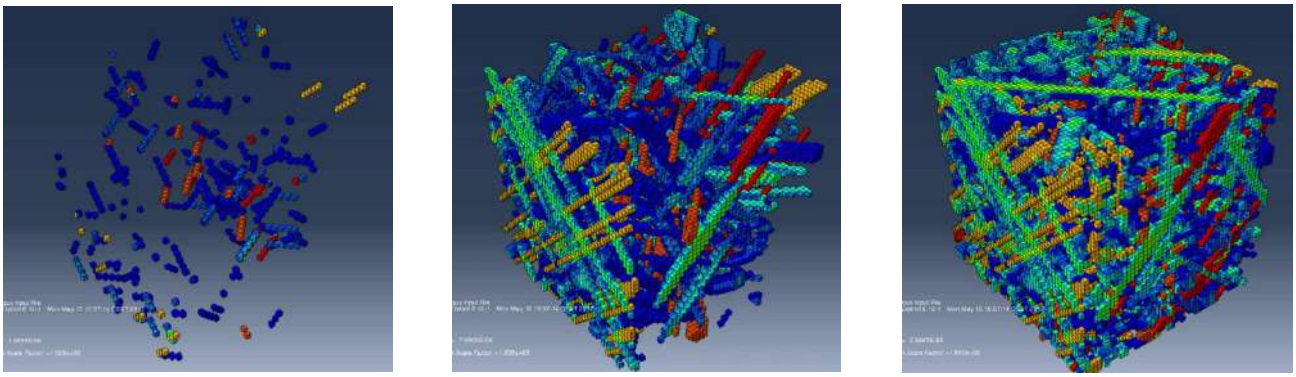

Figure 2. a) Representative volume element. The martensite fraction increases from left to right from 5% to 40% and 70%. The color coding indicates the reference to the habit plane. The elements representing the austenite are not shown.

CONCLUSIONS

A GUI-assisted implementation of the phenomenological theory of martensite enhanced by an incremental lattice orientation update produces the most probable set of transformation tensors of lath martensite variants. This information has been inserted into a RVE-based micromechanical model that allows the calculation of phase-specific stress and strain fields which can be used for the calibration of macroscopic models for materials undergoing martensitic transformation.

VARIATIONAL MODELING OF THE INFLUENCE OF CYCLIC THERMAL AND MECHANICAL LOADING ON THE PHASE TRANSFORMATION IN SHAPE MEMORY ALLOYS

Johanna Waimann*[1], Stefanie Reese[1], and Philipp Junker [2]
[1]Institute of Applied Mechanics, RWTH Aachen University, Aachen, Germany
[2]Institute of Continuum Mechanics, Ruhr-University Bochum, Bochum, Germany

Summary The phase transformation in shape memory alloys is induced by thermal as well as mechanical loading. The resulting special material properties can be summarized in the one-way and two-way effect as well as in the name giving shape memory effect. Under cyclic loading the material behaviour and thus the start of the phase transformation is influenced by the so-called effect of functional fatigue. We will present a material model which is based on the principle of the minimum of the dissipation potential and enables us to display the complex microstructural behaviour. In addition, we will show the model's implementation within a finite element scheme. Our results - on the material point level as well as on the finite element level show - the model's functionality.

INTRODUCTION

The microstructure of shape memory alloys (SMA) is highly influenced by the diffusionless phase transformation between austenite and several martensitic variants. Compared to classical steel, the transformation process is not only induced by thermal but also by mechanical loads. Due to this special microstructural evolution, SMA are very attractive for the industry, but their applicability is still limited by the so-called effect of functional fatigue. This effect comes along with the cyclic loading of the class of materials and results in a changed start of the transformation until convergence. During cyclic mechanical loading, the transformation from austenite to martensite is favoured and the reverse transformation is delayed. The transformation is accompanied by the accumulation of a remaining strain. The cyclic thermal loading leads to the opposite effect on the transformation behaviour: the transformation from austenite to martensite is delayed and the reverse transformation favoured [1].
Compared to our former works, we will present a material model which is able to show not only the material behaviour during mechanical but also during thermal cycling. In addition, we will present its finite element implementation and several numerical results.

INTERNAL VARIABLES AND VARIATIONAL CONCEPT

We use three internal variables to describe the complex microstructure: $\boldsymbol{\Lambda} = \{\boldsymbol{\lambda}, \rho, \boldsymbol{\alpha}\}$. The volume fraction of the austenite and the martensites $\boldsymbol{\lambda}$ describes the phase transformation. The transformation history variable ρ accounts for the fatigue effects. Based on [2], to additionally consider the polycrystalline structure of the material and thus the different oriented grains, a set of three Euler angles $\boldsymbol{\alpha}$ is used. The Euler angles describe the averaged orientation of the transformation which is taking place and thus, enable a faster computation than a grain-wise calculation of the phase transformations.
A first description of the model is presented in [3] and is based on the classical form of the principle of the minimum of the dissipation potential (PMDP) [4]. In its original form the PMDP is only applicable for isothermal problems. In [5], the method's extension for non-isothermal processes is given, which is also the base for the presented approach. The main idea of the PMDP is the minimization of a Lagrange function, which is an energetic term that describes the microstructure and its evolution of the observed material, with respect to the used internal variables' rates $\dot{\boldsymbol{\Lambda}}$. For non-isothermal processes the PMDP is formulated by

$$\mathcal{L} = \overline{\mathcal{D}} - \mathcal{D} \rightarrow \min_{\dot{\boldsymbol{\Lambda}}, \boldsymbol{q}} .$$

Therein, $\overline{\mathcal{D}}$ is a dissipation function which describes the energy which is necessary for the microstructural evolution. The variable $\mathcal{D}$ is the well-known dissipation. Compared to the classical PMDP the minimization is not only performed with respect to the rates of the internal variables but also with respect to the heat flux $\boldsymbol{q}$. The minimization automatically results in evolution equations for $\boldsymbol{\Lambda}$ and a modified form of the classical heat balance equation.
Finally, we will perform a Legendre transformation, which leads to a yield function for the phase transformation and the related Karush-Kuhn-Tucker conditions.

FINITE ELEMENT IMPLEMENTATION AND NUMERICAL RESULTS

After the derivation of the evolution equations, we will present the implementation of our model within a finite element algorithm. Therefore, we use an explicit scheme in form of a broken Taylor series.

*Corresponding author. E-mail: waimann@ifam.rwth-aachen.de.

The numerical results for a prescribed strain tensor and changing temperature [see Figure 1], show the functionality of our variational approach: The favouring transformation from austenite to martensite during the mechanical cycling (*left*) as well as the decrease of the transformation temperatures during thermal cycling (*right*). The presentation of first finite element results for the thermo-mechanically coupled variational material model, will show the applicability for more realistic problems.

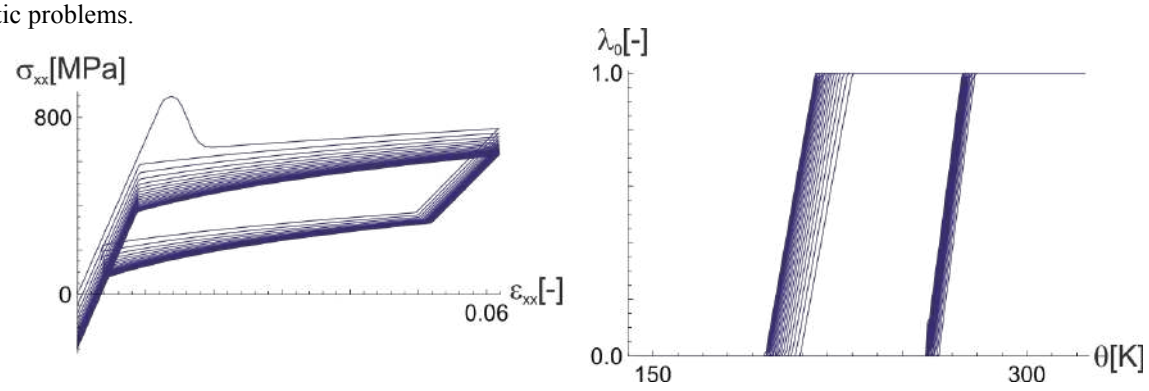

Figure 1. Simulations of cyclic mechanical loading (*left*): stress/strain-diagram; cyclic thermal loading (*right*): evolution of the austenite, see also [3].

CONCLUSIONS

In our talk, we will present the variational material model for thermal and mechanical cycling of shape memory alloys. Compared to our earlier works, we will use the principle of the minimum of the dissipation potential for non-isothermal problems and show the implementation within a finite element algorithm. The later numerical results show the models ability to display the complex material behaviour.

PHASE-FIELD MODELLING OF NANO-INDENTATION IN SHAPE MEMORY ALLOYS: MICROSTRUCTURE AND SIZE EFFECTS

Mohsen Rezaee-Hajidehi[1], Karel Tůma[2], and Stanisław Stupkiewicz*[1]
[1]Institute of Fundamental Technological Research (IPPT), Warsaw, Poland
[2]Faculty of Mathematics and Physics, Charles University, Prague, Czech Republic

Summary A finite-strain phase-field model has been developed for the analysis of multivariant martensitic transformation in shape memory alloys (SMAs). The complete evolution problem is formulated within the incremental energy minimization framework, and its computational treatment is based on the finite-element method. The model has been applied to study the stress-induced martensitic transformation during nano-indentation. The study has revealed several interesting effects such as the pop-in effect associated with the martensite nucleation event and the energy-lowering breakdown of the symmetry of microstructure.

INTRODUCTION

Instrumented micro- and nano-indentation is a powerful and popular experimental technique, and thus it has been the subject of extensive computational modelling. This concerns also numerical simulations of indentation in SMAs. However, the studies reported in the available literature are limited to the macro- and meso-scales where either macroscopic phenomenological models or micromechanical crystal-plasticity-like models are used, which does not allow direct simulation of microstructure formation and evolution. On the other hand, atomistic simulations that employ the molecular dynamics (MD) models are limited to very small spatial and temporal scales. Apparently, continuum modelling of spatially-resolved martensitic microstructures in SMAs during nano-indentation is missing. Accordingly, our aim has been to fill this gap, and the phase-field method, which is a suitable approach at the relevant scales, has been adopted in this work. The respective model and the results of preliminary 2D simulations have already been published [1], while 3D simulations are the subject of ongoing work.

FINITE-STRAIN MULTIPHASE-FIELD MODEL

The model is an extension of our recent finite-strain phase-field model [2]. In particular, the multiphase double-obstacle potential [3] has been employed with the order parameters representing the volume fractions of the phases or martensite variants. The complete evolution problem is formulated as a constrained minimization problem for the global incremental potential that comprises the increments in potential energy and dissipation, the latter of the viscous type. The inequality constraints imposed on the order parameters as well as the unilateral contact constraints are then regularized using the penalty method, which leads to a straightforward finite-element implementation. Interestingly, a parametric study has shown that the penalty method performs surprisingly well for the problem at hand, also in the case of large-scale problems (with several million unknowns) solved using iterative solvers. In fact, simulation of multivariant transformations in 3D inevitably leads to large-scale problems. This is because the global unknowns comprise the nodal displacements and several order parameters and a uniform fine mesh is needed to accurately resolve the evolving diffuse interfaces.

MICROSTRUCTURE AND SIZE EFFECTS IN NANO-INDENTATION

Selected results of phase-field simulations of nano-indentation in pseudoelastic SMAs are shown in Figs. 1–3 and are briefly commented below. Preliminary studies have been carried out for a model problem of the square-to-parallelogram transformation in 2D with four variants of martensite. Fig. 1 shows the respective stress-induced microstructures for the indenter radius R varied between 25 nm and 100 nm. The colours in Fig. 1 indicate the domains occupied by the individual martensite variants according to the legend included in Fig. 1. The three microstructures in Fig. 1 correspond to the same normalized indentation depth $h/R = 0.6$, and the differences in shape and size result from the substantial effect of the interfacial energy which delivers a size-dependent contribution to the total free energy. It can also be seen that the microstructure corresponding to $R = 100$ nm is non-symmetric. It has been checked that the non-symmetric microstructure is energetically more favourable than the symmetric one, and it is not a numerical artifact.

Size effects are also illustrated in Fig. 2a which shows the normalized load P/R as a function of the normalized indentation depth h/R for three indenter radii R. The initial elastic response is size independent, however, the load at which martensite nucleates (which is associated with a load drop that leads to the characterisitc pop-in effect) and the subsequent response visibly depend on the indenter radius. Specifically, the normalized load needed to achieve a specified normalized indentation depth is higher for a smaller indenter radius. This is also visible in Fig. 2b which shows the dependence of the hardness on the indenter radius. Here, the hardness is determined for the fixed ratio of $h/R = 0.5$ and exhibits the usual indentation size effect (‘smaller is stronger’).

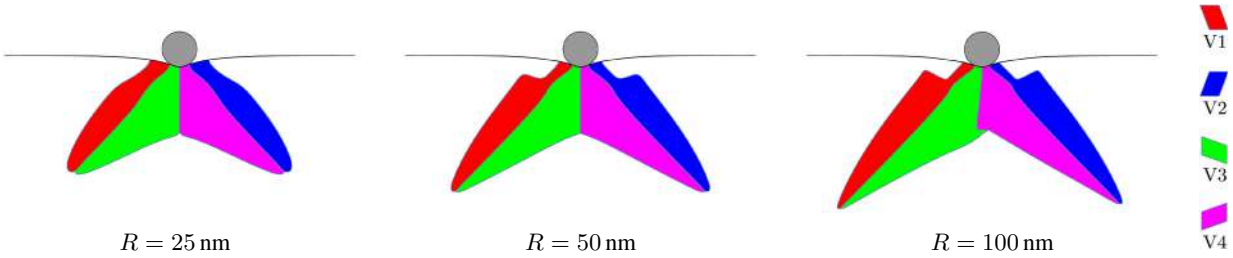

Figure 1: The effect of the indenter radius R on the microstructure for the square-to-parallelogram transformation in 2D [1].

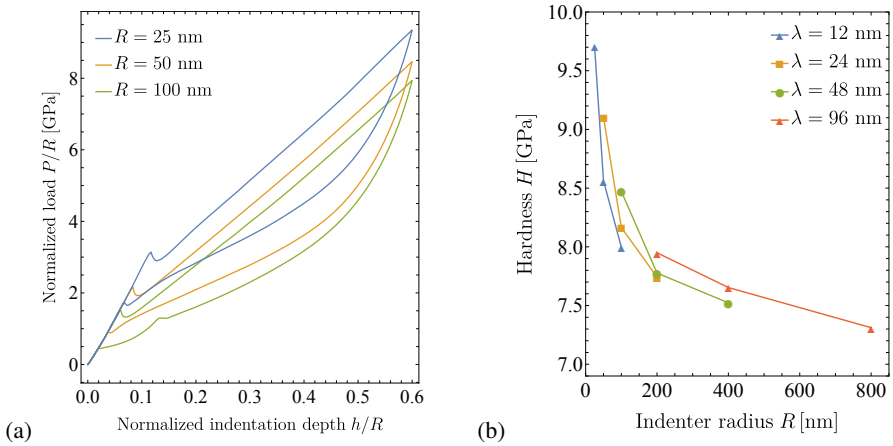

Figure 2: Size effects in nano-indentation: (a) normalized P–h curve; (b) dependence of the hardness on the indenter radius [1].

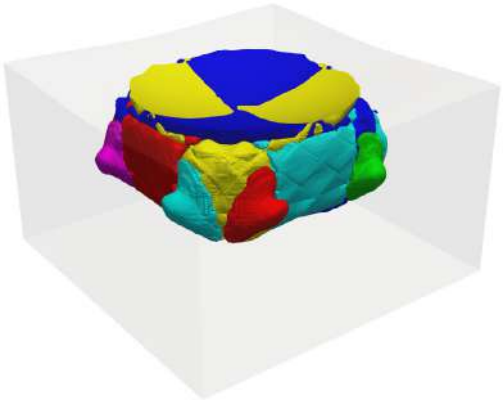

Figure 3: Stress-induced cubic-to-orthorhombic transformation in CuAlNi in nano-indentation, indenter radius $R = 200\,\text{nm}$.

Fig. 3 shows a 3D microstructure predicted for the cubic-to-orthorhombic transformation in a CuAlNi alloy for the indenter radius $R = 200\,\text{nm}$ and indentation depth $h = 28\,\text{nm}$ (the colours indicate the individual martensite variants, the austenite is transparent, the domain size is $280\times280\times160\,\text{nm}^3$). Note that there are six variants of martensite in this transformation, and thus six order parameters are needed in the respective phase-field model. The complete computational model involves thus nine global unknown fields that leads to a large-scale problem with about 10 million unknowns.

CONCLUSIONS

A finite-strain phase-field model has been developed for the analysis of multivariant martensitic transformation in SMAs. The model has been implemented in the finite-element code and successfully applied to simulate spatially-resolved microstructure evolution during nano-indentation revealing a number of important qualitative effects, including the size effects that are governed by the interfacial energy of phase boundaries.

Summary. Metastable austenitic steels show plastic strain driven transformation to martensite at low temperatures. We have developed a finite-strain coupled thermo-mechanical continuum theory to model this austenite-martensite phase transition and implemented the model in ABAQUS through a user material subroutine. Our simulation-based predictions show good agreement with full scale experiments on corrugated-pipe in the range of room temperature to cryogenic temperature.

INTRODUCTION/MOTIVATION

The mechanical properties of austenitic steels make them desirable for a wide range of applications ranging from automobile industry to extreme temperature applications [1-4]. Metastable austenitic steels with γ phase and face-centered cubic (FCC) crystal structure show *plastic strain driven phase transformation* to α'-martensite phase with body-centered cubic (BCC) structure and this effect becomes more prominent at cryogenic temperatures. In applications such as transport of liquefied natural gas (LNG) through flexible, pre-strained austenitic steel pipes, understanding the response of steel to complex thermomechanical loading is crucial to ensure the proper design and safety. Since the martensite phase is harder than the austenite phase, this transition results in a *second strain-hardening in the stress-strain* response. Following Olson's and Cohen's seminal contribution [5,6], we assumed the intersection of shear bands as nucleation sites for martensite embryos and modeled the temperature dependent evolution of martensite volume fraction. In this paper, we address an important gap by presenting a fully-coupled, finite-strain, continuum thermo-mechanical model for phase transitioning austenitic steels. Our model is capable of simulating complex thermomechanical loadings and loading histories that are typical in real applications. We implement our model in finite element software ABAQUS through a user material subroutine and validated the predictions by comparison with full scale experiments on corrugated pipes at both room and cryogenic temperatures.

KEY HIGHLIGHTS OF THE MODEL

Free Energy

$$\boldsymbol{F} = \boldsymbol{F}_{\gamma}^{e}\boldsymbol{F}_{\gamma}^{p} = \boldsymbol{F}_{\alpha'}^{e}\boldsymbol{F}_{\alpha'}^{p} \qquad \text{(Kröner – Lee Decomposition)}$$

$$\psi = \phi_{\gamma}\psi_{\gamma} + \phi_{\alpha'}\psi_{\alpha'} \qquad \text{(Voigt – type Composite)}$$

$$\psi_{\gamma} = G_{\gamma}\left|\boldsymbol{E}_{\gamma}^{e}\right|^{2} + \lambda_{\gamma}\boldsymbol{tr}\left(\boldsymbol{E}_{\gamma}^{e}\right)^{2} - \alpha_{th}\left(2G_{\gamma} + 3\lambda_{\gamma}\right)(\theta - \theta_{0})\boldsymbol{tr}\left(\boldsymbol{E}_{\gamma}^{e}\right) - \frac{C_{\gamma}}{2\theta_{0}}(\theta - \theta_{0})^{2} \qquad \text{(Free Energy Density)}$$

where $\boldsymbol{F}$ is the deformation gradient, $\boldsymbol{F^e}$ is the elastic part, $\boldsymbol{F^p}$ is the plastic part, subscripts γ, α' denote the phase. ψ denotes the free energy density, ϕ denotes the volume fraction of the phase, $\boldsymbol{E}$ is the Lagrange strain tensor, G is the shear modulus, λ is the Lamé constant, θ is the temperature, θ_0 is a particular reference temperature, α_{th} is the coefficient of thermal expansion, C is the heat capacity. Mathematical form for free energy expression for martensite is same as what is shown for austenite.

Stress

$$\boldsymbol{T} = \phi_{\gamma}\boldsymbol{T}_{\gamma} + \phi_{\alpha'}\boldsymbol{T}_{\alpha'} \qquad \text{(Cauchy Stress)}$$

$$\boldsymbol{T}_{\gamma} = J^{-1}\boldsymbol{F}_{\gamma}^{e}\frac{\partial\psi_{\gamma}}{\partial\boldsymbol{E}_{\gamma}^{e}}\boldsymbol{F}_{\gamma}^{e\,T} \text{ and } \boldsymbol{T}_{\alpha'} = J^{-1}\boldsymbol{F}_{\alpha'}^{e}\frac{\partial\psi_{\alpha'}}{\partial\boldsymbol{E}_{\alpha'}^{e}}\boldsymbol{F}_{\alpha'}^{e\,T};\ J = \det\boldsymbol{F}$$

where $\boldsymbol{T}$ is the Cauchy stress.

Flow Rule

$$\sqrt{3/2}\boldsymbol{M}_{\boldsymbol{0}}^{\boldsymbol{e}} = \left\{\phi_{\gamma}Y_{\gamma}\left(\bar{\epsilon}_{p}\right) + \phi_{\alpha'}Y_{\alpha'}\left(\bar{\epsilon}_{p}\right)\right\}\boldsymbol{N^p}$$

where $\boldsymbol{M}$ is the Mandel stress, Y is yield function, $\boldsymbol{N^p}$ is the direction of plastic flow.

Balance of Energy

$$C\dot{\theta} = -Div\,\boldsymbol{q} + \omega\left(\phi_{\gamma}\bar{\sigma}_{\gamma}\dot{\bar{\epsilon}}_{p\gamma} + \phi_{\alpha'}\bar{\sigma}_{\alpha'}\dot{\bar{\epsilon}}_{p\alpha'}\right) - l\dot{\phi}_{\alpha'}$$

where $\boldsymbol{q}$ is the heat flux, ω is the fraction of plastic work converted to heat, l is the latent heat due to martensitic phase transformation.

Hardening Behavior

$$\bar{\sigma}_{\gamma} = \bar{\sigma}_{Y\gamma} + K_{\gamma}\bar{\epsilon}_{p}^{m} \quad \text{and} \quad \bar{\sigma}_{\alpha'} = \bar{\sigma}_{Y\alpha'} + K_{\alpha'}\bar{\epsilon}_{p}^{n} \qquad \text{(Power – law hardening)}$$

where $\bar{\epsilon}_p$ is the equivalent plastic strain, $\bar{\sigma}$ is the equivalent tensile stress, and K, m, n are temperature-dependent strain-hardening parameters.

*Corresponding author. E-mail: vikas_srivastava@brown.edu.

Kinetics of Martensite Evolution

$$\dot{\phi}_{\alpha'} = (1-\phi_{\alpha'})\beta\dot{\phi}_{sb}^{a} \text{ and } \dot{\phi}_{sb} = (1-\phi_{sb})\alpha\dot{\epsilon}_{p} \quad \text{(From [5])}$$

where ϕ_{sb} and $\phi_{\alpha'}$ denote the volume fraction of shear bands and martensite respectively. α, β and a are parameters of the model that are obtained by fitting the predictions of the model to the experimental data.

RESULTS AND DISCUSSIONS

The parameters for the thermomechanical model were obtained from uniaxial tensile test data [7]. Figure 1 shows the fits and highlights the stark difference in stress-strain response and evolution of martensite volume fractions between the two temperatures. While there is no significant martensite formed at the room temperature, considerable martensite is produced at cryogenic temperature. Note the second strain hardening is well-captured in this model.

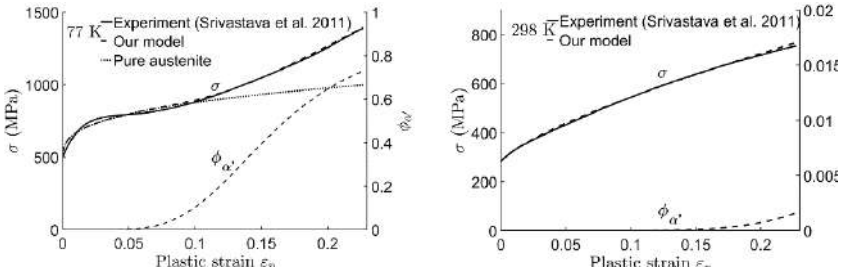

Figure 1. Model fit for 316L steel uniaxial tensile tests on flat dog-bone specimen at (a) room and (b) cryogenic temperatures. Left-axis: stress-strain curves. Right-axis: martensite evolution prediction by the model

Next, we evaluated the predictive capabilities of our model by carrying out tensile and compressive simulations of a full-scale C-pipe resulting in inhomogeneous local deformation and comparing the model predictions with experimental results. We replicated the steps involved in formation of the C-pipe as described in Figure 2. These steps were followed by tensile/compressive simulation and the results were compared with experiments. Figure 3 shows the force vs global strain response for tensile and compressive tests at both room and cryogenic temperatures. At 77 K, plastic straining produces a significant amount of martensite which makes the pipe stiffer than at 298 K. The figure shows good agreement between simulation predictions and experimental results.

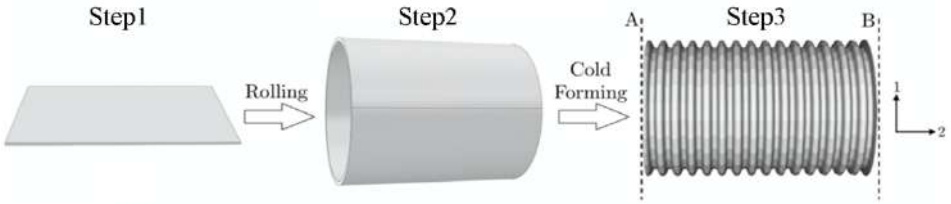

Figure 2. The steps involved in the manufacturing of the corrugated pipe.

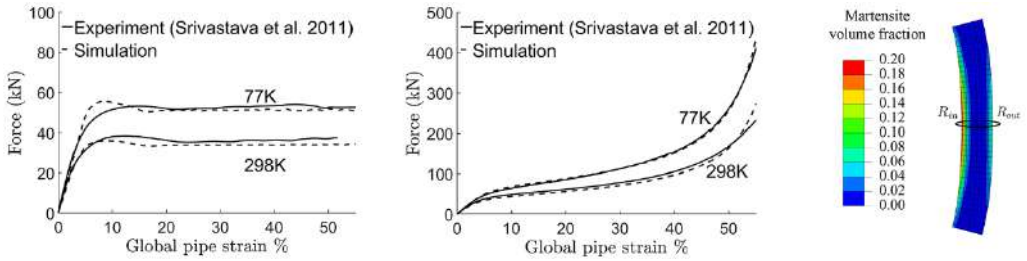

Figure 3. Force versus global pipe strain of a room temperature preformed C-pipe under (a) tensile load and (b) compressive load, (c) formed martensite across wall thickness of pipe corrugation under tension. In (a) and (b), simulation results (dotted lines) are plotted against experiments (solid lines) for room and cryogenic temperature.

Summary This work presents a three-dimensional phenomenological constitutive model considering plastic deformation and the two-way shape memory effect in severely pre-strained NiTi-based SMAs. A discussion about model calibration and implementation procedure within a finite element framework is addressed. Numerical responses for several loading conditions are compared against experimental results to validate the proposed modeling capabilities and to discuss the effect of plastic deformation on the one-way and two-way shape memory effect as well as on transformation temperatures.

INTRODUCTION

Shape Memory Alloys (SMAs) are smart materials possessing unique strain recovery capabilities due to reversible solid-state microstructural transitions, induced either by temperature changes or by mechanical loads, between a parent body-centered cubic phase (austenite) and a product monoclinic phase (martensite). Particularly, the two-way shape memory effect (SME) describes the ability of the SMA to change its shape reversibly during subsequent thermal cycles between its transformation temperatures under zero mechanical load. Such an effect is particularly exploited for the realization of dismountable and thermally-stable connection systems, operating without biasing elements [1].

The two-way SME is not a natural SMA feature, but can be induced in the material through a specific thermo-mechanical cyclic treatment (known as 'training' process) or a one-time martensite deformation. The latter treatment consists in deforming the SMA in the martensitic phase, unloading the material, and then in thermal cycling. Such a method generally causes two-way SME strains of limited magnitude; however, it has been shown by Liu et al. [2] that the two-way SME strains can be increased by imposing severe martensitic deformations, e.g., causing plastic yielding.

Differently from the two-way SME induced by training, the behavior induced by the one-time martensite deformation treatment has been less studied. In fact, to the authors' knowledge, no works from the current literature address the modeling of the effect of plastic deformation, occurring during severe martensitic pre-strain and possible subsequent constrained thermal cycles, on the two-way SME and on transformation temperatures.

The aim of the present work is to experimentally and numerically investigate plastic yielding and two-way SME in severely pre-strained SMAs. To this purpose, a three-dimensional constitutive model will be proposed and validated on experimental data from a performed experimental campaign. The assisted-design of fasteners and couplers will be presented and discussed.

METHODOLOGY

This work proposes to extend the three-dimensional small strain macroscopic phenomenological model by Souza et al. [3] to describe the response of severely pre-strained NiTi alloys.

Accordingly, in the framework of continuum thermodynamics with internal variables under small strain, two tensorial internal variables, i.e. the transformation strain and the plastic strain, are introduced to describe the macroscopic strain associated, respectively, to thermally-induced or stress-induced martensitic transformations and to plastic effects in SMAs. Constitutive equations and evolution laws are then written in a thermodynamically-consistent framework and a physical interpretation of model parameters is provided. Model equations are implemented within a finite element framework allowing for solving different boundary value problems. For the numerical implementation, the so-called Fischer–Burmeister complementarity function [4] is used since it allows to handle, in an easy way, complementarity inequality conditions deriving from physical constraints on internal variables and from the adopted yield surface-based formulation.

In order to calibrate and validate the model, an experimental campaign on a Ni rich NiTi alloy (50.8Ni-49.2Ti % at.) is performed. Uniaxial stress-free as well as constrained thermal recovery tests are carried out after mechanical pre-strain to measure both the transformation temperatures and shape recovery capabilities of the alloy, in terms of, e.g., one-way and two-way shape memory strains and recovery stresses.

*Corresponding author. E-mail: giulia.scalet@unipv.it.

RESULTS AND DISCUSSION

Several numerical simulations are performed, including uniaxial stress-free and constrained thermal recovery tests as well as finite element analyses for the assisted-design of a ring-shaped coupler and a C-shaped fastener (see Figure 1). Results from numerical simulations of uniaxial isothermal tests as well as free and constrained thermal recovery are validated through experimental data showing good agreement. Transformation temperatures as well as the two-way shape memory strain are shown to depend on the amount of plastic deformation obtained during pre-strain and unloading steps. Additionally, various aspects of SMA behavior, in particular low-stress phase transformations, phase-dependent material properties, and thermal strains, are also shown to affect the two-way SME.

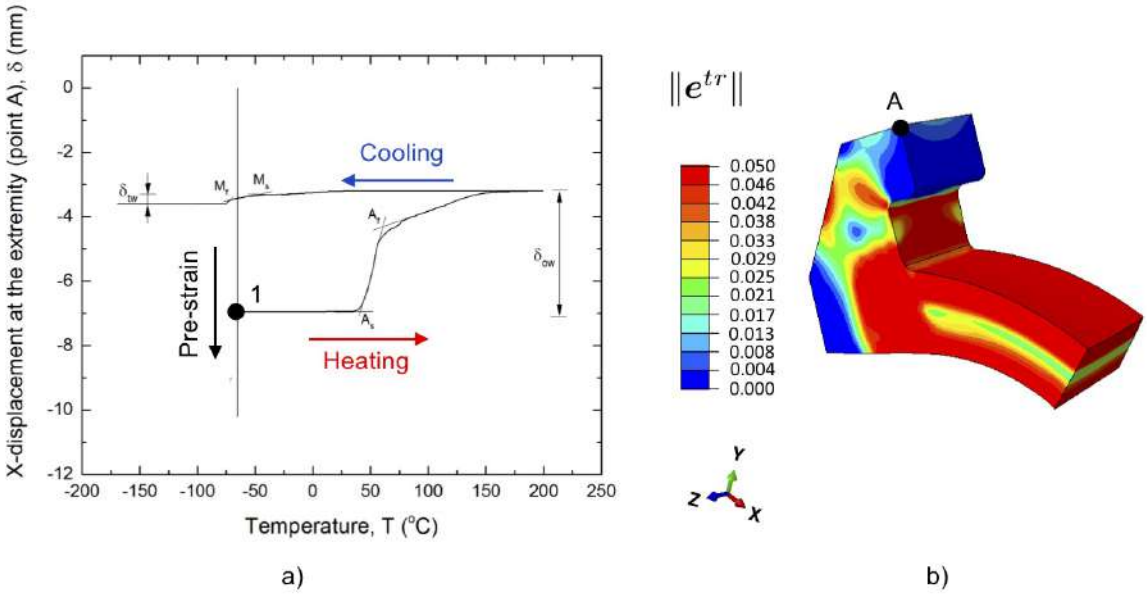

Figure 1: Finite element analysis of a C-shaped fastener. (a) Temperature-displacement diagram obtained after martensitic pre-strain, unloading, and subsequent stress-free heating and cooling cycle; (b) deformed mesh of half of the C-shape fastener after martensitic pre-strain and unloading with the contour plot of the norm of the transformation strain.

CONCLUSIONS

This paper has investigated the two-way SME and plastic effects in severely pre-strained SMA materials by formulating an extended three-dimensional macroscopic model. The achieved results demonstrate the possibility of using the model for the design of components under such a complex SMA material behavior.

THERMODYNAMICALLY CONSISTENT JOHNSON-COOK-LIKE MATERIAL MODEL IN COSSERAT MEDIA UNDER LARGE DEFORMATIONS FOR FUTURE MANUFACTURING SIMULATION

Raffaele Russo[1], Franck Girot Mata *[1,2], and Samuel Forest †[3]

Summary Simulations of manufacturing techniques involving metals deserve proper attention when material softening occurs. It is, in fact, well known that the classical set of equations governing the equilibrium yields to non-unique solutions when the material experiences softening. In this article we make use of the Cosserat theory as a possible solution to this problem. We present a Cosserat theory under a large deformation framework, enriched with a thermodynamically-consistent Johnson-Cook-like description of the material behavior. The theory has been used to simulate localization phenomena in a Hat-Shaped Specimen test.

MOTIVATIONS

Most metal transformation processes, such as machining, friction stir welding and superplastic forming, induce large deformations and high deformation rates in the material. In some cases, at high strain rate, and for specific metals, the deformation localizes into adiabatic shear bands, i.e. zones in which the material exothermically deforms, mostly by shear. At this location, the heat production rate due to plastic deformation may result larger than the heat diffusion rate, thus inducing the material to locally retain high temperature and to subsequently experience thermal softening.

Under these circumstances, the classical models used in Continuum Mechanics result to be inadequate to predict the deformation of the media and material behavior, and the causes lie in the loss of hyperbolicity of the *Partial Differential Equations* (PDE) governing the equilibrium [De Borst and Mühlhaus 1992]. This inadequacy appears as mesh dependency if these PDEs were to be discretized through *Finite Element Methods* (FEMs). The set of PDEs therefore requires a regularization method. One possible solution involves the introduction of non-local quantities at the constitutive law level (gradient-enhanced models). Among many other possible candidates, in the current work we decided to employ a Cosserat description of the media to solve the problem.

The Cosserat description of the media is a generalization of the classical continuum mechanical model, in the specific, the Cosserat brothers [E. Cosserat and F. Cosserat 1909] provided a model in which the microstructural rotation is decoupled from the material rotation. In the classical models instead, by adopting the point of view of the Cosserats, the microstructure rotation follows inertially the material rotation.

Within our scopes, the Cosserat model would allow us to enlarge the domain in which the ellipticity of the PDEs is retained, thus avoiding problems related to non-uniqueness of the solution and mesh dependency when metal manufacturing processes ought to be simulated. This is achieved through the adoption of the gradient of the microrotation as an additional deformation measure, consequently introducing a characteristic length in the model.

Another fundamental feature introduced by the adoption of the Cosserat model is that we are able to characterize the material response with more sophisticated models. The microstructural rotation and its gradient are used as additional deformation measures, thus contributing in defining the constitutive behavior of the material.

MODEL DESCRIPTION

The hyper-elastic version of the Cosserat model can be initially described by explicitly stating the definition of the internal power $p^{(i)}$ as:

$$p^{(i)} = \underset{\sim}{\sigma} : (\underline{\mathbf{v}} \otimes \underline{\nabla} - \underset{\sim}{\omega}) + \underset{\sim}{\mathbf{m}} : \left(\overset{\times}{\underline{\omega}} \otimes \underline{\nabla}\right); \tag{1}$$

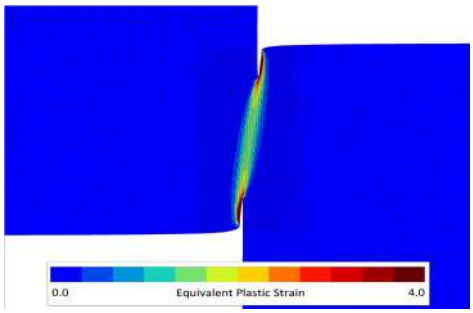
where $\underset{\sim}{\sigma}$ is the non-symmetric stress tensor, $(\underline{\mathbf{v}} \otimes \underline{\nabla} - \underset{\sim}{\omega})$ is the Cosserat strain rate, $\underset{\sim}{\omega}$ is the skew-symmetric matrix created from the pseudo-vector of the microstructure rotation velocity, $\underset{\sim}{\mathbf{m}}$ is the couple stress tensor and $\left(\overset{\times}{\underline{\omega}} \otimes \underline{\nabla}\right)$ is the Cosserat wryness rate.

The Cosserat deformations, indicated with a sharp sign, can be written according to the Lagrangian description as:

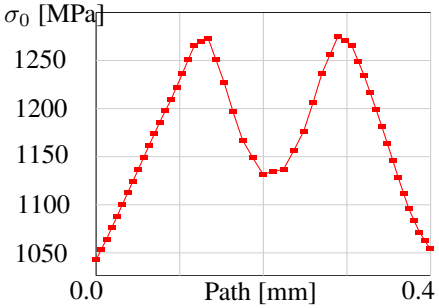
$$^{\sharp}\mathbf{F} = \underset{\sim}{\mathbf{R}}^T \cdot \underset{\sim}{\mathbf{F}}; \tag{2}$$

$$^{\sharp}\mathbf{\Gamma} = \underset{\sim}{\mathbf{R}}^T \cdot \underset{\sim}{\Gamma}; \tag{3}$$

*Corresponding author. E-mail: frank.girot@ehu.eus.
†Corresponding author. E-mail: samuel.forest@mines-paristech.fr.



(a)



(b)

Figure 1: Equivalent plastic strain distribution at the localization band during Hat-Shaped specimen test under compression **(a)** and flow stress distribution along the cross section passing through the shear band**(b)**.

where $\underset{\sim}{\mathbf{F}}$ is the deformation gradient, $\underset{\sim}{\mathbf{R}}$ is the rotation matrix describing the microstructure rotation and $\underset{\sim}{\mathbf{\Gamma}}$ is the Cosserat wryness. To provide a robust material characterization, the constitutive response of the hyper-elastic model is derived from the Helmholtz free energy, which we defined as:

$$\rho\psi\left({}^{\sharp}\underset{\sim}{\mathbf{F}}, {}^{\sharp}\underset{\sim}{\mathbf{\Gamma}}\right) = \frac{\lambda}{2}\left(\mathrm{J}-1\right)^2 + \mu||\mathrm{sym}\left({}^{\sharp}\underset{\sim}{\mathbf{F}}\right) - \underset{\sim}{\mathbf{I}}||^2 + \mu_c||\mathrm{skew}\left({}^{\sharp}\underset{\sim}{\mathbf{F}} - \underset{\sim}{\mathbf{I}}\right)||^2 + \frac{\beta}{2}||\,{}^{\sharp}\underset{\sim}{\mathbf{\Gamma}}||^2; \tag{4}$$

Work has already been done on a thermodynamically-consistent visco-plastic material model in the small deformation framework. A Johnson-Cook-like model has been implemented in the Cosserat theory where the thermal variation is evaluated through a robust thermodynamic approach. The Taylor-Quinney coefficient, built on assumptions that are not valid anymore for our applications, has been replaced with an explicit evaluation of the contribution of the plastic work to the thermal variation:

$$\dot{T} = \frac{\left(\underset{\sim}{\boldsymbol{\sigma}} : \dot{\underset{\sim}{\mathbf{e}}}^p + \underset{\sim}{\boldsymbol{\mu}} : \dot{\underset{\sim}{\mathbf{k}}}^p - \frac{\partial\psi_\alpha}{\partial p}\dot{p}\right)}{\rho\left[C_\varepsilon + \frac{\partial C_\varepsilon}{\partial T}\left(T - T_0\right)\right]}; \tag{5}$$

The Equations of the hyper-elastic model above have been first simplified such that only one rotation is allowed (bi-dimensional rotation) while keeping a full three dimensional displacement field, and then they have been discretized such as to be implemented in a Finite Element solver. Finally, the thermodynamically-consistent Johnson-Cook-like model has been implemented in the theory.

RESULTS

By simulating the compression of a Hat-Shaped Specimen [Peirs et al. 2010], it has been shown that the Cosserat theory is a possible solution to the mesh dependency problem (Figure 1a), but, more importantly, it has also been shown that the theory can simultaneously predict material viscous hardening and thermal softening (Figure 1b).

The results of the on-going work will be presented at the ICTAM in August. In particular, a similar thermodynamically consistent visco-plastic model will be implemented in the large deformation framework, and it will be subsequently calibrated through the Hat-Shaped specimen test, in which it will also be possible to identify the effect of the characteristic length of the model.

Summary The growth of the intermetallic compound of copper and tin in tin-based solders is modeled based on the chemical affinity tensor, which determines the configurational force driving the growth. The influence of temperature and mechanical stresses arising during operation of the soldered parts on the growth kinetics is studied. A high temperature storage experiment with microprocessor chips containing tin solder is carried out. The results of numerical modeling are compared with the obtained experimental data.

INTRODUCTION

The present work is devoted to the study of IMC (Intermetallic Compound) formation of tin (Sn) and copper (Cu) in tin-based solders, which are widely used in the microelectronic industry. These intermetallic phases are more brittle in comparison with pure metals. Therefore, during cyclic temperature loading, due to the difference in the coefficients of thermal expansion and elastic moduli, defect nucleation and destruction may arise. Predicting the growth kinetics of the intermetallic phase, in particular under temperature loading, mainly allows to determine the life of microelectronic elements.

The formation of intermetallic compounds is the result of diffusion and chemical processes [1]. Morphological changes during the formation of the intermetallic phase are accompanied by transformation strains, which, together with the change of temperature, cause mechanical stresses. In addition, during use of the microelectronic component, soldered joints are also subjected to shear stresses [2] due to different coefficients of thermal expansion of the substrate and the microchip. Thus, the growth of intermetallic compounds occurs under conditions of varying temperatures, varying thermal stresses, and cyclic external shear loads. Such complex loading affects the kinetics of the intermetallic compounds growth.

In the present work, the influence of mechanical stresses on the copper and tin intermetallic phase growth kinetics is modelled using the chemical affinity tensor concept [3, 4, 5]. A set of problems with various loading scenarios is modeled numerically and analytically. The effect of temperature loading on the kinetics of the IMC transformation front is studied. A quantitative evaluation of the proposed model was carried out according to the experimental results [6] obtained by heat treatment of the microchips with solder bumps at a constant high temperature [7].

THE KINETICS OF IMC FORMATION FRONT

The growth of the intermetallic phase is determined by by two chemical reactions taking place at two propagating reaction fronts:

$$6\ \mathrm{Cu} + 5\ \mathrm{Sn} \longrightarrow \mathrm{Cu_6Sn_5}, \qquad 3\ \mathrm{Cu} + \mathrm{Sn} \longrightarrow \mathrm{Cu_3Sn}. \tag{1}$$

The influence of mechanical stresses on the reaction front velocity are modelled using the chemical affinity tensor concept. According to this concept, the chemical reaction occurs at the sharp interface on the oriented surface element with the reaction rate expressed by

$$\omega = k_* c \left(1 - \exp\left(-\frac{\mathrm{A_{NN}}}{RT}\right)\right), \tag{2}$$

where k_* is the kinetic parameter of the chemical reaction, c is the concentration of the diffusing component (copper or tin atoms, depending on the chemical reaction under consideration) at the front of the chemical reaction, R is the universal gas constant, T is the temperature, $\mathrm{A_{NN}}$ is the normal component of the chemical affinity tensor, which in turn is a linear combination of chemical potentials. The normal component of the chemical affinity tensor can be expressed in terms of stresses and strains at the reaction front [4, 5, 8]:

$$\mathrm{A_{NN}} = \frac{n_- M_-}{\rho_-}\left(\gamma - [\![W]\!] + \mathbf{P}_-^{\mathrm{T}} : [\![\mathbf{F}]\!]\right) + n_* RT \ln\frac{c}{c_*}, \tag{3}$$

where M_- and ρ_- are the molar mass and mass density of the initial phase, n_- is a stoichiometric coefficient from (1), W is a Helmholtz free energy of the solid constituent, $\mathbf{P}$ is a first Piola-Kirchhoff stress tensor, $\mathbf{F}$ is a deformation gradient. In (3), the indices $-$, $+$ and $*$ refer to the initial solid phase, the final reaction product and the diffusive component (e.g.,

*Corresponding author. E-mail: morozov@tu-berlin.de.

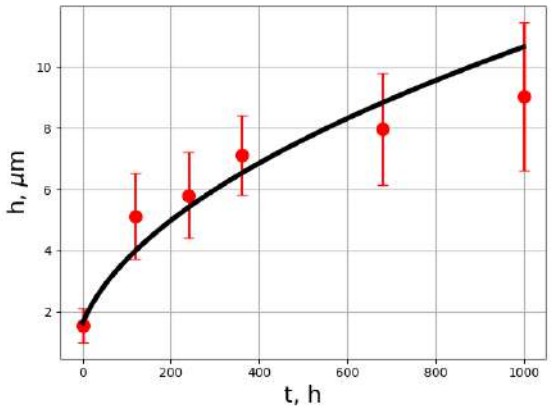

Figure 1: Cu_6Sn_5 phase growth kinetics. Comparison of the analytical (solid line) and experimental (dots with error bars) results.

Sn, Cu_6Sn_5 and Cu, respectively, for the reaction occurring at the boundary between IMC and tin). Square brackets denote the jump of a value across the reaction front $[\![\phi]\!] = \phi_+ - \phi_-$.

The simple problem for planar interface and linear elastic solid reactants was solved in order to validate material, diffusion and chemical reaction parameters used in (2)-(3) quantitatively. Comparison of theoretical and analytical thickness of the IMC layer during the high temperature storage test is shown in Fig. 1.

The numerical procedure for modeling the moving interface is based on the finite element method, which is used to determine the stresses, strains and the corresponding concentration at the reaction front. The propagation of the chemical interface is realized with a remeshing technique, similarly to [8, 9].

CONCLUSIONS

The growth of the Cu_6Sn_5 intermetallic compound was modeled analytically and numerically for various loading scenarios. The effects of high temperature during the storage test and temperature cycling on the IMC growths kinetics were studied. It has been shown experimentally that the intermetallic phase growth occurs non-uniformly along the interface of materials. The developed experimental method allows to measure the local change of layer thickness, which in turn leads to the evaluation of the kinetics of intermetallic growth in a specific area of the sample. The experimental results were used to determine the kinetic parameters in the chemical affinity tensor model for the first time.

[2]Institute of Mechanics and Fluid Dynamics, TU Bergakademie Freiberg, Freiberg, Germany
[3]Division of Solid Mechanics, Lund University, Lund, Sweden

Summary The macroscopic behaviour of ferroic functional materials such as magnetic shape memory alloys (MSMA) is highly affected by mechanisms at the microscale which drive the formation and further evolution of microstructures. The following mechanisms shall be taken into account within this contribution: (i) domain wall motion in terms of evolving domain volume fractions, (ii) local spontaneous magnetisation vectors (in each domain) that may rotate away from their respective easy axis, and (iii) variant switching in terms of evolving variant volume fractions. The material model is embedded into a fully magnetomechanically coupled finite element framework. This particularly allows the numerical analysis of the behaviour of arbitrarily shaped MSMA specimen where the demagnetisation tensor concept is no longer applicable, respectively valid.

VARIATIONAL FRAMEWORK

The material model is embedded into a variational framework, where the underlying field variables are the displacements $\boldsymbol{u}$, the magnetic field strength $\boldsymbol{h}$, and the magnetisation $\boldsymbol{m}$. The magnetic field strength $\boldsymbol{h} = \overline{\boldsymbol{h}} + \widetilde{\boldsymbol{h}}$ is decomposed into a prescribed contribution $\overline{\boldsymbol{h}}$ and a part referred to as the demagnetisation field $\widetilde{\boldsymbol{h}}$. Furthermore, the latter contribution is related to a scalar-valued magnetic potential $\widetilde{\phi}$ in terms of a gradient field, namely $\widetilde{\boldsymbol{h}} := -\nabla_{\boldsymbol{x}}\widetilde{\phi}$. In the present modelling approach, the magnetisation $\boldsymbol{m}$ does not appear as independent variable but shall be parametrised by state variables introduced in general form as $\boldsymbol{p}$, so that $\boldsymbol{m} = \widehat{\boldsymbol{m}}(\boldsymbol{p})$. Hence, the field variables used in the proposed framework are $\boldsymbol{u}$, $\widetilde{\phi}$, and $\boldsymbol{p}$. As a basis for the forthcoming finite element formulation, the micromagnetics-inspired energy-enthalpy function

$$\mathit{\Pi} := \int_{\mathcal{B}} \psi(\nabla_{\boldsymbol{x}}\boldsymbol{u}, \boldsymbol{p}) \, \mathrm{d}V - \frac{\mu_0}{2} \int_{\mathbb{R}^3} \|\nabla_{\boldsymbol{x}}\widetilde{\phi}\|^2 \, \mathrm{d}V - \mu_0 \int_{\mathcal{B}} \left[\overline{\boldsymbol{h}} - \nabla_{\boldsymbol{x}}\widetilde{\phi}\right] \cdot \boldsymbol{m}(\boldsymbol{p}) \, \mathrm{d}V - \int_{\partial\mathcal{B}} \overline{\boldsymbol{t}} \cdot \boldsymbol{u} \, \mathrm{d}S \tag{1}$$

is utilised. To take dissipation into account, this function is embedded into the power-type potential

$$\mathcal{L} := \dot{\mathit{\Pi}} + \int_{\mathcal{B}} \zeta(\dot{\boldsymbol{p}}, \boldsymbol{p}) \, \mathrm{d}V \, , \tag{2}$$

wherein $\zeta(\dot{\boldsymbol{p}}, \boldsymbol{p})$ represents the dissipation function and $\dot{\bullet}$ denotes the time derivative. Applying the stationarity principle

$$\left\{\dot{\boldsymbol{u}}, \dot{\widetilde{\phi}}, \dot{\boldsymbol{p}}\right\} = \arg\left[\min_{\dot{\boldsymbol{u}}} \max_{\dot{\widetilde{\phi}}} \min_{\dot{\boldsymbol{p}}} \{\mathcal{L}\}\right] \tag{3}$$

enables us to derive the localised balance equations, Neumann-type boundary conditions as well as the Biot-type evolution equations for $\boldsymbol{p}$. The first variation of the potential $\mathcal{L}$ with respect to the rates $\dot{\boldsymbol{u}}$, $\dot{\widetilde{\phi}}$, and $\dot{\boldsymbol{p}}$ is the basis for the subsequent finite element formulation, since the related set of equations corresponds to the weak form of the balance equations.

CONSTITUTIVE FRAMEWORK

The material model is governed by the definition of the energy density ψ, which generally depends on the displacement gradient and the magnetisation, and which is designed to capture the behaviour of an MSMA single crystal with tetragonal martensite variants. Therefore, variant volume fractions ξ_i with $i = 1, \ldots, 3$ as well as domain volume fractions α_j with $j = 1, \ldots, 6$ are introduced. For each domain, a specific energy density

$$\psi_j := \tfrac{1}{2}\left[\boldsymbol{\varepsilon}_j - \boldsymbol{\varepsilon}_j^{\mathrm{tr}}\right] : \mathbf{E}_j : \left[\boldsymbol{\varepsilon}_j - \boldsymbol{\varepsilon}_j^{\mathrm{tr}}\right] + K\left[1 - \left[\frac{1}{m_s}\boldsymbol{m}_j^{\mathrm{dom}} \cdot \boldsymbol{n}_j^{\mathrm{ea}}\right]^2\right] , \quad j = 1, \ldots, 6 \, , \tag{4}$$

is defined, which consists of an elastic contribution and a part related to the magnetocrystalline anisotropy energy. Here, $\boldsymbol{\varepsilon}_j$ denotes the total strain in each domain, $\boldsymbol{\varepsilon}_j^{\mathrm{tr}}$ is the Bain strain for each martensite variant, $\mathbf{E}_j$ the fourth order elasticity tensor, K is a material constant related to the magnetocrystalline anisotropy energy, and m_s is the saturation magnetisation. The vector $\boldsymbol{m}_j^{\mathrm{dom}}$ with $\|\boldsymbol{m}_j^{\mathrm{dom}}\| = m_s$ denotes the local spontaneous magnetisation in each domain being initially aligned with the so-called easy axis $\boldsymbol{n}_j^{\mathrm{ea}}$. In this regard, the second term in (4) can be interpreted as a penalisation for the

The additional lines reflect isolines of the magnetic potential ϕ.

magnetisation when rotating away from the respective easy axis. It is remarked that the quantities referring to the first energy term are identical for each martensite variant, i.e. $\varepsilon_1 \equiv \varepsilon_2$, $\varepsilon_3 \equiv \varepsilon_4$, $\varepsilon_5 \equiv \varepsilon_6$, which analogously holds for the related Bain strains and elasticity tensors.

The total linearised strains for each variant generally differ from each other. The precise relations among them is governed by a specific homogenisation assumption, where we follow two different methods, namely (i) an approach based on first order laminates, and (ii) an approach based on convexification. In general, a mixture rule according to

$$\psi := \sum_{j=1}^{6} \alpha_j \, \psi_j \tag{5}$$

is applied in order to define the energy density. To complete the constitutive framework, the magnetisation has to be specified as a function of $\boldsymbol{p}$ which is chosen as

$$\boldsymbol{m}(\boldsymbol{p}) := \sum_{j=1}^{6} \alpha_j \, \boldsymbol{m}_j^{\mathrm{dom}} \, . \tag{6}$$

FINITE ELEMENT IMPLEMENTATION

The magnetomechanically fully coupled constitutive framework does not allow a condensation of certain variables to integration points. Thus, all state variables, i.e. the variant and domain volume fractions as well as the local magnetisation vectors (in case of the convexification approach), have to be treated as global fields in addition to $\boldsymbol{u}$ and $\widetilde{\phi}$. In this regard, it is noteworthy that shape functions with different polynomial order have to be used to avoid oscillations in the solutions of the resulting fields. Furthermore, different degrees of freedom are present in the material body and the surrounding free space which also affects the finite element formulation. Another important aspects is exemplified in the fact, that the evolution of state variables is subjected to several equality and inequality constraints. Hence, the associated Karush-Kuhn-Tucker system has to be solved at each node of the finite element mesh.

Results

The overall magnetomechanically fully coupled framework is capable of analysing inhomogeneous problems — which mainly refer to arbitrarily shaped specimens — and predicting the spatial distributions of, e.g., the magnetisation and martensite variants, as well as the averaged sample response in terms of, e.g., strains and magnetisation, cf. Fig. 1.

Summary Sintering is a thermomechanical degradation process driven by surface and grain boundary energy. During extended exposure to elevated temperature in gas turbines, thermal barrier coating systems go through such process, resulting in losses of strain tolerance and thermal protection capacity. To counteract the thermomechanical degradation, strain tolerant structures were proposed and implemented in conventional lamellar-structured coating. In-situ bending tests at 1200 °C indicated improvements in both compliance and sintering resistance. A mass diffusion-based constitutive model was further formulated by variational principle and integrated in finite element analysis through user defined subroutines, confirming the significance of strain tolerant structures. This work shed light on the concept of structure design for the progress of coating technology.

BACKGROUND

Thermal barrier coating systems (TBCs) represent the cutting-edge thermal protection techniques in advanced gas turbines. With the increase of inlet gas temperature for thermal efficiency improvement, accelerated mass diffusion driven by surface and grain boundary energy leads to healing of microcracks and densification of porous structure, which deprives strain tolerance towards thermal shock and thermal insulation to hot gas. This thermomechanical degradation process, also known as sintering, is especially detrimental to conventional plasma-sprayed TBCs with limited strain tolerance due to the nature of lamellar microstructure. Rare-earth elements have been doped to improve sintering resistance at high costs. Alternatively, structure design has been proved to be an efficient way to counteract sintering induced thermomechanical degradation, as noted in our previous work [1].

Sintering of TBCs has been addressed by experimental characterizations of microstructure and property evolutions. The state-of-the-art method integrates bending or indentation test in high temperature field for in-situ evaluation of mechanical properties during sintering. In addition, a few mechanism-based sintering models have been proposed for lamellar-structured TBCs. Employing variational method, Clyne's group obtained structural and thermal conductivity evolutions [2], while constitutive models were proposed by Cocks and Fleck [3]. Nevertheless, in-depth analyses of the sintering behaviour of TBCs with strain tolerant structures require the integration of experimental, theoretical and numerical methods, which is the main purpose of this work.

METHODS AND MODELS

Four types of TBC samples with different strain tolerant structures were prepared via air plasma spray (APS) and suspension plasma spray (SPS) approaches, including micro-cracked APS TBC (Mc. APS), segmented APS TBC (Sg. APS), columnar structured SPS TBC (CS SPS), and vertically cracked SPS TBC (VC SPS). After the deposition of TBC on bond-coated substrate, samples were laser cut into millimetre-scaled rectangular bars at high precision and electrochemically etched to obtain free-standing TBC eliminating damage to strain tolerant structures during detaching. Confocal white light inspection system was utilized for high-resolution characterizations of dimension and interfacial topography, while microstructure examinations of polished and fractured cross-sections were performed by scanning electron microscopy (SEM) with image analyses. Thermo-mechanical analysis (TMA) was conducted by in-situ three-point bending test equipped with graphite furnace at 1200 °C. More details can be found in ref [4].

A constitutive model was developed for VC SPS TBC by variational principle through the derivation of system energy functional, considering sintering induced mass diffusion on free surface and grain boundary. Based on experimentally observed microstructure features (Figure 1(e)), rectangular grains were assumed with microcracks in between and partially connected by sintering necks, composing large lamellar structures with circular pores at boundary due to the layer-by-layer deposition of liquid feedstock made of nanopowders, as illustrated in Figure 1(f). Taking two separated grains as the reference energy state, the introduction of a single sintering neck, under a prescribed force f across the neck with the height of w, leads to an increase in the free energy G,

$$G = \int \gamma_{SUR} \mathrm{d}A_{SUR} + \int \gamma_G \mathrm{d}A_G - fw \tag{1}$$

where γ_{SUR} and γ_G are surface and grain boundary energy, respectively, with A_{SUR} and A_G being the corresponding area. For the energy dissipation due to mass diffusion, the potential Ψ is expressed in terms of mass fluxes J_{SUR} and J_G,

$$\Psi = \int J_{SUR}^2 / 2D_{SUR} \mathrm{d}A_{SUR} + \int J_G^2 / 2D_G \mathrm{d}A_G \tag{2}$$

where D_{SUR} and D_G are surface and grain boundary diffusion coefficients, respectively. During sintering, the system evolves so as to minimize the functional $\Omega(\dot{w}) = \dot{G} + \Psi$, where the point denotes time differentiation. The minimization

*Corresponding author. E-mail: wangtj@mail.xjtu.edu.cn (Tiejun Wang), fangdn@bit.edu.cn (Daining Fang)

relates the prescribed force f to neck deformation rate $\dot{w}$ and sintering force $f_{SIN(1)}$, satisfying mass conservation. Local deformation and force are converted to global strain and stress by consistency conditions. Taking account of the sintering stress contribution by circular pores $\sigma_{(2)}^{SIN}$, the constitutive relation reads

$$\{\varepsilon\}=[C]\{\sigma\}+[\Lambda]^{-1}\{\sigma\}-[\Lambda]^{-1}\left(\{\sigma_{(1)}^{SIN}\}+\{\sigma_{(2)}^{SIN}\}\right) \quad (3)$$

with [C] being the compliance matrix, [Λ] the viscous matrix, $\dot{\varepsilon}$ the strain rate and $\dot{\sigma}$ the stress rate. Subscripts (1) and (2) refer to the two domains without and with pores, respectively. Eq. (3) is rewritten in incremental form and implemented in finite element analysis (FEA) by programing user defined subroutines. Through-thickness vertical cracks of VC SPS were modelled in FEA, as shown in Figure 1(g).

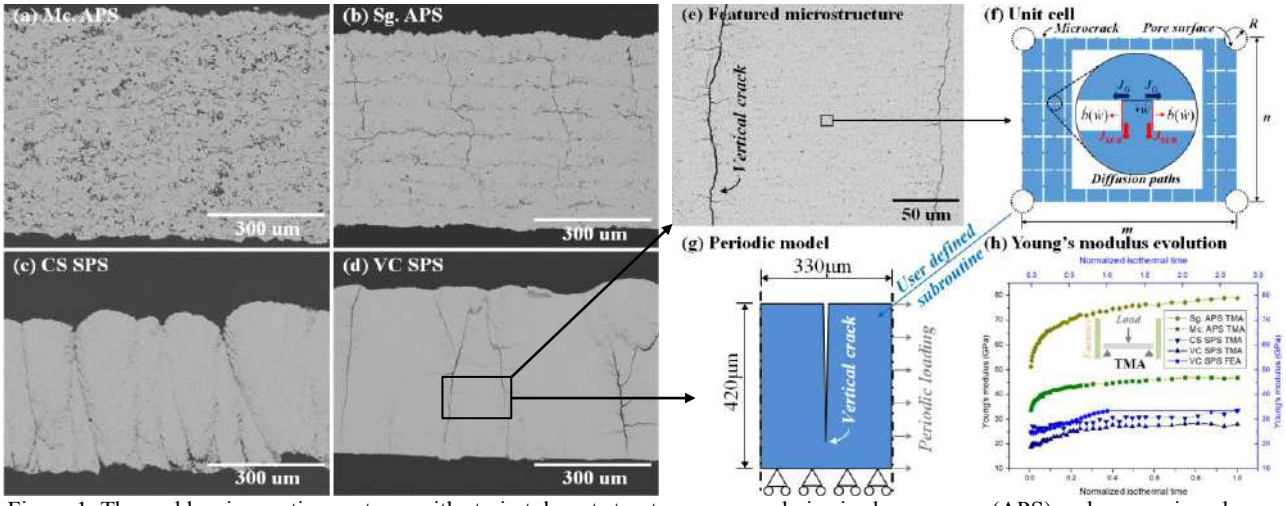

Figure 1. Thermal barrier coating systems with strain tolerant structures prepared via air plasma spray (APS) and suspension plasma spray (SPS) approaches: (a) micro-cracked (Mc.) APS; (b) segmented (Sg.) APS; (c) columnar structured (CS) SPS; (d) vertically cracked (VC) SPS; (e) featured microstructure of VC SPS; (f) unit cell with mass diffusion paths; (g) periodic model for finite element analysis (FEA); (h) sintering induced Young's modulus evolution obtained by thermomechanical analysis (TMA) and FEA.

MAIN RESULTS

TBCs with inter-columnar gaps and vertical cracks (Figure 1(c) and (d)) exhibited simultaneously improved strain tolerance and sintering resistance, according to experimental (TMA) and numerical (FEA) results. Young's modulus level was reduced by around 50% due to the introduction of strain tolerant structures, comparing the TMA results of CS and VC SPS with those of Mc. APS (Figure 1(h)). Significant reduction in Young's modulus level was confirmed by FEA with and without vertical cracks. Although the coating structure between two adjacent cracks/gaps had lower porosity level than the conventional coating (e.g. ~3% for VC SPS and ~12% for Mc. APS), relatively high crack/gap density (4 mm^{-1} for VC SPS and 7 mm^{-1} for CS SPS) provided extra strain tolerance by crack/gap opening. Regardless of coating structure, sintering induced stiffening of all the four TBCs well followed a power law, $E=E^{*}\cdot t^{S}$, with E being Young's modulus, E^{*} being characteristic modulus, t being isothermal sintering time and S being stiffening index. The stiffening index S is simple and elegant with clear physical interpretation as the slope of Young's modulus curve in log-log plot. It is proposed as a new evaluation parameter of sintering resistance for scientific and engineering applications.

In addition to stiffening induced by sintering, multi-scale structure evolution was elucidated by FEA. Mass diffusion driven by surface and grain boundary energy resulted in two-staged flattening of sintering neck and microcrack healing due to transversely anisotropic grain geometry at microscopic scale. Consequently, different coating shrinkage behaviours were predicted in horizontal and vertical directions at macroscopic scale. In brief, the two-staged neck flattening was responsible for non-uniform coating densification.

CONCLUSIONS

A new approach of structure design was proposed and examined to counteract thermomechanical in-service degradation of lamellar-structured TBCs at elevated temperature. Strain tolerance and sintering resistance were improved by introducing through-thickness vertical cracks and inter-columnar gaps, indicated by both in-situ bending tests and mass diffusion-based numerical analyses. Neck flattening driven by mass diffusion resulted in non-uniform densification and stiffening that followed power law. Furthermore, a new parameter, stiffening index S, was proposed for the evaluation of sintering resistance of TBCs.

A GENERAL VARIATIONAL FRAMEWORK FOR THE THERMOMECHANICS OF GRADIENT-TYPE DISSIPATIVE SOLIDS INCLUDING STABILITY ANALYSIS

Marc-André Keip *[1] and Stephan Teichtmeister[1]
[1]Institute of Applied Mechanics (CE), Chair I, University of Stuttgart, Stuttgart, Germany

Summary We present a variational framework for the thermomechanical coupling in gradient-extended dissipative solids at large deformations. Such intrinsically symmetric formulations provide an elegant way to couple different macro- as well as microscopic fields. The key of the discussed formulation is the identification of the entropy as well as the entropy rate as the canonical variables on the energetic and dissipative side, respectively. By rigorous treatment of dual variables, extended variational formulations can be derived that are attractive for a numerical treatment by the finite element method. As model problem we consider additive thermo-gradient-plasticity and show representative numerical examples that are related to classical shear band formations. We further discuss the stability of homogeneous thermoplastic solutions in a one-dimensional tensile bar undergoing small deformations.

GENERAL MOTIVATION

Beside energy storage, the dissipation of mechanical work into heat is the fundamental process in solid materials. This energy conversion stems from kinematic changes in the material's microstructure such as the movement of dislocations which manifests oneself in plastic deformations or the irreversible growth of micropores resulting in damage. To model the physical coupling of different micro- as well as macroscopic quantities, incremental variational formulations provide a very elegant way. If such are available, implementations into typical finite element codes essentially require first and second derivatives of the underlying potential density with respect to the state variables resulting into *symmetric* algebraic systems. In this talk, we present a general variational framework for the thermomechanics of *gradient-extended* dissipative solids undergoing large deformations. It is an extension of the isothermal theory presented in [1] towards the evolution of thermal states in the solid with non-local effects based on length scales.

VARIATIONAL FORMULATION OF THERMOMECHANICS IN GRADIENT-TYPE SOLIDS

Point of departure is the the definition of two constitutive functions, namely the internal energy function formulated in terms of the entropy and a canonical dissipation potential function that is assumed to depend on the entropy rate. Then, the evolution of the macro- and micromotion fields $\boldsymbol{\varphi}$ and $\mathfrak{q}$ as well as the evolution of the entropy η are governed by a *canonical minimization principle*. However, since the explicit forms of the introduced internal energy and dissipation potential functions are in general unknown an extended formulation with the temperature (dual to the entropy) and a thermal driving force (dual to the entropy rate) as additional fields is introduced via generalized Legendre transformations. The obtained time-continuous saddle point principle is in line with the seminal work [2] on the variational treatment of local thermoplasticity.

By construction of consistent time integration algorithms, variational formulations valid for the time increment under consideration are obtained. In especially, we point out a procedure that renders the algorithmically correct form of the mechanical dissipation. All thermomechanical fields at current time are then determined by the incremental variational statement

$$\inf_{\boldsymbol{\varphi},\mathfrak{q},\eta} \sup_{\theta,T} \{ \int_{\mathcal{B}_0} \widehat{\pi}^\tau(\mathfrak{c},\eta,\theta,T,\nabla T)\, dV - P^\tau_{ext}(\boldsymbol{\varphi},T) \} \tag{1}$$

that yields as necessary condition all coupled field equations. Note, that the evolution of the entropy is additionally driven by mechanical gradient-type dissipative effects. Extended settings that include mechanical driving forces dual to the micromotions are highly attractive for numerical treatment by the finite element method, see [3]. However, finding finite element formulations that satisfy the LBB-condition is a non-trivial and difficult task, see [4].

THERMO-GRADIENT-PLASTICITY AND ITS STABILITY ANALYSIS

The presented framework is very versatile and can be applied to fully coupled non-isothermal theories of e.g. gradient-type damage and plasticity or phase transitions. As a model problem we consider an additive approach to the kinematics of plasticity and specify the array of micromotions to (i) the Lagrangian plastic Hencky strain tensor that is defined as the logarithm of an evolving plastic metric and (ii) a scalar hardening variable together with its first gradient. Due to plastic heating, a temperature-induced softening behavior is at hand and typical mesh-dependencies of finite element solutions of local theories can be circumvented by gradient extensions. With this regard, we present numerical examples that are typically related to the formation of shear bands with large plastic deformations.

*Corresponding author. E-mail: marc-andre.keip@mechbau.uni-stuttgart.de.

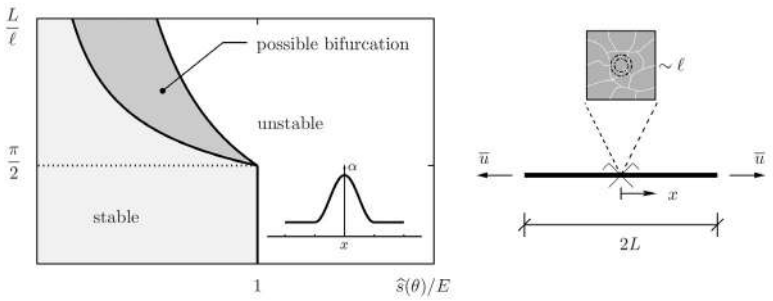

Figure 1: Stability analysis of homogeneous plastic solutions of a one-dimensional bar under tension. Depending on the temperature the solution may be stable, instable or even show bifurcations.

Furthermore, we discuss the *stability* of homogeneous plastic solutions with regard to its localization behavior by considering a simple one-dimensional bar under tension that undergoes small deformations. In contrast to (1), the temperature within this analysis will be treated as an external variable. Then, a second-order incremental stability condition results in a typical Rayleigh quotient minimization problem, see [5] as well as Figure 1 for a graphical illustration.

Our attention is also caught by the stability of homogeneous solutions obtained by the micromorphic plasticity approach in the sense of [6]. Within this theory, sharp elastic-plastic boundaries are regularized by the introduction of a micromorphic and a local hardening variable that are connected via a penalty term that requires an additional (material) parameter, see [7] for the application in phase field modeling of ductile fracturing and [8] for the application in variational thermomechanics of multiplicative gradient-type plasticity.

THE KINETICS OF POLARIZATION SWITCHING IN SINGLE CRYSTAL FERROELECTRICS

Vignesh Kannan*[1] and Dennis M. Kochmann[1]
[1]Department of Mechanical and Process Engineering, ETH Zürich

Summary We present an experimental study on polarization switching in ferroelectric crystals and the resulting mechanical deformation using barium titanate as a model material. An in-situ experimental technique, developed in-house, is used to apply time-varying electric fields to millimeter-scale cantilever beams made of single crystal barium titanate. The evolution of the resulting polarization is measured at different rates of electrical loading. Finally, these macroscopic switching kinetics are interpreted using data collected from ex-situ microscopy techniques like piezoresponse force microscopy and electron microscopy.

INTRODUCTION

Ferroelectric crystals are characterized by permanent polarization due to a non-centrosymmetric crystal structure. Reversal of this polarization begins to occur on application of large electric fields in the direction opposite to the existing state of polarization. This reversal is often termed 'spontaneous', although physically, it is governed by the kinetics of nucleation and growth of individual domains within the crystal. These domains are characterized by a different local polarization state than the parent crystal.

During this talk, we will discuss the kinetics of domain switching using a combination of an in-house experimental setup named Broadband Electromechanical Spectroscopy (BES) and post-mortem microscopy. Using the BES experiment, we apply large time-varying electric fields to cantilever beam samples made of barium titanate crystals. In-situ measurements of macroscopic polarization within the sample and strain fields on the sample surface offer insight into the electrical hysteresis and the coupled mechanical deformation of the crystal. Microscale domains are imaged ex-situ using piezoresponse force microscopy. The resulting phenomenological connection between macroscopic polarization and microscale domain patterns pave way for a physically robust kinetic law to describe polarization switching in ferroelectric crystals.

MATERIALS AND METHODS

Measuring macroscopic kinetics: Broadband Electromechanical Spectroscopy

Broadband Electromechanical Spectroscopy [1,2] is an experimental technique that allows for application of large time-varying electric fields to bulk ferroelectric materials while measuring their macroscopic polarization and coupled mechanical response in-situ. A schematic of the experiment is shown in Figure 1(a). A cantilever beam of dimensions 40 mm x 3 mm x 1 mm, made of a ferroelectric material, is held between two grips coated with conductive copper tape. The sample is sputter-coated with a thin conductive layer of nickel or gold film. High time-varying voltages of the order of ± 1.5 kV are applied across the samples via the conductive grips. The effective polarization in the sample is measured in-situ using a Sawyer-Tower circuit [3]. Strain fields on the sample surface due to polarization switching are measured using a 3-dimensional digital image correlation system (not shown in figure). A pair of Helmholtz coils in combination with a 5 mW Helium-Neon laser source and a 2D position sensing detector allow for measurements of the bending (and shear) modulus and corresponding loss tangent in-situ across a large mechanical frequency range, however these measurements will not be discussed in the current study. Figure 1(b) shows an example measurement of the electrical hysteresis curve during electrical cycling of a polycrystalline lead zirconate titanate ceramic sample at 1 Hz. The polycrystalline ceramic was used as a test material for the measurement system.

Material: Single crystal Barium Titanate

Single crystal barium titanate samples are used as a model material to maintain consistent and controllable initial and boundary conditions in the experiment. Moreover, the tetragonal crystal structure of barium titanate restricts the number of potential polarization directions to six unlike in lead zirconate titanate where additional rhombohedral phases are also present. Figure 1(c) shows a schematic of the sample geometry with the coordinate axes indicating crystallographic orientations. Electrodes are deposited on the 40 mm x 3 mm face, hence electric field is applied along the [001] direction.

Post-mortem microscopy

The micro-scale distribution of polarized domains are then measured using an ex-situ scanning probe technique called piezoresponse force microscopy (PFM) [4]. PFM data provides spatially resolved distribution of polarization vectors in the sample that, in conjunction with macro-scale data, offers insight into the multi-scale effects of polarization kinetics in ferroelectric crystals. The technique has been demonstrated in polycrystalline ceramic samples as well.

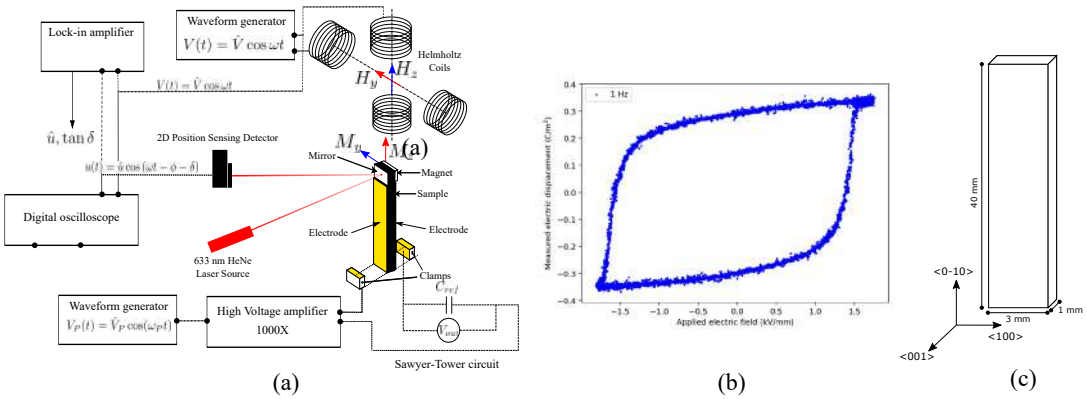

Figure 1: (a) Schematic of the Broadband Electromechanical Spectroscopy apparatus; (b) P-E switching curves for *polycrystalline* PZT samples; (c) Single crystal sample schematic, coordinate axes indicate crystallographic orientation relative to sample configuration

CONCLUSION

The broadband electromechanical spectroscopy experiment was developed to measure the kinetics of macroscopic polarization switching and the coupled mechanical response in millimeter-scale cantilever beams made of ferroelectric materials. The technique is applied to single crystal barium titanate samples at different rates of applied electric field. The measured macroscopic polarization kinetics are then interpreted in conjunction with post-mortem ex-situ measurements of the spatial distribution of micro-scale polarized domains. The resulting experimental data provide deeper insight into the kinetic laws that govern nucleation and growth of microscopic polarized domains and their effect on ferroelectric switching in these crystals.

A PHASE-FIELD MODEL FOR FERROELECTRICS WITH GENERAL DOMAIN WALL KINETICS

Laurent Guin*[1] and Dennis M. Kochmann[1]
[1]Mechanics&Materials, Department of Mechanical and Process Engineering, ETH Zürich, Zürich 8092, Switzerland

Summary In existing phase-field models for ferroelectric switching, the evolution equation for the polarization is governed by the Allen-Cahn equation. Such models help understanding the evolution of domain patterns and the macroscopic response of ferroelectrics under slow enough electromechanical loadings. However, they do not embed the complex kinetics of 180° and 90° domain walls, which is expected to have a strong influence on the response to high rate loadings. To address this issue, we propose an enhanced phase-field model for ferroelectrics where the kinetic relations for 180° and 90° domain walls can be independently prescribed. In addition, in the new formulation, these kinetic relations are extended to nonlinear functions which, in particular, allows us to account for the effect of pinning at low electric fields.

DOMAIN WALL KINETICS UNDERLYING THE ALLEN-CAHN EQUATION

For over two decades, phase-field models have been used to simulate the ferroelectric switching process, whereby the application of an electromechanical loading changes the electric polarization from one state to another. With a focus on ferroelectric perovskite ceramics (e.g., materials such as PZT, PTO, $BaTiO_3$), phase-field models have the advantage of properly accounting for the local electric and mechanical interactions between domains. With these assets, they have been particularly successful in predicting the shape of the electric and strain hystereses curves under slow electromechanical loading (see e.g. [1]).

These models are typically based on an electromechanical free-energy of the ferroelectrics that depends on an order parameter related to the polarization state of the ferroelectrics. An example of these models is the one proposed in Ref. [2], where the chosen order parameter is the spontaneous polarization $\boldsymbol{p}^s(\boldsymbol{x},t)$ (i.e., the electric polarization minus its piezoelectric and dielectric components). Denoting by $\boldsymbol{\varepsilon}(\boldsymbol{x},t)$ the small-strain tensor and $\boldsymbol{e}(\boldsymbol{x},t)$ the electric field, the phase-field formulation of Ref. [2] is based on the electric enthalpy

$$W(\boldsymbol{\varepsilon},\boldsymbol{e},\boldsymbol{p}^s,\nabla\boldsymbol{p}^s)=\Psi(\boldsymbol{\varepsilon},\boldsymbol{e},\boldsymbol{p}^s)+\Psi_{inter}(\nabla\boldsymbol{p}^s), \tag{1}$$

where Ψ_{inter} is a regularizing interface energy density and Ψ can be decomposed as

$$\Psi(\boldsymbol{\varepsilon},\boldsymbol{e},\boldsymbol{p}^s)=\Psi_{mech}(\boldsymbol{\varepsilon},\boldsymbol{p}^s)+\Psi_{piezo}(\boldsymbol{\varepsilon},\boldsymbol{e},\boldsymbol{p}^s)+\Psi_{diel}(\boldsymbol{e})-\boldsymbol{e}\cdot\boldsymbol{p}^s+\Psi_{sep}(\boldsymbol{p}^s). \tag{2}$$

Here the first three terms denote the mechanical (elastic strain) energy density, the piezoelectric-coupling energy density, and the dielectric energy density respectively, while the last one is a six-well potential energy density with equal minima at the six spontaneous polarization states associated with the tetragonal variants of the ferroelectric perovskite. In this formulation—as in all phase-field models for ferroelectrics, as far as we are aware—the phase field $\boldsymbol{p}^s$ is assumed to be governed by the Allen-Cahn equation:

$$\eta\dot{\boldsymbol{p}^s}=-\frac{\partial W}{\partial\boldsymbol{p}^s}+\operatorname{div}\left(\frac{\partial W}{\partial\nabla\boldsymbol{p}^s}\right), \tag{3}$$

where the superimposed dot denotes the time derivative and $\eta>0$ is a drag coefficient.

We see the phase-field model as a regularization of a sharp-interface interface model where a domain wall is represented by a surface $\mathcal{S}$ of discontinuity for $\boldsymbol{\varepsilon}$, $\boldsymbol{e}$, and $\boldsymbol{p}^s$. Denoting by $\boldsymbol{n}(\boldsymbol{x},t)$ the unit normal vector to $\mathcal{S}$, and by $v_n(\boldsymbol{x},t)$ its normal velocity, the above formulation is tantamount to assuming a linear kinetic relation between v_n and the driving force f:

$$v_n=cf, \tag{4}$$

where c is a non-negative constant and f is given by

$$f=\boldsymbol{n}\cdot[\![\boldsymbol{\Psi}\mathbb{1}-(\nabla\boldsymbol{u})^{\mathbf{T}}\cdot\boldsymbol{\sigma}+\boldsymbol{e}\otimes\boldsymbol{d}]\!]\boldsymbol{n}+\gamma\kappa, \tag{5}$$

where $\boldsymbol{u}(\boldsymbol{x},t)$ and $\boldsymbol{\sigma}(\boldsymbol{x},t)$ denote the displacement and stress fields, respectively; $\boldsymbol{d}(\boldsymbol{x},t)$ is the electric displacement, γ is the surface energy of the interface and $\kappa(\boldsymbol{x},t)$ is twice its mean curvature (taken positive when the center of curvature lies in the side of $\boldsymbol{n}$). The notation $[\![\phi]\!]=\phi(x^+,t)-\phi(x^-,t)$ denotes the jump at $x\in\mathcal{S}$ for any field $\phi(\boldsymbol{x},t)$ with the $+$ side corresponding to the one where $\boldsymbol{n}$ is pointing.

With such a perspective, it appears that the use of an Allen-Cahn equation in the phase-field model amounts to assuming a unique kinetics for 180° and 90° domain walls, which takes the form of a linear kinetic relation. The identity of the kinetics of the two types of domain walls seems physically unlikely and the linearity of the kinetic relation is only an approximation. Indeed, experimental measurements of the velocity of domain walls rather suggests a stick-slip type kinetic relation [3]. Note that these observations hold for phase-field models using the total polarization $\boldsymbol{p}(x,t)$ as the principal order parameter such as in Ref. [1].

A PHASE-FIELD FORMULATION WITH GENERAL KINETICS

To address the limitations of the Allen-Cahn formulation that we have pointed out, we propose a new phase-field model with the following features:

- The order parameter is a vector $\boldsymbol{\varphi} \in \mathbb{R}^6$ such that each of the six polarization states (corresponding to the six variants of the tetragonal phase in perovskite ferroelectrics) is associated with $\varphi_i = 1$ for a particular $i \in 1, .., 6$ and $\varphi_j = 0$ for all $j \neq i$.
- The electric enthalpy $\tilde{W}(\boldsymbol{\varepsilon}, \boldsymbol{e}, \boldsymbol{\varphi}, \nabla\boldsymbol{\varphi})$ that we introduce is built upon $W(\boldsymbol{\varepsilon}, \boldsymbol{e}, \boldsymbol{p}^s, \nabla\boldsymbol{p}^s)$ in (1) from Ref. [2].
- The evolution equation for $\boldsymbol{\varphi}$ is inspired from the so-called hybrid model of Ref. [4] (see also Ref. [5]) which allows us to depart from the restriction of a linear kinetic relation between the driving force f and the domain wall normal velocity v_n. In addition, we extend the evolution equation proposed in Refs. [4] and [5] by generalizing it to the case of multiple phases and prescribe different kinetics for 180° and 90° domain walls. Indeed, the normal velocity of domain walls follows, in the proposed model, from the relations

$$\begin{aligned} v_n &= G_{180}(f) \quad \text{for } 180^\circ \text{ domain walls,} \\ v_n &= G_{90}(f) \quad \text{for } 90^\circ \text{ domain walls,} \end{aligned} \tag{6}$$

  where G_{180} and G_{90} are two arbitrary functions that map $\mathbb{R}$ into itself and satisfy $G_{180/90}(x) \cdot x \geq 0$ for all $x \in \mathbb{R}$.

The proposed formulation, when seen as the regularization of a corresponding sharp-interface model yields independent kinetic relations for the 180° and 90° domain walls, which, in addition, take very arbitrary functional dependence (allowing us to prescribe, for instance, the stick-slip behavior above mentioned). In conclusion, it allows us to address the shortcoming pointed out with regards to the treatment of the kinetics of ferroelectric switching in existing phase-field models.

THERMOMECHANICAL MODEL FOR NITI-BASED SHAPE MEMORY ALLOYS COVERING MACROSCOPIC LOCALIZATION OF MARTENSITIC TRANSFORMATION

Miroslav Frost*[1], Barbora Benešová[2], Petr Šittner[3], and Petr Sedlák[1]

Summary We present an extended thermomechanical model for polycrystalline NiTi-based shape memory alloys covering the deformation mode-dependent localization of the martensitic transformation. This is thanks to the introduction of a new austenite-martensite interaction term responsible for the strain-softening of the material. A time-discrete approximation of the constitutive model is proposed and used for numerical implementation to the finite-element method software Abaqus. Model performance is illustrated on several numerical simulations; some of them are compared with available experimental data.

INTRODUCTION

NiTi-based shape memory alloys (SMA) are usually utilized in the form of thin structures, e.g., wires, strips, tubes, or plates. In such samples, the stress-induced martensitic transformation tends to occur in a spatially inhomogeneous manner on the macroscopic scale: localized "martensitic bands" appear within the austenitic sample and the transformation propagates by their growth or multiplication. They can be visualized by various experimental means, and their occurrence and particular geometric form depend on many aspects, mainly on composition of the alloy, its texture, applied deformation mode, or deformation rate [1].

Because the localization gives rise to high gradients of strain concentrated in small volumes of material, it is supposed to be a critical factor for the fatigue lifetime. Hence, good understanding and effective modeling of the phenomenon would have direct practical impacts. Although several macroscopic (continuum) models incorporating localization have been developed recently, they either disregard the deformation mode-dependence of localization [2, 3] or include it purely heuristically [4]. In this contribution, we extend a well-established constitutive model for NiTi SMA by a specific internal energy term, which deals with this feature more formally and allows for applicability in general loading scenarios. Moreover, the chosen approach motivates a rigorous mathematical regularization of the complete model.

MODELING

We extend the continuum mechanics-based rate-independent constitutive model introduced in [5, 6], which is particularly suitable for simulations of the mechanical response of NiTi-based SMA components in complex loading modes. It has been formulated within the *generalized standard solids* thermodynamic framework, within the small-strain realm. The core of the original model consists of two material functions: one captures the energy stored in the material at a given thermodynamic state (free energy), the other defines the energy released during irreversible processes, and it is often called the dissipation function. The irreversible processes are related to changes of the microstructure of the material – crystallographic changes as phase transformations and reorientation – via a set of internal variables. Namely, we introduce a scalar variable, ξ, representing the volume fraction of martensite and a tensorial variable, $\varepsilon^{\mathrm{tr}}$, representing the mean macroscopic transformation strain. Specific constraints on these variables allow taking into account the (crystallographically) limited transformation strains, the isochoric nature of the transformation, and the tension-compression asymmetry [5].

The constitutive response in a material point is then determined via the so-called *principle of minimum dissipation potential*, which is an alternative to common definitions of domain(s) of admissible force(s) complemented by flow rule(s):

$$\text{Minimize}\,\{f_k + d_k + r_k\}\,\text{subject to}\,(\varepsilon^{\mathrm{tr}}, \xi). \tag{1}$$

Subscript $_k$ denotes a suitable numerical time-discretization of the free energy, f, dissipation, d and regularization, r, functions. The regularization function encompasses the numerical treatment of constraints imposed on internal variables. The alternative minimization technique is then employed for numerical implementation of the model into Abaqus FEA software (via UMAT subroutine) as thoroughly described in [6].

The experimental investigations suggest that the localization phenomena are rooted in the microstructural interactions between martensite and austenite phases on the level of grains forming the pollycrystaline material. The competition of the energy contribution stemming from interaction of differently oriented neighboring grains during phase transition (tending towards strain-hardening response in the conventional sense) and the interaction energy related to the growth of martensite inclusions within austenitic matrix inside grains (leading to strain-softening type of response) might lead either to homogeneous transformation response or to the localized one.

*Corresponding author. E-mail: mfrost@it.cas.cz.

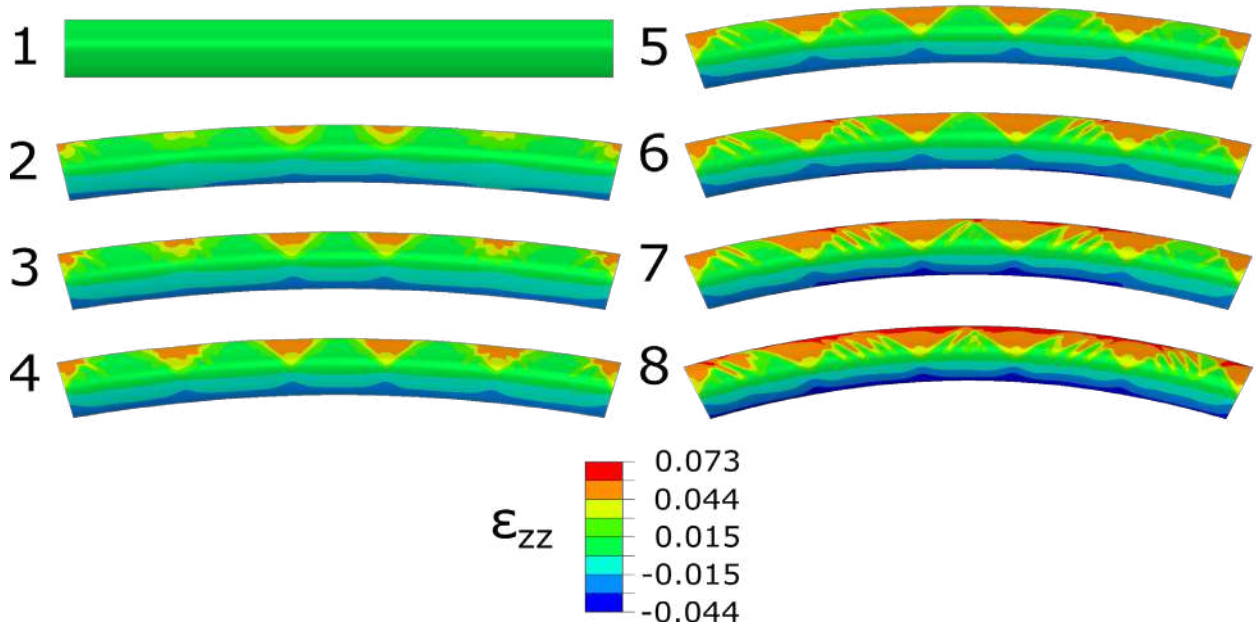

Figure 1: Snapshots from a three-dimensional numerical simulation of bending of a thin-walled NiTi tube plotted with the distribution of the axial component of strain (in the reference configuration) in color. Several common features of the localization patterning are reproduced: the appearance of isolated wedge-shaped regions of high strain, their growth and multiplication via crisscrossing and coalescence of martensitic "needles", which finally cover most of the (upper) tube surface undergoing predominantly tensile straining. Note that a homogeneous deformation develops on the (lower) tube surface that undergoes predominantly compressive straining.

Derivation of the elastic energy per unit volume of the specimen containing elliptical inclusions with transformation strain $\varepsilon^{\mathrm{tr}}$, as performed by Mori and Tanaka, motivates the new interaction term, which enables a strain-softening material response:

$$E^{\mathrm{int}} = C^{\mathrm{int}}_{\mathrm{MA}}\xi(1-\xi)^2\|\varepsilon^{\mathrm{tr}}\|^2 + C^{\mathrm{int}}_{\mathrm{AM}}\xi^2(1-\xi)\|\varepsilon^{\mathrm{tr}}\|^2, \tag{2}$$

where $C^{\mathrm{int}}_{\mathrm{MA}}, C^{\mathrm{int}}_{\mathrm{AM}}$ are suitable material parameters. By tuning these parameters and the parameters of the dissipation function, which incorporates the strain-hardening in the model, we can reach strain-softening in uniaxial tension and, simultaneously, strain-hardening in uniaxial compression as often observed in experiments. Since the localization contribution energy E^{int} makes the overall energy non-convex, a proper regularization treatment is needed. A possible solution is the non-local integral regularization approach proposed in [7]. Figure 1 shows a numerical simulation of a bending deformation of a NiTi thin-walled tube performed in Abaqus FEA software with our own-developed UMAT subroutine as an illustration of the capability of the complete model.

CONCLUSIONS

We extended a well-established constitutive model tailored for NiTi-based SMA by an interaction energy term, which is motivated by the Mori-Tanaka method and enables us to capture the localization effects. Thanks to two independent constants appearing in Eq. (2), we gained more freedom to adjust the strain-softening constitutive law to available experimental measurements. Thanks to the factor $\|\varepsilon^{\mathrm{tr}}\|^2$ in E^{int}, we reached the deformation mode-dependency of the response as observed in experiments. The motivation stemming from the Mori-Tanaka approach also provided a hint for a physically plausible regularization of the inherently non-convex model.

PROPAGATION AND STABILITY OF STRESS-AFFECTED CHEMICAL REACTION FRONTS IN SOLIDS

Alexander B. Freidin*[1],Aleksandr Morozov[1,2],Wolfgang H. Müller[2],Mikhail Poluektov[3],and Igor K. Korolev[1]

Summary Localized stress-affected chemical reactions between solid and diffusing reactants are studied on the basis of the chemical affinity tensor. A kinetic equation in a form of the dependence of the chemical reaction front velocity on the normal component of the chemical affinity tensor is formulated and used for solving coupled boundary value problems "diffusion–chemistry–mechanics". It is shown that mechanical stresses can accelerate, retard and block the front propagation, and the reaction front can be stable or unstable in the blocking position. Then it is studied how the front converges to the stable and unstable blocking positions, and the competition between global and local kinetics of the front propagation is discussed in the context of the stability analysis. Finally it is studied how the unsteadiness of the diffusion may affect the front propagation.

INTRODUCTION

Interconnections between chemical reactions and mechanical stresses has been recognized and intensively studied during last decades, see e.g. the reference represented in [1]. Oxidation of silicon in integrated-circuit technologies, oxidation and fracture processes in polycrystalline silicon microscale parts of MEMS, lithiation of silicon in Li-ion batteries, formation of intermetallic phases in lead-free solders are among important examples of stress-affected chemical reactions. In all cases one deal with a reaction between diffusive and solid constituents which is accompanied by transformation strain, and mechanical properties including rheological behaviour change due to the reaction. It may be questionable whether the front propagation is controlled by the diffusion or by the reaction rate itself (see e.g. [2]). We consider the case for which the velocity of the reaction front is controlled rather by the reaction rate than by the diffusion (see e.g. [4, 3] and reference therein) and study a reaction front propagation within the frames of the mechanics of configurational forces.

As it was derived and approbated during last years (see [1] and reference therein), the configurational force driving the reaction font is determined by the normal component of a chemical affinity tensor. Then a kinetic equation can be formulated in the form of the dependence of the reaction front on the normal component of the affinity tensor. The chemical affinity tensor, in turn, depends on stresses and strains, and this quantifies how stresses and strains affect the chemical reaction rate and reaction front velocity. Note that the expression of the affinity tensor was derived from fundamental laws and entropy inequality for solid constituents of arbitrary rheology [5, 6]) (see also [7]).

Theory built on the chemical affinity tensor has been applied to a number of problems for the cases of linear elastic solid constituents, for finite strains of nonlinear viscoelasic solid constituents with applications to two-phase lithiation of Si particles, for the case a collection of interacting particles embedded into inelastic matrix, for intermetallic compound formations (see, e.g., the reference in [1, 8]). It was shown that stresses can accelerate, retard and even block the reaction front propagation, and forbidden regions were constructed in the strain space formed by strains at which the reaction cannot go [10].

Now we present results on the reaction front propagation and stability analysis, including numerical simulations of the front propagation validated by the comparison with analytical solutions. We develop a procedure of the stability analysis and study how the front converges to a blocking position if this position is stable or unstable. Then we study the front kinetics for various cases.

CHEMICAL AFFINITY TENSOR AND KINETIC EQUATION

We consider a chemical reaction between solid and diffusive constituents of the type $n_- B_- + n_* B_* \to n_+ B_+$ where B_-, B_* and B_+ are the chemical formulae of an initial solid constituent, a diffusive constituent and a transformed solid constituent, $n_\pm$ and n_* are stoichiometric coefficients. The reaction is localized at the reaction front and sustained by the diffusion of the gaseous constituent. It can be derived that the the energy dissipation per unit area of the propagating reaction front takes the form

$$D_g = \omega_N A_{NN} \geq 0$$

where ω_N is the reaction rate at the surface element with the normal $\mathbf{N}$, $A_{NN} = \mathbf{N} \cdot \mathbf{A} \cdot \mathbf{N}$ is the normal component of the chemical affinity tensor

$$\mathbf{A} = n_- M_- \mathbf{M}_- + n_* M_* \mu_* \mathbf{I} - n_+ M_+ \mathbf{M}_+ + \{\text{dynamical terms}\},$$

*Corresponding author. E-mail: alexander.freidin@gmail.com

THEMATIC SESSION SM

$\mathbf{M}_-$ and $\mathbf{M}_+$ are the chemical potential tensors of the solid constituents (the Eshelby stress tensors divided by the referential mass densities), μ_* is the chemical potential of the diffusing constituent. To find $\mathbf{M}_\pm$ and μ_* one has to find stresses and strains at the reaction front and to solve the diffusion problem.

Substituting A_{NN} instead of the scalar chemical affinity into the classical formula leads to a kinetic relationships which define the reaction rate and the normal component of the reaction front velocity W by the formulas

$$\omega_N = k_* c \left\{ 1 - \exp\left(-\frac{A_{NN}}{RT} \right) \right\}, \quad W = \frac{n_+ M_+}{\rho_+} k_* c \left\{ 1 - \exp\left(-\frac{A_{NN}}{RT} \right) \right\}.$$

where k_* is the kinetic constant, ρ_+ is the referential mass density of B_+, c is the concentration of the diffusive constituent.

KINETICS AND STABILITY OF THE REACTION FRONT

We study the stability of the reaction front in a blocking position following [9] and developing the procedure of so-called kinetic stability analysis and say that the front is unstable if interface perturbations grow due to the kinetic equations. We also relate strains at the equilibrium reaction front with strains belonging to the boundary of forbidden zone [10] which coincides with the phase transition zone (e.g., [11]) in the case of stress-induced phase transformation. This gives necessary stability conditions. Considering simplest problems for linear elastic solid reactants, we analyze analytically the stability of the reaction fronts and study how material parameters and stress state affect the stability.

After that we develop a FEM procedure for numerical simulations of the reaction front propagation. We study how the front propagates if the blocking position is stable or unstable. We demonstrate that in both cases the interface may propagate in the direction of the blocking position, but the interface converges smoothly to the blocking position in the stable case, and the initially smooth interfaces becomes unstable with the tendency to finger-type instabilities prior to reaching the blocking position if the position is unstable. We explain such a behavior by the competition between global kinetics of the front propagation and local kinetics of the interface perturbations. We study stress concentrations induced by the front instabilities and note that instabilities developing due to the front retardation and blocking may be the source of further intensive plastic deformations, damage and fracture. We also give example of the reaction front propagation in the vicinity of stress-concentrations like inhomogeneities. Finally, we study the unsteadiness of the diffusion may affect the front propagation.

CONCLUSIONS

An approach to study the influence of stresses on the chemical reaction front propagation was developed based on the chemical affinity tensor and implemented in a numerical procedure. Effects of the front retardation and blocking were explained within the framework of the theory developed. Stability analysis of the reaction front in a blocking position was done and stable and unstable reaction front propagations were simulated numerically. Stresses induced by the growth of the instability amplitudes were analyzed. The front propagation in the vicinity of stress concentrators was studied. Various diffusion regimes were discussed in the context of the front propagation.

A THERMODYNAMICALLY CONSISTENT PHASE-FIELD THEORY FOR COUPLED DEFORMATION-DIFFUSION-REACTIONS IN SOLIDS: APPLICATION TO CONVERSION-TYPE ELECTRODES

Claudio V. Di Leo*[1] and Arman Afshar[1]
[1]School of Aerospace Engineering, Georgia Institute of Technology, Atlanta, USA

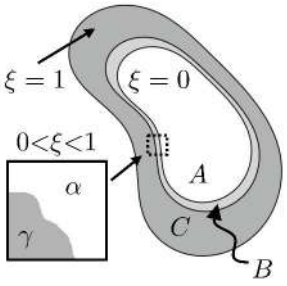
Summary We developed a thermodynamically consistent framework for materials undergoing large deformations coupled to deformation-diffusion-reaction phenomena with sharp interfaces. Our framework captures phenomena involving both diffusion- and reaction-controlled sharp interfaces. In addition, we present a novel decomposition of the deformation gradient to account for possible macroscopically stress free inelasticity due to incompatibilities at the microstructure. We apply our framework to modeling the experimentally relevant reaction of FeS_2 crystals with Li and Na ions and demonstrate that differences in the sharp interface morphologies are driven by stress effects on the thermodynamic reaction driving force. We conclude by studying the range of diffusion-reaction properties which enhance electrode performance and the role of mechanical stress in this relationship.

INTRODUCTION

Current state of the art lithium-ion batteries make use of active particles, such as graphite and cobalt oxide, whose primary mechanism of lithium storage is intercalation. Alternatively, next generation electrode materials made of transition metal oxides which store charge carrying ions via chemical conversion mechanism have recently been given attention as their theoretical capacity dwarfs that of intercalation based electrodes. The conversion reaction, however, is accompanied by *structural and chemical phase transformations* of the host material.[1] Recently, researchers have found that reaction of FeS_2 crystals with ions (Li^+, Na^+, and K^+) resulting in different volume changes drastically impacts the reaction morphology and susceptibility to fracture.[2] In order to understand this phenomena one must capture the complex coupled physics between diffusion, sharp interface reactions, and large deformations occurring in these materials.

SUMMARY OF THE THEORETICAL FRAMEWORK

Consider a general reaction of the form $A + B \to C$, as shown on the figure to the right. We characterize this system through a phase-field variable ξ which physically represents the volume fraction of reacted phase γ to unreacted phase α in a representative volume element (RVE), and through a molar concentration c of the diffusing species moving through the system. We employ a decomposition of the deformation gradient of the form



$$\mathbf{F} = \mathbf{F}^{\text{mech}}\mathbf{F}^{\text{chem}}, \quad \text{with velocity gradient} \quad \mathbf{L} = \mathbf{L}^{\text{mech}} + \mathbf{F}^{\text{mech}}\mathbf{L}^{\text{chem}}(\mathbf{F}^{\text{mech}})^{-1}. \tag{1}$$

Here, $\mathbf{F}^{\text{chem}}$ accounts for the combined distortions due to all chemical processes (diffusion and reaction), while $\mathbf{F}^{\text{mech}}$ accounts for subsequent stretching and rotations which may be elastic or inelastic in nature. The chemical velocity gradient is further decomposed into

$$\mathbf{L}^{\text{chem}} = (1-\xi)\mathbf{L}^{\alpha} + \xi\mathbf{L}^{\gamma} + \xi(1-\xi)\mathbf{L}^{\text{acc}}, \quad \text{with} \quad \mathbf{L}^{\alpha} = \dot{c}\mathbf{N}^{\alpha}, \quad \mathbf{L}^{\gamma} = \dot{\xi}\mathbf{N}^{\gamma}, \quad \text{and} \quad \mathbf{L}^{\text{acc}} = \dot{\kappa}\mathbf{N}^{\text{acc}}. \tag{2}$$

Here, $\mathbf{L}^{\alpha}$ and $\mathbf{L}^{\gamma}$ represent incompatible deformations associated with the diffusing species and the reaction induced phase transformations respectively. $\mathbf{L}^{\text{acc}}$ is then an accommodation deformation necessary to make the total deformation compatible. Importantly, through $\mathbf{L}^{\text{acc}}$ it is possible to have inelastic deformations which are macroscopically stress free, i.e. chemically induced inelastic deformation. In this abstract, for conciseness, we will not specify $\mathbf{L}^{\text{acc}}$ any further, we will assume $\mathbf{N}^{\alpha}$ and $\mathbf{N}^{\gamma}$ to be compatible, and will focus on the diffusion-reaction behavior.

The diffusing species is governed by a diffusion-reaction equation of the form

$$\begin{aligned} &\dot{c} = -J(\operatorname{div}\mathbf{j} - \dot{\bar{\xi}}), \quad \mathbf{j} = -m\nabla\mu, \quad \text{and} \\ &\mu = (1-\xi)\mu_0^{\text{UR}} + \xi\mu_0^{\text{R}} + R\vartheta\ln\left(\frac{\bar{c}}{1-\bar{c}}\right) - J^{\text{chem}}(1-\xi)\mathbf{M}^e : \mathbf{N}^{\alpha} \end{aligned} \tag{3}$$

Here $\mathbf{j}$ is the spatial flux of the mobile species, m is the mobility, μ the chemical of the diffusing species which is both concentration and stress dependent through the Mandel stress $\mathbf{M}^e$. Further, $J = \det\mathbf{F}$, $J^{\text{chem}} = \det\mathbf{F}^{\text{chem}}$, $\bar{\xi} = \xi c_{\text{max}}^{\text{react}}$ is a dimensional reaction coordinate, $\bar{c} = c/c_{\text{max}}^{\text{unreact}}$ is a dimensionless concentration, R is the gas constant, ϑ is the absolute temperature, μ^{UR} and μ^{R} are reference potentials for the unreacted and reacted phases respectively.

We employ a linear relationship between the reaction rate and the thermodynamic force $\mathcal{F}$ of the form

$$\dot{\bar{\xi}} = R_0\mathcal{F}, \quad \mathcal{F} = \mu^{\xi} - \mu, \quad \text{and} \quad \mu^{\xi} = \frac{\partial\psi}{\partial\bar{\xi}} - J^{\text{chem}}\bar{\xi}\,\mathbf{M}^e : \mathbf{N}^{\gamma} + \operatorname{div}(\lambda\nabla\bar{\xi}). \tag{4}$$

Here μ^{ξ} is the chemical potential of the species in the reacted phase which is also both concentration dependent through the free energy ψ, and stress dependent. The term $\operatorname{div}(\lambda\nabla\bar{\xi})$ is introduced for numerical reasons and arises from the free energy as a penalty on sharp interfaces such that we may treat them as diffuse. Combining μ from (3) and μ^{ξ} from (4) and neglecting the gradient term, we may write the thermodynamic driving force $\mathcal{F}$ as:

*Corresponding author. E-mail: cvdileo@gatech.edu

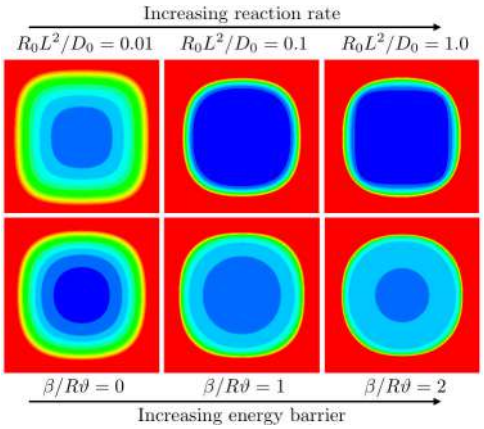
$$\mathcal{F} = \underbrace{\Big(\bar{c} + (1-\xi)\Big)(\mu_0^{\mathrm{R}} - \mu_0^{\mathrm{UR}}) + \frac{d\psi^R(\bar{\xi})}{d\bar{\xi}}}_{\text{energetic}} - \underbrace{R\vartheta \ln\left(\frac{\bar{c}^{\mathrm{C}}}{1-\bar{c}^{\mathrm{C}}}\right)}_{\text{entropic}} + \underbrace{J^{\mathrm{chem}}\mathbf{M}^e : \Big((1-\xi)\mathbf{N}^\alpha - \xi\mathbf{N}^\gamma\Big)}_{\text{mechanical}} \tag{5}$$

with $\psi^R(\bar{\xi}) = \beta\bar{\xi}^2(1-\bar{\xi}^2)$ a double-welled reaction free-energy giving rise to an energy barrier for the chemical reaction characterized through the parameter β which is on the order of $20 \cdot R\vartheta$.[3] The reaction driving force $\mathcal{F}$ is thus driven by: i) an energetic component which has both a global driving force (proportional to $(1-\xi)$) which drives the reaction forward, and a local driving force (related to $d\psi^R/d\bar{\xi}$) which serves as an energy barrier, ii) an entropic component, and iii) a mechanical term which can serve to enhance or supress the reaction.

For the mechanical behavior of the material we consider a simple isotropic elastic-plastic constitutive behavior with the Mandel stress given by $\mathbf{M}^e = 2G\mathbf{E}^e + (K - (2/3)G)\mathrm{tr}\mathbf{E}^e)\mathbf{1}$, with G and K phase dependent elastic moduli. The plastic behavior is elastic-perfectly plastic.

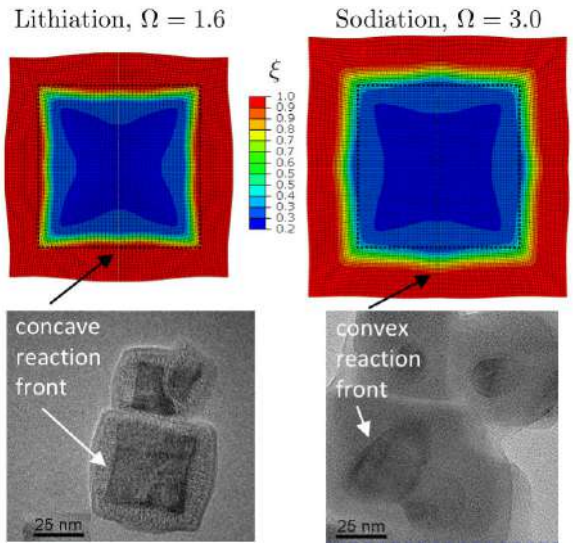
KINETIC VS. THERMODYNAMIC SHARP INTERFACES

We first demonstrate the manner in which our framework can capture both kinetically (diffusion controlled) and thermodynamically (reaction controlled) driven sharp interfaces. The figure to the right shows contours of reaction coordinate ξ for two sets of simulations (colorbar on the bottom figure). The top row shows simulations as we increase the reaction rate R_0 in relation to the diffusivity D_0 which in turn leads to a sharp interface as all diffusing species is quickly consumed, this sharp interface is hence driven by the kinetics of the system. However, some sharp interface reactions of relevance (cf. [2, 3]) have sluggish reaction kinetics (i.e. R_0 is not much larger than D_0). The second row of simulations shown on the right demonstrates our ability to capture a sharp interface by increase the energy barrier through an increase of β to a few times the thermal energy. This is critical as experiments (cf. [2]) show an anisotropic interface due to anisotropy in R_0 and can only be modeled if one simulates a thermodynamically driven sharp interface.



CHEMO-MECHANICS OF CONVERSION BATTERY MATERIALS

In this talk we will also present an in-depth study on the role of mechanics in the reaction of FeS_2 crystals with Li^+, Na^+, and K^+ ions each of which results in a different volume change and a different sharp interface morphology.[2] For conciseness of this abstract the results presented here assume that $\mathbf{L}^\alpha = \mathbf{L}^{\mathrm{acc}} = \mathbf{0}$, and we choose $\mathbf{N}^\gamma$ such that $\mathbf{F}^{\mathrm{chem}} = (1 + \Omega\bar{\xi})^{(1/3)}\mathbf{1}$ which leads to an isotropic reaction induced deformation characterized by Ω. The reaction rate R_0 is anisotropic with reactions being 30% faster in the horizontal and vertical directions, $R_0L^2/D_0 = 0.005$ and $\beta/R\vartheta = 20$. As shown on the bottom row in the figure to the right, when changing the reaction of FeS_2 from Li to Na ions, the interface goes from a concave sharp interface to a convex interface.[2] The top row on the figure shows the corresponding simulations using our model where we note that the *only parameter varied between the two simulations is the partial volume* Ω (the dashed lines show the undeformed configuration). The simulations recover the observed experimental behavior whereby chemical reactions with larger induced volume changes lead to concave reaction fronts and significantly lower stresses. This unintuitive result is critical, as it can be demonstrated that reactions with larger induced volume changes do not always result in higher stresses and larger degrees of damage and fracture.



SUMMARY

We developed a thermodynamically consistent framework for materials undergoing large deformations coupled to deformation-diffusion-reaction phenomena with sharp interfaces. During this talk we will present the theoretical framework as well as its application to modeling conversion-type electrodes with suitable comparison to experiments. We will discuss the importance of mechanics in capturing the reaction-diffusion behavior of these systems as well as the reaction induced inelastic deformations during phase transformations of the host material.

MATHEMATICAL MODELS AND IDEAS FOR DISCLINATIONS

Pierluigi Cesana *[1]
[1]Institute of Mathematics for Industry, Kyushu University, Japan

Summary In this talk, we describe some recent results on the modeling of self-similar martensitic microstructure and on the modeling of rotational mismatches at the level of a crystal lattice, two phenomena which appear to be strongly interconnected.

First, we present a probabilistic model for the description of martensitic microstructure as an avalanche process. A martensitic phase-transformation is a first-order diffusionless transition occurring in elastic crystals and characterized by an abrupt change of shape of the underlying crystal lattice. It is the basic activation mechanism for the Shape-Memory effect. Our approach to the analysis of the model is based on an associated general branching random walk process. Comparisons are reported for numerical and analytical solutions and experimental observations. This is a joint project with John M. Ball and Ben Hambly (Oxford).

Then, we introduce an energy functional defined over a triangular lattice accounting for nearest-neighbor interactions. We design special rotational-type boundary value problems on the lattice so that the minimizers necessarily exhibit non-homogeneous rotations. We are interested in the asymptotics of the energy minima and minimizers as the lattice spacing vanishes which we compute exactly with Gamma-convergence. We perform some numerical calculations for the discrete model and show that both the shape of the solutions as well as the values of the energies are in agreement with classical results for positive and negative disclinations. This is a collaboration with P. van Meurs (Kanazawa).

MARTENSITIC AVALANCHES

The austenite-to-martensite phase-transformation is a first-order diffusionless transition observed in elastic crystals and characterized by an abrupt change of shape of the underlying crystal lattice [3]. It manifests itself to what in materials science is called a martensitic microstructure, an intricate highly inhomogeneous pattern populated by sharp interfaces that separate thin plates composed of mixtures of different martensitic phases (i.e., rotated copies of a low symmetry lattice) possibly rich in defects and lattice mismatches. In the first part of this talk we review some results on the modeling of self-similar martensitic microstructure, a phenomenology observed in various experiments [6], [7].

Inspired by Bak's cellular automaton model for sand piles [1], we introduce a conceptual model for a martensitic phase transition and analyze the properties of the patterns obtained. Nucleation and evolution of martensitic variants are modeled as a fragmentation process in which the microstructure evolves via formation of thin plates of martensite embedded in a medium representing the austenite. While the orientation and direction of propagation of the interfaces separating the plates is determined by kinematic compatibility of the crystal phases, their nucleation sites are inevitably influenced by defects and disorder, which are encoded in the model by means of random variables.

To sketch our model, we consider a single crystal which transforms from austenite into martensite along a negative temperature gradient. In the simplest version of the model, martensite evolves over a unit square via nucleation of segments (representing thin martensitic plates which are parallel to their habit planes) that evolve until they encounter the boundary of the domain or an existing plate. We initially consider only two possible habit plane directions, which are taken to be, without loss of generality, horizontal and vertical. A point with coordinates measured by two uniform random variables is chosen in the unit square. The propagation of an interface is chosen to be vertical with probability p or horizontal with probability $1-p$, with $0 < p < 1$. After the first step the square is divided into two rectangles. Then, a new nucleation point is selected in one of the two rectangles and, starting from the chosen rectangle, another fragmentation process is activated as in step one. As this process is iterated, successive fragmentations result in formation of smaller and smaller rectangles. A realization of a microstructure obtained according to this fragmentation model is displayed in Fig. 1-left for 3000 interfaces and $p = \frac{1}{2}$. Extensions of the 2-direction model are obtained by allowing for additional habit planes. In Fig. 1-center we show a microstructure obtained according to a fragmentation model with 3 directions, that are, horizontal, vertical and $\frac{\pi}{4}$ (chosen with an equal probability) and composed of 3000 interfaces. In Fig. 1-right we show another microstructure composed of 3000 interfaces and obtained according to a fragmentation model with 4 directions (again, selected with an equal probability), which are, horizontal, vertical and $\pm\frac{\pi}{4}$.

We investigate distribution of the lengths of the interfaces in the pattern and establish limit theorems for some of the asymptotics of the interface profile. In particular, we prove that the density of the length of the interfaces generated corresponds to a power law for which we compute the exponent exactly [2]. We also show that the density of the rectangles generated during the fragmentation process are described by [4]

$$f(x,y) = \begin{cases} \sqrt{1-(2p-1)^2}\sqrt{1-(x-y)^2} + (1-2p)(x-y) & x+y=1, \\ -\infty & x+y \neq 1, \end{cases}$$

where $0 \leq x, y \leq 1$ are variables that parametrize the coordinates of the rectangles. We also discuss numerical realizations of microstructures according to these fragmentation models, describe computations of the density profile and power laws and present comparisons with experimental data. These results are from a collaboration with J.M. Ball and B. Hambly (Oxford).

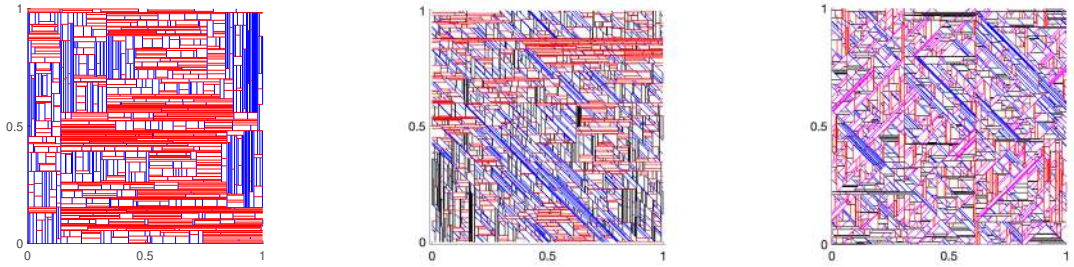

Figure 1: Realizations of microstructure as a fragmentation process with 2 (Left), 3 (Center) or 4 (Right) possible directions.

DISCRETE MODELS FOR PLANAR WEDGE DISCLINATIONS

In the second part of the talk we describe some recent results on the mathematical modeling of wedge disclinations. These are rotational defects caused by angular mismatch at the level of the crystalline lattice that were predicted by Volterra in his celebrated 1907 paper [8]. Unlike dislocations, which have received considerable attention since the 1930s, disclinations have received disproportionally less interest. However, disclinations are not uncommon as they accompany, as a relevant example, rotated and nested interfaces separating (almost) kinematically compatible variants as in martensitic avalanche experiments.

Our approach consists of an atomistic model measuring nearest-neighbor interactions over a triangular lattice. We describe the asymptotic behavior of the energy as the spacing of the lattice vanishes (continuum limit) via Gamma-convergence and we compute some numerical solutions of boundary value problems. Comparisons with data from literature on disclinations are also discussed. Some of these results are from a collaboration P. Van Meurs (Kanazawa) [5].

NON LOCAL AND THERMAL EFFECTS IN NANOWIRES PHASE TRANSITION

Luca Bellino*[1], Giuseppe Florio[1], Stefano Giordano[2], and Giuseppe Puglisi[3]
[1]Department of Mechanics, Mathematics and Management, Polytechnic University of Bari, Bari, Italy
[2]Institute of Electronics, Microelectronics and Nanotechnology - UMR 8520, Univ. Lille, CNRS, France
[3]Department of Civil and Environmental Engineering, Polytechnic University of Bari, Bari, Italy

Summary Interface energy and thermal effects are comparable when micro dimensional scales are considered, leading to a temperature dependent phase transition strategy that, from a macroscopic point of view, often leads to the presence of a stress-peak characterizing the nucleation stress and the size of the first phase from the propagation ones. To account for these phenomena, in a Statistical Mechanics framework, we consider next to nearest neighbor (NNN) interactions on a chain of bi-stable elements, and we obtain fully analytical result describing the aforementioned effects on the thermo-mechanical response of the system. Moreover, we validate our model by comparing it with the temperature dependent phase transition behavior experimentally observed on memory shape nanowires.

Effective, microstructure based models have been shown to be able to describe the thermo-mechanical response of different materials undergoing phase transitions (*e.g.* new bio-inspired materials [1] or shape memory alloys, SMA [2]). Here, by extending [3, 4], we consider a prototypical example constituted by a chain of elements with bistable potentials, describing a material with two distinct phases (i.e folded→unfolded configuration in a macromolecule or austenitic and martensitic phases in SMA [2]). As in the continuous analogue of higher order gradient theories [5], here we describe the important role of interfacial energy by considering NNN interactions (see Figure 1). The zero temperature behavior of this system was described in [6, 3, 4]. Here we consider the role of temperature analyzing the behavior of the bistable chain with non local NNN interactions in the framework of equilibrium Statistical Mechanics [7, 8, 9].

The energy function –adimensionalized with respect to lk, where k is the stiffness and l the reference length in the first phase– for a chain of n bistable oscillators is (see Figure 1a)

$$\varphi(\{S_j\},\{\varepsilon_j\}) = \varphi_{NN}+\varphi_{NNN} = \frac{1}{2}\sum_{j=1}^{n}\left[(\varepsilon_j+\varepsilon_0)^2\frac{(1-S_j)}{2}+\Big(\zeta(\varepsilon_j-\varepsilon_0)^2+2\eta\Big)\frac{(1+S_j)}{2}\right]+\frac{1}{2}\sum_{j=1}^{n-1}\alpha(\varepsilon_j+\varepsilon_{j+1})^2, \quad (1)$$

where ε_j is the strain of $j-$th domain, $\pm\varepsilon_0$ is the reference strain of the two configurations, respectively. Here ζ is the relative stiffness between the two wells, η is the relative transition energy and $\alpha < 0$ (ferromagnetic interaction) is the reference stiffness of the NNN harmonic springs. We have also introduced the *"spin"* variable S_j that can assume the value ±1 depending on the phase of the bi-stable oscillator, as shown in figure 1b.

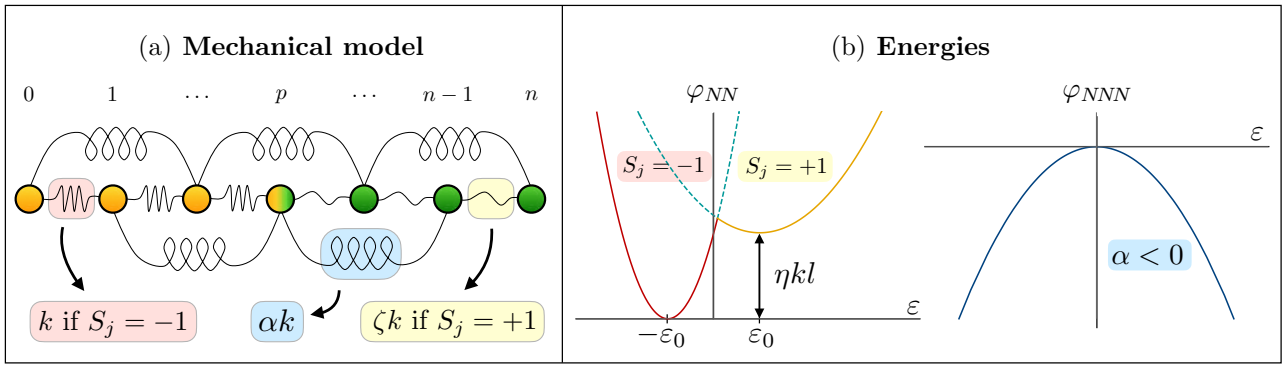

Figure 1: (a) Scheme of the chain with bistable units and NNN interactions. (b) NN and NNN energies.

To obtain fully analytical results, the NNN interaction is introduced in a perturbative framework (*i.e.* $|\alpha| \ll 1$) and the two parabolas modeling the NN energy terms are extended beyond the spinodal point [10, 8, 9] (see Fig 1b). We study the system in thermal equilibrium in the regimes of both soft (Gibbs ensemble) and hard (Helmholtz ensemble) devices, when a constant force σ or a fixed displacement δ are applied, respectively [11]. In the former case we obtain the expressions for the stress strain relation and the expectation values of both number of interfaces and nucleated phase fraction:

$$\langle\bar{\varepsilon}\rangle = (1-4\alpha)\Big[2\varepsilon_0\langle\chi\rangle_{\mathcal{G}}+(\sigma-\varepsilon_0)\Big], \quad \langle\chi\rangle_{\mathcal{G}} = \frac{\sum_{p=0}^{n}\sum_{i=0}^{n-1}\mathcal{W}_{p,i}\,\chi\,e^{\Gamma_{p,i}(\sigma)}}{\sum_{p=0}^{n}\sum_{i=0}^{n-1}\mathcal{W}_{p,i}\,e^{\Gamma_{p,i}(\sigma)}}, \quad \langle i\rangle_{\mathcal{G}} = \frac{\sum_{p=0}^{n}\sum_{i=0}^{n-1}\mathcal{W}_{p,i}\,i\,e^{\Gamma_{p,i}(\sigma)}}{\sum_{p=0}^{n}\sum_{i=0}^{n-1}\mathcal{W}_{p,i}\,e^{\Gamma_{p,i}(\sigma)}}, \quad (2)$$

*Corresponding author. E-mail: luca.bellino@poliba.it

where p is the number of elements in phase 2, i is the number of interfaces and $\beta = \frac{1}{k_B T}$, with k_B the Boltzmann constant and T the absolute temperature ($\zeta = 1$ for simplicity of the expression), $\mathcal{W}_{p,i}$ is a combinatorial counting coefficient and $\Gamma_{p,i}(\sigma)$ is a characteristic function for the Gibbs ensemble (see [11] for details).

On the other hand, at fixed displacement δ, we obtain

$$\langle\sigma\rangle = \frac{\left[\bar{\varepsilon} - (1-4\alpha)\big(2\langle\chi\rangle_{\mathscr{H}} - 1\big)\varepsilon_0\right]}{\left(1 - \dfrac{4\alpha}{n}(n-1)\right)}, \quad \langle\chi\rangle_{\mathscr{H}} = \frac{\sum_{p=0}^{n}\sum_{i=0}^{n-1}\mathcal{W}_{p,i}\,\chi\, e^{\Omega_{p,i}(\delta)}}{\sum_{p=0}^{n}\sum_{i=0}^{n-1}\mathcal{W}_{p,i}\, e^{\Omega_{p,i}(\delta)}}, \quad \langle i\rangle_{\mathscr{H}} = \frac{\sum_{p=0}^{n}\sum_{i=0}^{n-1}\mathcal{W}_{p,i}\, i\, e^{\Omega_{p,i}(\delta)}}{\sum_{p=0}^{n}\sum_{i=0}^{n-1}\mathcal{W}_{p,i}\, e^{\Omega_{p,i}(\delta)}}, \tag{3}$$

where $\Omega_{p,i}(\delta)$ is a characteristic function for the Helmholtz ensemble (see [11] for details).

In figure 2 we show the theoretical results obtained with our model (Fig. (a)) and the comparisons with the experimental data of Molecular Dynamic simulations performed by Lu at al [12] (Fig. (b)) and Wu [13] (Fig. (c)). In the first row of figure 2, can be observed that as the discreetness of the system increases, the nucleation (peak) stress becomes higher with respect to propagation one. On the other hand, as the temperature increases the stress peak decreases while the regime is opposite for increasing interfacial energy, showing a direct competition between the two energies during the transition process. In the second row of figure 2 we present the comparison of our analytical results with two different molecular dynamic simulations, obtaining an excellent agreement among the data.

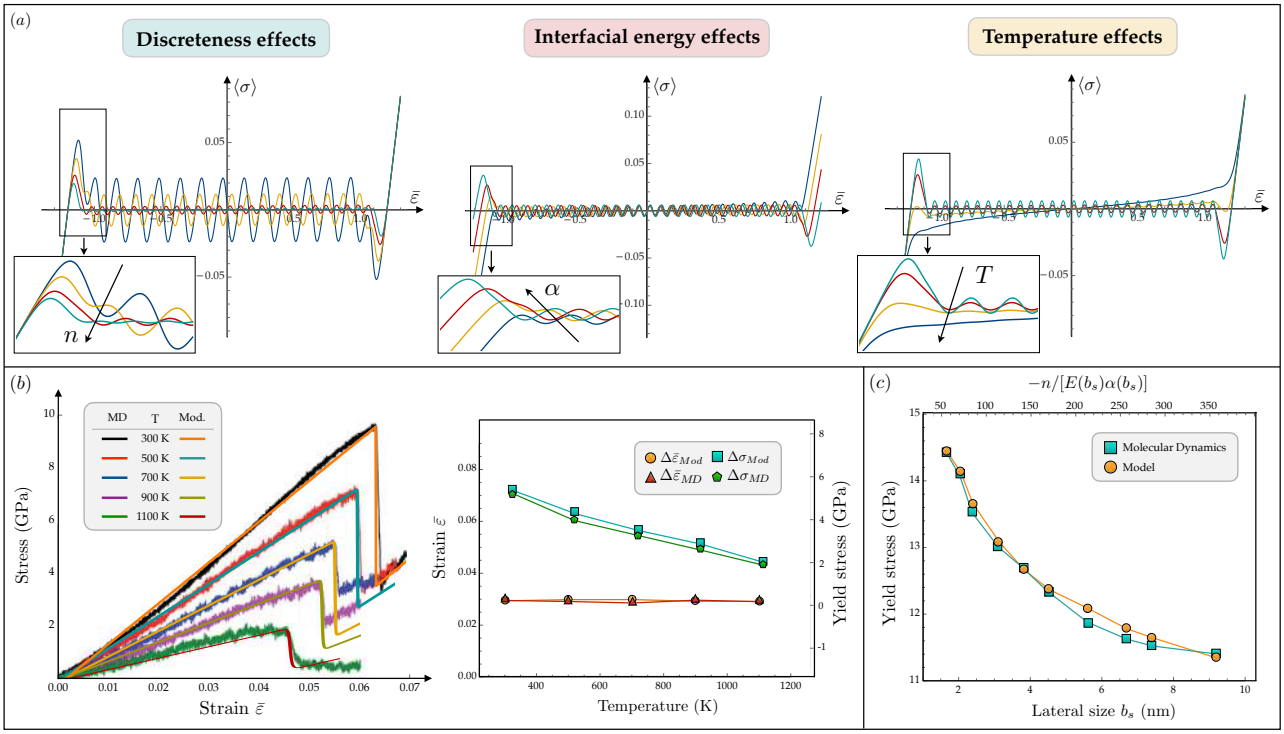

Figure 2: First row: theoretical results showing the effects of the discreteness of the system, of the interfacial energy and of the temperature in the case of applied displacement. Bottom row: comparison with the Molecular Dynamic simulations of memory shape nanowires of Lu et al. in figure (b) [12] and of Wu in (c) [13].

A COUPLED ELECTRO-CHEMO-MECHANICAL MODEL FOR ALL-SOLID-STATE THIN FILM LI-ION BATTERIES

Fenghui Wang*, Xu Song, Yongjun Lu, and Xiang Zhao
Bio-inspired and Advanced Energy Research Center, School of Mechanics, Civil Engineering and Architecture, Northwestern Polytechnical University, Xi'an 210129, PR, China

Summary For all-solid-state thin film batteries (TFBs) with high requirements for mechanical flexibility, stable electrochemical output and mechanical reliability are very important. Recently, mechanical-related problems in TFBs have drawn considerable attention. Herein, a fully coupled electro-chemo-mechanical theoretical model in continuum-scale for TFBs is proposed considering three main processes in the battery. The diffusion of lithium in electrode phase; the diffusion and migration of lithium in solid-state electrolyte phase; the interfacial transport reaction kinetics. This model provides an effective way for studying the TFBs respect different initial states, materials combination, and structural parameters.

MODEL DESCRIPTION

A TFB with non-porous anode, non-porous cathode, non-porous solid-state electrolyte, and perfectly bonded interfaces are considered in present work. The component in the system present are regarded as homogeneous isotropic linear elastic solids in which the deformation is infinitesimal. The Li transport process during charging is shown in fig. 1, the Li in the cathode released as a Li ion via an oxidation reaction taken place at the interface; the Li ion then arrive at the interface between anode and solid-state electrolyte and taken-up by anode as Li via a reduction reaction.

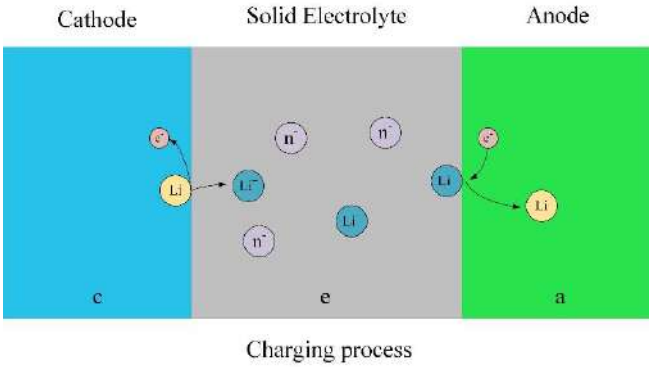

Figure 1. Schematic diagram of Li transport

Diffusion process of Li in electrode phase

The electrode material was considered as ideal intercalation storage materials, with lithium, vacancy and immobile host. We follow the frame work of Bohn. et al. to describe the diffusion process in electrode phase by an equation deduced from basic thermodynamics and statistical physics [1]. The Li-Li interactions are ignored in present work then the equation is given by

$$\frac{\partial c}{\partial t} - \nabla \cdot D\left[\nabla c - (1 - c/c^{\mathrm{m}})\frac{\Omega}{RT} c \nabla \sigma_{\mathrm{h}}\right] = 0, \tag{1}$$

where c, Li concentration; t, time; D, the diffusion coefficient; Ω, the partial molar volume; R, universal gas constant; T, temperature; $\sigma_{\mathrm{h}} = \frac{1}{3}\sigma_{kk}$, the hydrostatic stress; c^{m}, the maximum Li concentration.

Diffusion and migration in binary solid-state electrolyte

Several theoretical researches have been carried out to describe the diffusion and migration process of Li ion in solid-state phase. Here, a binary solid polymer electrolyte of particular interest is considered in which the electrolyte molecule dissociates into a monovalent cation and a monovalent anion. The coupled stress and ionic transport within solid polymer electrolyte are modeled following the framework of Grazioli et al. A charge balance equation is given by

$$\nabla \cdot \left[-F(D_+ - D_-)\nabla c - \frac{F^2(D_+ + D_-)}{RT} c \nabla \Phi + \frac{F(D_+\Omega_+ - D_-\Omega_-)}{RT} c \nabla \sigma_{\mathrm{h}}\right] = 0, \tag{2}$$

the subscripts $+$ and $-$ represent the corresponding variables of cation and anion in solid-state electrolyte; F, Faraday's constant; Φ, electric potential. In addition, a mass balance equation in solid-state phase is given by

$$\frac{\partial c}{\partial t} + \nabla \cdot \left(-D\nabla c + \frac{D\Omega}{2RT} c \nabla \sigma_{\mathrm{h}}\right) = 0. \tag{3}$$

Electrode-electrolyte interface chemical reaction kinetics

For the interface in a solid-state battery where the stress fields are inevitably involved, the reaction kinetics at interfaces are expected to be altered with stresses of adjacent region [2-4]. An extended Butler-Volmer equation including the effects of stress in electrode phase is presented to describe the interface reaction,

$$i = i_0 \left[\exp\left(\frac{(1-\beta)}{RT}F\eta\right) - \exp\left(-\frac{\beta}{RT}F\beta\right)\right], \tag{4}$$

where the exchange current density is given by

$$i_0 = Fk(c_{\mathrm{ed}})^{\beta}[c_{\mathrm{el}}(c_{\mathrm{ed}}^{\mathrm{m}} - c_{\mathrm{ed}})]^{1-\beta} \exp\left(\frac{(\alpha-\beta)}{RT}\left(\Omega_{\mathrm{ed}}\sigma_{\mathrm{h,ed}} - \Omega_{\mathrm{el}}\sigma_{\mathrm{h,el}}\right)\right), \tag{5}$$

the subscripts ed and el represent the corresponding variables in electrode and electrolyte phase; i, current density; β, symmetry factor; α, mechanically symmetry factor; η, overpotential; k, rate constant. An equilibrium potential at interface is given as

$$(\Phi_{\mathrm{ed}} - \Phi_{\mathrm{el}})^{\mathrm{eq}} = \Phi_{\mathrm{ref}} + \frac{RT}{F}\ln\left(\frac{c_{\mathrm{el}}(c_{\mathrm{ed}}^{m} - c_{\mathrm{ed}})}{c_{\mathrm{el}}^{\mathrm{ref}} c_{\mathrm{ed}}}\right) + \frac{1}{F}\left(\Omega_{\mathrm{ed}}\sigma_{\mathrm{h,ed}} - \Omega_{\mathrm{el}}\sigma_{\mathrm{h,el}}\right), \tag{6}$$

the overpotential can be expressed as

$$\eta = \Phi_{\mathrm{ed}} - \Phi_{\mathrm{el}} - (\Phi_{\mathrm{ed}} - \Phi_{\mathrm{el}})^{\mathrm{eq}}, \tag{7}$$

Mechanics

The stress under the assumption of infinitesimal strain can be expressed as

$$\sigma_{ij} = C_{ijkl}\left[\varepsilon_{kl} - \frac{1}{3}\Omega(c - c_0)\delta_{kl}\right], \tag{8}$$

where the elastic modulus tensor, $C_{ijkl} = \frac{E}{2(1-v)}\left(\delta_{il}\delta_{jk} + \delta_{ik}\delta_{jl}\right) + \frac{Ev}{(1+v)(1-2v)}\delta_{ij}\delta_{kl}$; strain tensor, $\varepsilon_{ij} = (u_{i,j} + u_{j,i})$; u, displacement; c_0, initial concentration; E, elastic modulus; v, Poisson's ratio.

Cell potential

The potential drops in electrode phase are ignored, then the cell potential is given as

$$V_{\mathrm{cell}} = \Phi_{\mathrm{c}} - \Phi_{\mathrm{a}}, \tag{9}$$

the subscripts a and c represent the corresponding variables in anode and cathode.

CONCLUSIONS

In view of the fact that there are few full-cell models to describe the electro-chemo-mechanical coupling behavior for TFBs, while the mechanical problems in TFBs have attracted considerable attentions [5, 6]. Based on the original electrochemical model of all-solid-state batteries, the mechanical effects are introduced into the model to establish a fully coupled electro-chemo-mechanical model. The model can be used to investigate the effects of external loads on battery performance.

ON CORROSION OF A PIPE WITH THE REDUCTION IN THE STRENGTH TAKING INTO ACCOUNT

Yulia Pronina[1*], Marina Elaeva [1]
[1]Department of Computational Methods in Continuum Mechanics, Saint-Petersburg State University, Saint-Petersburg, Russian Federation

Summary The paper concerns modelling the stress-assisted general corrosion of a pressurised pipe accompanied by the reduction in the strength of the pipe material. Analytical solution of the problem is obtained. Problems of optimal design are also considered with taking into account the presence of protective coatings on the pipe surfaces. The effect of the nonuniform temperature field on the synergistic growth of mechanical stress and corrosion rate is discussed in comparison with the effect of the elastic stress component.

INTRODUCTION

Most structures are exploited while being subjected to both mechanical loads and operating environments. Such conditions may activate the process of mechanochemical corrosion, which is more severe than the corrosion independent of stress. A lot of experimental data show a linear dependence of general corrosion rate on the effective stress [1]. Moreover, corrosion can degrade the useful properties of materials and structures including their strength [1].

When corrosion rate depends on stress, and stress, in turn, depends on changing – due to corrosion – geometry of an element, we have to consider initial boundary value problems with unknown evolving boundaries. Such problems are mostly studied by numerical methods. However, a number of analytical solutions have been found for uniform mechanochemical dissolution of structural elements, e.g. by the authors of [2, 3]; previous solutions for pressurised vessels have been built for the cases when the effective stresses on their inner and outer surfaces were assumed to be equal to each other. Authors could find analytical solutions for such problems taking into account the change in the effective stress through the shell thickness, as well as a possible inhibition of corrosion [4, 5]. The present paper also takes into consideration the reduction in the strength of the pipe material and the presence of protective coatings on the pipe surfaces. The effect of the thermal stresses on the durability of the pipe under the mechanochemical corrosion conditions is also discussed in comparison with the effect of the elastic stresses. The problems of optimal design are investigated on the base of the obtained solution.

FORMULATION OF THE PROBLEM

Consider an elastic circular pipe subjected to internal p_r and external p_R pressure of aggressive media that may have different temperatures T_r and T_R, correspondingly. Electrochemical reaction with these environments causes general dissolution of the pipe material and degrades its strength. The rates of corrosion inside (v_r) and outside (v_R) are linear functions of the maximum in absolute-value principal stress, σ_r and σ_R, at the corresponding surface [1, 2, 5]:

$$v_r = \frac{\mathrm{d}r}{\mathrm{d}t} = [a_r + m_r \sigma_r(r,R)]\exp(\beta_r[T_r - T_r^o]) \text{ at } t \ge t_r^c, \quad (1)$$

$$v_R = -\frac{\mathrm{d}R}{\mathrm{d}t} = [a_R + m_R \sigma_R(r,R)]\exp(\beta_R[T_R - T_R^o]) \text{ at } t \ge t_R^c. \quad (2)$$

Here $a_r, a_R, m_r, m_R, \beta_r, \beta_R, T_r^o, T_R^o$ are empirically determined constants of corrosion kinetics; t_r^c and t_R^c are the lives of the protective coatings on the inner and outer surfaces; r and R are the variable inner and outer radii of the pipe; t is time. If $T_r \le T_r^o$ and/or $T_R \le T_R^o$, then $\beta_r = 0$ and/or $\beta_R = 0$. The strength limit, $\sigma^* = \sigma^*(t)$, of the pipe material is supposed to decrease with time linearly or tending to a certain constant level.

It is required to analyse the effect of the strength degradation and other parameters on the durability of the pipe. Contribution of the elastic and thermal stress components in the mechanochemical effect is also compared.

The problem of optimal design is formulated in two senses: to find an initial thickness of the pipe wall which provides (I) a specified service life of the pipe and a minimum material consumption or (II) a minimum material consumption per the unit of the pipe life; the pipe capacity being given.

RESULTS

First, we found the conditions when the circumferential stress can serve as the effective stress in the corrosion kinetic equations. The stresses are determined by the sum of the elastic and thermal components. Although stresses σ_r and σ_R on the inner and outer surfaces depend on both evolving radii r and R, we could find analytical solution of the system of basic differential equations (1)–(2) at arbitrary coatings lives t_r^c and t_R^c. It has been revealed that despite the fact that the thermal stress can noticeably increase the absolute value of the mechanical stress in the pressurized vessel, thermal component does not have such a strong effect on the stress enhanced acceleration of corrosion process, as the elastic component.

The problem (I) of optimal design has a unique solution corresponding to the case when the maximum allowable stress is reached at the end of a specified service life of the pipe. In problem (II), it is necessary to find the minimum of the objective function proportional to the ratio of the initial mass of the pipe to its life. As one can see from Fig. 1, difference in the coating lives can noticeably change the behaviour of the objective function, other parameters being equal. The results were generalised with taking into account reduction in the strength of the pipe material.

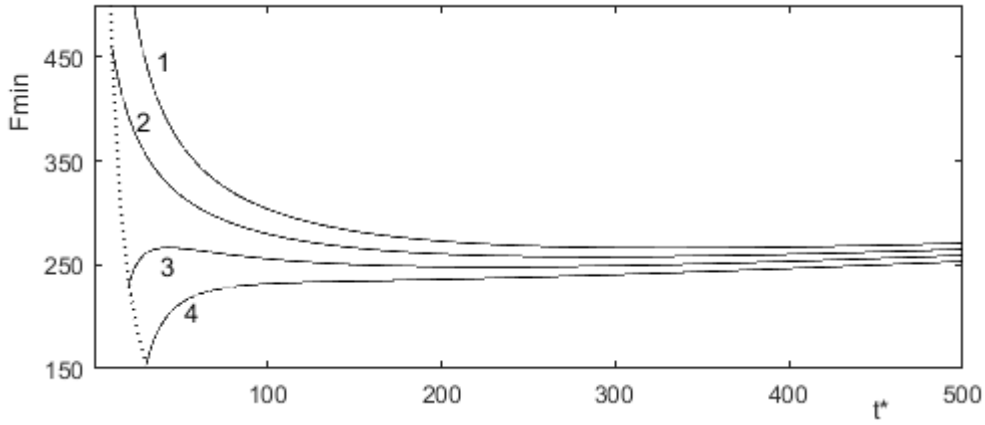

Figure 1. Objective function vs life of the pipe (in conventional units of time) for different coating lives t_R^c: 0 (line 1), 10 (line 2), 20 (line 3) and 30 (line 4) .

The obtained solutions can serve as benchmarks for numerical analysis and for design purposes.

APPLICATION OF MECHANOCHEMISTRY MODEL TO OXIDATION OF PURE NICKEL SPHERES

Svetlana Petrenko*[1], Eric Charkaluk [1], Alexandre Tanguy[1], and Cecile Davoine[2]

Summary In this work, we study the two-phase chemical reactions on the example of the oxidation of nickel. We have carried out an experiment of high-temperature oxidation of nickel balls, and obtained the experimental data for the growth of the oxide layer over time. To select the best analytical solution we consider three different rheology for the oxide of nickel: elastic, elastoplastic and viscoelastic. We compare the solution for each rheological model with experimental data.

INTRODUCTION

In this contribution we discuss an extension of a microscopic model of oxidation to macro scale. In particular, we sketch a protocol of experimental validation of it based on measurements for (approximately) spherically-symmetric samples.

Stress-assisted chemical reactions are relevant in various industrial and medical applications and in modern technologies. It is enough to mention for instance batteries charging/discharging cycles: along with the introduction of silicon instead of carbon the issue of the dramatic change of volume in the active material is observed, which results in massive cracking when inappropriately handled [2]. In MEMS the oxidation process is responsible for rapid fatigue effects [3]. For composite material meant for high temperature resistance, the metallic inclusions being heated up and oxidized, expand and induce internal strain to the matrix [4, 5]. All these and a lot of other processes can be described using the two-phase reaction model, it is thus important to be able to handle it efficiently. The model however relies heavily on the rheological properties of the involved materials, which are in general to be defined. Here we present a procedure of identification of a proper model, based on few experimental data.

First we recall the general theoretical model, and some steps to reduce it to analytically tractable problem. Then we describe the available experimental data and some features to be taken into account during its acquisition. We conclude by some preliminary analysis of the experiment, the details of which will be described in [1].

TWO-PHASE REACTION MODEL

To describe the two-phase chemical reactions such as oxidation processes or charging/discharging of batteries, we consider the following model. We have some initial solid, we can set the geometrical parameters, boundary conditions and the mechanical properties of the body. There is a diffusion of some chemical, for example, it can be oxygen in the case of the oxidation or lithium in the case of the lithiation of silicon (charging of batteries), etc. A chemical reaction between the initial solid body and some diffusive constituent is of the following type: it begins from the outer surface of the initial solid, localized on the interface between initial and transformed material and maintained by the diffusion of the diffusive constituent through the transformed material.

To obtain the equation for the chemical reaction front propagation, taking into account the effect of the stress-strain state in the body, we use the classical kinetic equation ([8]) from the chemical thermodynamics. We substitute the normal component of the chemical affinity tensor A_{NN} ([9]) instead of scalar chemical affinity A in the equation for the reaction rate, hence we obtain the kinetic equation for the surface element of reaction front with the normal $\mathbf{N}$:

$$\omega_N = \frac{\nu_- M_-}{\rho_-} k_* c \left(1 - exp\left(-\frac{A_{NN}}{RT}\right)\right) = 0 \tag{1}$$

where ν_- is the stoichiometric coefficient, M_- is the molar mass and ρ_- is the mass density of the initial solid; k_* is the reaction constant; c is the molar concentration of the diffusive constituent; A is the chemical affinity; R is the universal gas constant; T is the temperature. And the normal component of the chemical affinity tensor in the case of the small deformations is defined ([9]) as follows :

$$A_{NN} = \frac{n_- M_-}{\rho_-}\left\{\gamma(T) + \frac{1}{2}\boldsymbol{\sigma}_- : \left(\boldsymbol{\varepsilon}_- - \boldsymbol{\varepsilon}_-^{ch}\right) - \frac{1}{2}\boldsymbol{\sigma}_+ : \left(\boldsymbol{\varepsilon}_+ - \boldsymbol{\varepsilon}_+^{ch}\right) + \boldsymbol{\sigma}_- : [\![\boldsymbol{\varepsilon}]\!]\right\} + \nu_* RT \ln\frac{c}{c_*} \tag{2}$$

where γ is the temperature-dependent parameter of the reaction; $\boldsymbol{\sigma}_\pm$ and $\boldsymbol{\varepsilon}_\pm$ are the stress and strain tensors for the transformed and initial material, respectively; $\boldsymbol{\varepsilon}_\pm^{ch}$ are the strain tensors which define the volumetric change due to the chemical transformation; ν_* is the stoichiometric coefficient of the diffusive constituent; c_* is the solubility of the diffusive constituent in the transformed material.

EXPERIMENTAL SETUP

In the current work we consider the oxidation of nickel balls. Nickel oxide nano-particles and nickel are widely used in heavy industries [6, 7]. To obtain the kinetic equation we have to choose the rheological model for the transformed material (initial material is elastic) and solve the mechanical problem in the spherical coordinates. To get the best analytical solution for this experiment we will consider three different rheology for the transformed material: elastic, viscoelastic and elastoplastic. For each rheological model we obtain the specific solution and the kinetic equation. This permits to spell-out the solutions to be compared with experimental data.

Several balls were oxidized in the air at temperature 800^{o}C for up to 500h: each ball was oxidized for a different amount of time: the first one for 100h, the second for 200h, ... and the fifth for 500h. After that, each ball was cut in halves, polished, and the outer layer was captured in the electronic microscope.

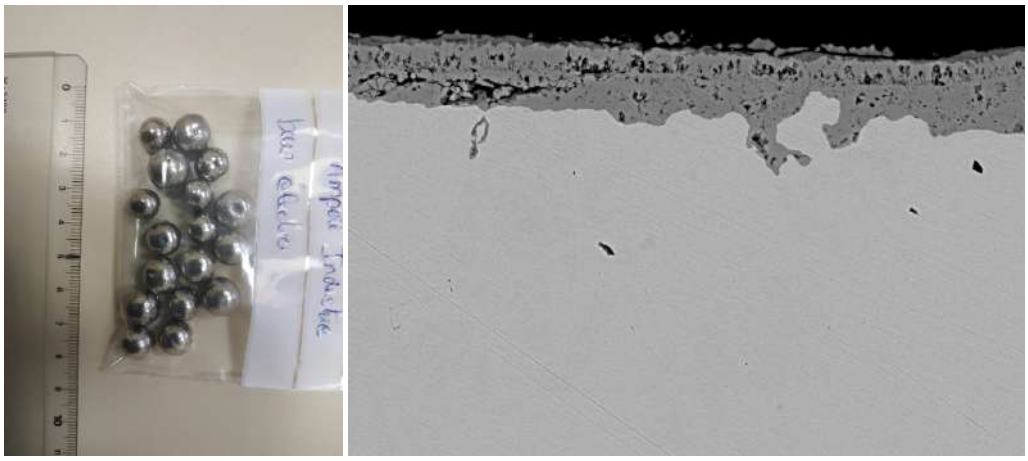

Figure 1: Experiments. Available samples (left) to be chosen for oxidation. Measurement results (right) – TEM imaging.

PRELIMINARY CONCLUSIONS AND PERSPECTIVES

Several remarks about the experiment are in place here. First, nikel oxide has a very fragile structure, however NiO is much stiffer than pure nickel. That makes the process of polishing hard: debris of NiO tend to scratch the pure metallic surface. It is thus very complicated to obtain precise mechanical properties of the oxide layer close to the interface. Second, with transmission electron microscopy we make the chemical analysis, study the morphology of the oxide, get the grain boundaries and measure the oxide thickness. However the balls used for different times of oxidation are slightly different in size and are not of perfectly spherical shape. Hence, measuring of the thickness of the oxide layer for each ball has to be relative to the initial radius of the ball. Here it is important to note, that the experiment confirms the validity of small deformations hypothesis. It means that the linearized model 2 is valid, and the time-dependence of the averaged renormalised thickness of the oxide layer is relevant.

Having analysed the dependence of the thickness of the oxide layer on time, we can say the best guess for the rheological properties would be elastoplastic. We will give proper details about this conclusion in a longer article ([1]). In the same paper we will also comment on the processing of images obtained by microscopy: renormalisation, reassembling and segmentation.

THERMODYNAMIC DISLOCATION THEORY

Le, Khanh Chau[1,2]*

[2]Faculty of Civil Engineering, Ton Duc Thang University, Ho Chi Minh City, Vietnam

Extended Abstract

This paper proposes the thermodynamic dislocation theory for uniform and non-uniform plastic deformations, which takes into account the effective disorder temperature. The latter occurs as the dynamic state variable characterizing the disorder of the configurational subsystem that contains degrees of freedom associated with the rearrangement of atoms during the motion of dislocations. We verify two laws for plastic flows of face-centered cubic crystals that deform at constant strain rates and fixed ambient temperatures. The first law relates steady-state flow stress to ambient temperature and strain rate. The second law requires an increase of configurational entropy towards a maximum reached in the steady state. The large-scale least squares analysis is provided which allows the physics-based parameters of the dislocation mediated plasticity proposed by Langer, Bouchbinder, and Lookman [1] to be identified in accordance with these laws [2]. The system of equations of LBL-theory has been extended based on the first and second laws of thermodynamics for the configurational and kinetic-vibrational subsystems to take into account the change of kinetic-vibrational temperature and the non-redundant dislocations. We then use it to simulate the stress-strain curves for single and polycrystals of copper, aluminum, and steel alloys that are subjected to simple shear, tension/compression tests, and torsion and compare them with the experimental results (see [3-12]). The theory can predict the stress-strain curves in a wide range of temperature and strain rates. We show the size and the Bauschinger effects due to the non-redundant dislocations, as well as the strain rate sensitivity and the thermal softening due to the redundant dislocations. Finally, we make a simple model of a weak notch-like disturbances that, when driven hard enough, triggers shear banding instabilities that are quantitatively comparable to those of Marchand and Duffy's experiments.

Abstract Silicon (Si) nanostructures are widely used in microelectronics and nanotechnology. Brittle to ductile transition in nanoscale Si is of great scientific and technological interest, but this phenomenon and its underlying mechanism remain elusive. By conducting in situ temperature-controlled nanomechanical testing inside a transmission electron microscope (TEM), here we show that the crystalline Si nanowires under tension are brittle at room temperature, but exhibit ductile behavior with dislocation-mediated plasticity at elevated temperatures. We find that reducing the nanowire diameter promotes the dislocation-mediated responses, as shown by 78 Si nanowires tested between room temperature and 600 K. In situ high resolution TEM imaging and atomistic reaction pathway modeling reveal that the unconventional ½⟨110⟩{001} dislocations become highly active with increasing temperature and thus play a critical role in the formation of deformation bands, leading to transition from brittle fracture to dislocation-mediated failure in Si nanowires at elevated temperatures. This study provides quantitative characterization and mechanistic insight for the brittle to ductile transition in Si nanostructures.

Introduction

Silicon nanostructures have been used extensively in modern microelectronics. The ever-increasing integration density in microelectronic chips inevitably leads to a marked temperature rise of Si nanostructures, which are required to withstand large thermal stresses for maintaining their proper functions. Si nanostructures are also the building blocks for many novel nanotechnology applications, including energy harvesting and storage, flexible and stretchable electronics, sensors and nanoelectromechanical systems.[1] The reliability concerns of these applications call for a fundamental understanding of the mechanical behavior of Si nanostructures at elevated temperatures. Here we report the *in situ* tensile testing of single crystal Si NWs in the temperature range of RT to 600 K.[2] We employ a newly developed microelectromechanical system (MEMS) for conducting the nano-thermo-mechanical testing inside a transmission electron microscope (TEM). This platform allows stress-strain measurement with simultaneous TEM imaging of atomic-scale deformation at different temperatures.[2,3] An on-chip heater is built into the MEMS-based platform, allowing the controlled heating of the specimen.

Results

Single crystal Si NWs were synthesized by chemical evaporation deposition through the vapor-liquid-solid mechanism. The Si NWs used for mechanical testing are ⟨112⟩-oriented and have a central {111} twin boundary running parallel to the axial direction of the NW. *In situ* TEM tensile testing of individual Si NWs was performed at temperatures ranging from 295 to 600 K. In Fig. 1, we compare the brittle response at RT (295 K) with the moderate ductile behavior at 600 K for Si NWs with similar diameters. Figure 1a shows the stress-strain curve of a Si NW with a diameter of 61 nm at 295 K. This NW initially exhibited a linear elastic response. As the tensile strain increased to 7.4% and the corresponding tensile stress to 11.5 GPa, brittle fracture occurred. The inset in Fig. 1a shows a TEM image of the sharp {111} cleavage surfaces, which are known to have the lowest surface energy and also typically observed during brittle fracture of bulk Si crystals.[4] The two fracture surfaces in the upper and lower twin variants are symmetric and tilted at ~70° with respect to the axial direction.

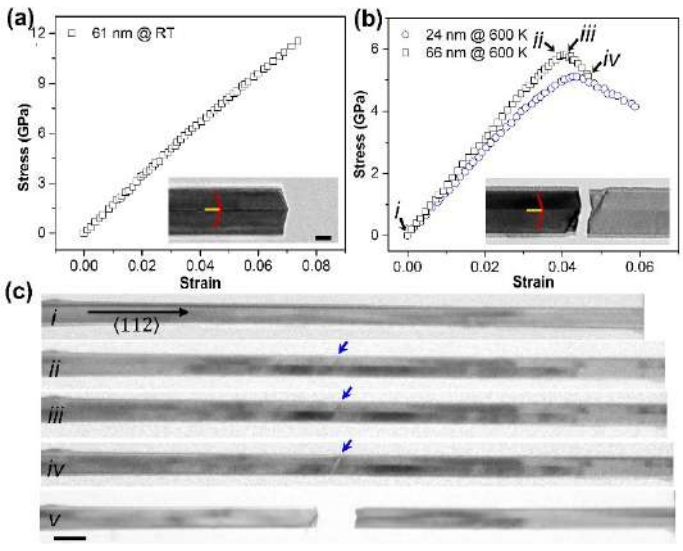

Figure 1. *In situ* MEMS-based measurement and TEM observation of mechanical behavior of individual Si NWs under uniaxial tension at room and elevated temperatures.

In contrast, the Si NW with a diameter of 66 nm at 600 K exhibited moderate ductile behavior. As shown in Fig. 1b, the tensile stress-strain curve was initially linear and became slightly nonlinear with increasing stress, until the maximum stress of 5.8 GPa was reached at the critical strain of 4.0%. Subsequently, the stress decreased with increasing strain, and this softening response continued until fracture occurred at the strain of 4.7%. The inset in Fig. 1b shows the TEM image of fracture surfaces, which exhibit the features of ductile failure such as localized necking, deformation bands and rough fracture planes. Figure 1c shows the TEM snapshots during *in situ* tensile testing at 600 K, and the corresponding stress/strain for each snapshot is marked in Fig. 1b. It is seen that the maximum stress and ensuing softening response can be associated with surface nucleation and migration of dislocations as well as dislocation interactions with the twin boundary, as marked

by blue arrows in Fig. 1c *ii-iv*. These continued dislocation processes resulted in large plastic strains in Si NWs at elevated temperatures. Overall, Fig. 1 reveals that the Si NWs under tension are brittle at RT, but exhibit pronounced plastic deformation followed by fracture at elevated temperatures (e.g., 600 K).

We found that a decrease in the NW diameter can lead to enhanced plastic deformation. Figure 1b also includes the tensile stress-strain curve of a thinner Si NW with a diameter of 24 nm at 600 K, which is qualitatively similar to the Si NW with a diameter of 66 nm at 600 K. However, in this thinner NW, a lower maximum stress of 5.1 GPa was attained at a smaller critical strain of 4.3%, signifying a stronger tendency to plastic deformation. Moreover, the subsequent softening response was sustained over a strain range of 1.6% until the fracture strain ϵ_f of 5.9%; this strain range is defined as plastic strain ϵ_p. Hence, both ϵ_p and ϵ_f measured for the thinner Si NW are larger than the corresponding ϵ_p of 0.7% and ϵ_f of 4.7% for the thicker Si NW (Fig. 1b). The more extensive plasticity in the thinner Si NW was manifested by the formation of a number of deformation bands that are uniformly distributed throughout the entire NW, which contrasts with fewer deformation bands in the thicker NW (Fig. 1c).

Our *in situ* HRTEM experiments [2] at elevated temperatures indicated that the formation of deformation bands originates from the dominant operation of ½⟨110⟩{001} full dislocations, which were observed in all Si NWs tested at elevated temperatures, irrespective of existence of a central twin boundary. This stands in contrast with the dominant activities of ½⟨110⟩{111} full dislocations or 1/6⟨112⟩{111} partials during plastic deformation of bulk Si structures [5]. Atomistic simulations suggested that the surface nucleation of ½⟨110⟩{1$\bar{1}$1} dislocations is less favorable than ½⟨110⟩{001} dislocations in <112>-oriented Si NWs under tension at elevated temperatures. The higher primary barrier of surface nucleation of the ½⟨110⟩{1$\bar{1}$1} loop can be partly attributed to the relatively small Schmid factor of 0.41 under axial loading, as opposed to 0.47 for the ½⟨110⟩{001} loop. In addition, differences in surface ledge energy and dislocation line tension can also affect the primary energy barriers for the two competing dislocation modes. It should be noted that the lack of (or substantially weaker) secondary barriers for nucleation of a ½⟨110⟩{1$\bar{1}$1} loop can be attributed to the close-packed {1$\bar{1}$1} slip planes in diamond cubic Si, which facilitate dislocation glide by eliminating (or largely reducing) the secondary barriers at high loads. Hence, ½⟨110⟩{1$\bar{1}$1} dislocations could become active at RT, when the primary energy barrier is sufficiently reduced by increasing load, provided that the tensile stress component on the potential cleavage planes is sufficiently low for averting brittle fracture.

To further understand the size and temperature dependence of dislocation-mediated plasticity and fracture, we tested 78 Si NWs with the diameter range of 24-160 nm and in the temperature range of 295-600 K. As shown in Fig. 2a, the plastic strain ϵ_p increases with decreasing NW diameter. For example, at 600 K, ϵ_p increases from 0.27 to 1.6%, as the NW diameter decreases from 160 to 24 nm. For the same diameter, ϵ_p increases with temperature. The results of the 78 Si NWs tested are summarized in a deformation mechanism map of Fig. 2b. In this map, green circles represent Si NWs with dislocation-mediated failure, while black squares Si NWs with brittle cleavage fracture. A transition line, as defined by a critical ϵ_p of 0.1%, is drawn to separate the regimes of brittle and dislocation-mediated responses. The map also reveals that as the NW diameter decreases, the critical temperature associated with dislocation-mediated plastic deformation decreases. For example, the Si NW with diameter of 110 nm showed brittle fracture at 398 K, while the NW with diameter of 30 nm exhibited plastic deformation with dislocation activities even at 362 K. Hence, Fig. 2b indicates that both the increase of temperature and the decrease of NW diameter can promote plastic deformation in Si NWs, leading to dislocation-mediated failure.

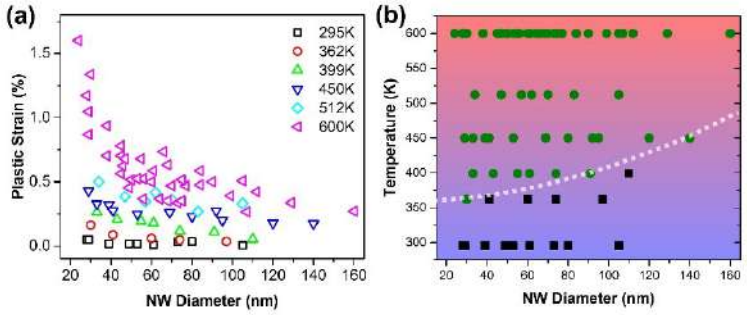

Figure 2. Size and temperature dependence of brittle versus ductile behaviors of 78 Si NWs tested in the temperature range of 295 to 600 K.

STRAIN GRADIENT COUPLED CHEMO-MECHANICAL MODELLING OF HETEROGENEOUS CATHODE

Avtar Singh[1] and Siladitya Pal[1]
[1]Department of Mechanical and Industrial Engineering, IIT Roorkee, Roorkee, India

Summary Next generation electrodes for lithium-ion battery (LIB) are composite systems composed of heterogeneous microstructure. During charging and discharging process the electrodes are subjected to stress field due to misfit strain associated with diffusion of lithium ions in the host electrode. The attendant stress field further alters the phase kinetics of lithium. When the spatial dimension is reduced to nano-meter length, size effect plays significant role; thus, it may considerably influence coupled phenomena. Therefore, the size effect must be accounted to describe the chemo-mechanical behaviour. In order to accommodate the effect of strain gradient, we employ previously developed staggered strain gradient theory in which an intermediate displacement field utilized. In this study we developed novel multi-field numerical framework to take into account the effect of strain gradient.

FORMULATION

The mass-conservation equation for lithium ions is governed by

$$\frac{\partial c}{\partial t} + \nabla \cdot \mathbf{J} = 0 \tag{1}$$

in which flux **J**, chemical potential μ and concentration dependent mobility $M(c)$ are expressed as

$$\mathbf{J} = -M(c)\nabla\mu, \quad \mu = RT\left[\chi(1-2\tilde{c}) + \ln\frac{\tilde{c}}{1-\tilde{c}}\right] - \beta\sigma_h \quad \text{and} \quad M(c) = \frac{D}{RT}c(1-\tilde{c}) \tag{2}$$

where $\tilde{c}$ defines the normalized concentration field ($\tilde{c} = c/c_{\max}$), whereas $c_{\max}$ is the solubility limit of the intercalated lithium ions, D/RT represents the mobility of the dilute solution with D being the diffusivity of lithium ions in host material.

During the insertion/extraction of the lithium ions, host material expands or contracts and if it is constrained then stress results due to eigen strain. In order to account the effect of strain gradient, we employ previously developed staggered strain gradient theory in which additional computational complexities is avoided arising from higher order continuity requirement of regular displacement field by introducing the intermediate set of kinematic and kinetic variables, $\bar{\boldsymbol{u}}$, $\bar{\varepsilon}$ and $\bar{\sigma}$ as

$$\bar{\boldsymbol{u}} = \boldsymbol{u} - l_c^2\nabla\cdot\nabla\boldsymbol{u}, \quad \bar{\varepsilon} = \frac{1}{2}\left(\nabla\bar{\boldsymbol{u}} + \nabla\bar{\boldsymbol{u}}^T\right) \quad \text{and,} \quad \bar{\boldsymbol{\sigma}} = \boldsymbol{C} : \bar{\varepsilon}^e \tag{3}$$

where $\boldsymbol{C}$ is the fourth order elasticity tensor, $\bar{\varepsilon}^e = \beta(c - c_0)\boldsymbol{I}$ is the elastic strain in which β defines the expansion tensor and c_0 is the reference concentration, and l_c material length parameter associated with the strain gradient. The resulting diffusion induced stress in the electrode material must satisfy, $\nabla\cdot\bar{\sigma} = 0$ with traction boundary condition as $\mathbf{t}^p = \bar{\boldsymbol{\sigma}}\cdot\boldsymbol{n}$. After, the essential displacement boundary condition, $\bar{\boldsymbol{u}} = \boldsymbol{u}^p$ along with equilibrium equation, Eq. $(3)_3$ yields the standard equations of elasticity in terms of intermediate displacement field $\bar{\boldsymbol{u}}$. Finally, the gradient enriched displacement field, $\boldsymbol{u}$ can be obtained by solving the Helmholtz equation i.e., Eq. $(3)_1$ as follows

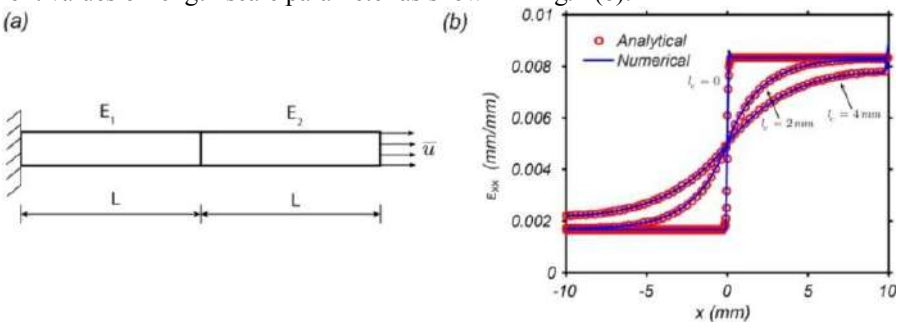
$$\boldsymbol{u} - l_c^2\nabla\cdot\nabla\boldsymbol{u} = \bar{\boldsymbol{u}}$$

with essential and natural boundary conditions as $\boldsymbol{u} = \boldsymbol{u}^p$, and $\partial_n\boldsymbol{u} = \tilde{\boldsymbol{u}}^p$, respectively.

VALIDATION

For the purpose of validation, two separate problems have been considered. One dimensional uniaxial bar is considered to validate the strain gradient theory and cylindrical particle for the coupled chemo-mechanical model.

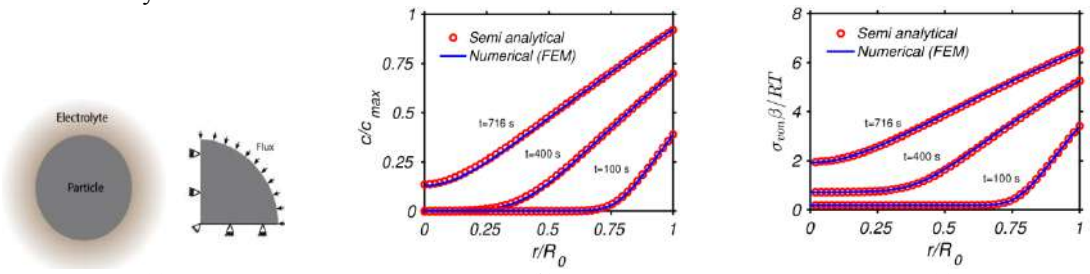
One dimensional uniaxial bar: Fig. 1(a) depicts the inhomogeneous uniaxial bar made of two materials with different Young's modulus, $E_1/E_2 = 5$, $L = 10$ *mm* and $\bar{u} = 0.1$ *mm* respectively, while the length parameter, l_c is the same for both materials. It has been seen numerically predicted results are in good agreement with analytical (Askes et. al., 2008) model for different values of length scale parameter as shown in Fig. 1(b).



*Corresponding author. E-mail: avtarsinghh1991@gmail.com

Figure 1. (a) Schematic diagram inhomogeneous uniaxial bar and (b) distribution of axial strain along the length of uniaxial bar with different values of length parameter (l_c = *0, 2 and 4 mm*).

Cylindrical particle for coupled diffusion: A cylindrical particle of radius R_0 is considered to verify the coupled chemo-mechanical model subjected to galvanostatic loading with properties taken from Singh et. al., 2020 (Fig. 2(a)). It has been observed that the concentration and von-Mises stress profiles i.e., Fig. 2(a) and (b) obtained FEM is exactly overlaps the semi-analytical model.

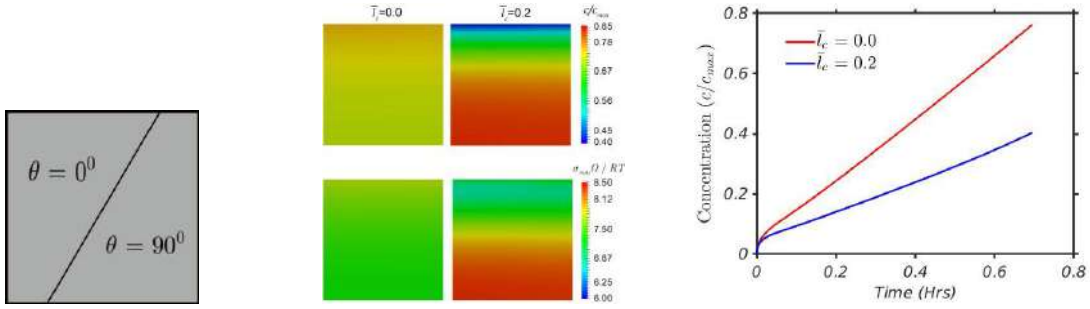


(a) (b) (c)

Figure 2. (a) Schematic diagram of cylindrical particle. (b) Normalised concentration profiles, and (c) von-Mises stress profiles obtained from both semi-analytical and FEM framework under fully coupled chemo-mechanical environment.

RESULTS AND DISCUSSION

In the present study, the $LiMn_2O_4$ cathode having a inclined junction is employed to simulate the effect of strain gradient as shown in Fig. 3(a). Further, the contour plots of concentration and von-Mises stress for with and without considering the size effect are provided in Fig. 3(b). It has been observed in Fig. 3(b) that the concentration and von-Mises stress fields are uniform for without size effect simulation. On the contrarily, size effect drives the lithium-ions into the domain and sharp gradient in the concentration field likely to be seen. We have also seen that as the charging continues, the size effect tends to hold and enhance the gradient within the concentration field. It is due to the fact that for $\bar{l}_c$=*0*, the hydrostatic pressure field is high which drives the lithium ion within the domain and diminishes the effect of interaction parameter. However, for $\bar{l}_c$=*0.2* the size effect plays significant role which reduces the order of hydrostatic stresses and strengthens the effect of interaction parameter. Likewise, the attendant von-Mises stress fields show similar behavior. Accordingly, the evolution of surface concentration with time is plotted in Fig. 3(c) for normalised length scale parameters, $\bar{l}_c$=*0* and $\bar{l}_c$=*0.2*.



(a) (b) (c)

3. (a) Schematic diagram cathode having an inclined interface. (b) Contour plot for (a) concentration and (b) von-Mises stress distribution without ($\bar{l}_c$=*0*) and with ($\bar{l}_c$=*0.2*) considering the size effect.

CONCLUSIONS

Strain gradient significantly alters the distribution of Li-ions as well as stress field. Subsequently, the mechanical integrity will be influenced by the attendant stress field. Additionally, the voltage profile will also be altered in the presence of gradient.

MULTISCALE DISCRETE DISLOCATION DYNAMICS SIMULATION OF GRADIENT NANO-GRAINED MATERIAL

Songjiang Lu[1], Xu Zhang*[1], Guozheng Kang [1], Qianhua Kan [1]
[1]School of Mechanics and Engineering, Southwest Jiaotong University, Chengdu, China

Summary Gradient nanostructured materials have synergetic strength and ductility. Multiscale discrete dislocation dynamics (DDD) method can track the evolution of dislocation microstructures and thus can help reveal the underlying mechanisms for curtain plastic behavior. However, the DDD investigations on gradient nano-grained metals are few due to the lack of a reasonable grain boundary (GB) model. In the present study, we first introduce a penetrable GB model, which is suit for arbitrary GB types, to the DDD framework. Then we conduct the DDD simulation to investigate the uni-axial compression of gradient nano-grained (GNG) polycrystals. The simulated results show that the dislocations initially activate and multiplicate in the larger grains, then propagating to the smaller grains gradually. The flow stress and strain hardening rate of the GNG samples are higher than the value calculated by the rule of mixtures. It turns out that the extract hardening of gradient nano-grained materials may come from the back stress induced by GNDs accumulation in front of GBs.

MULTISCALE DISCRETE DISLOCATION DYNAMICS FRAMEWORK

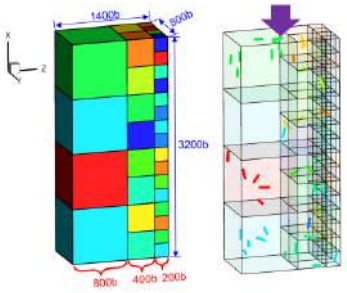
In present study, we use a three dimensional (3-D) hybrid model [1-3], which couples discrete dislocation dynamics (DDD) with finite element method (FEM), to conduct simulations on gradient nano-grained (GNG) face-centered cubic metals.

GRAIN BOUNDARY MODEL

So far, the GB models in 3-D DDD framework are still limited, especially for high-angle non-symmetrical GBs. In current study, we establish a GB model that is suit for a variety of GB types. In our GB model, two GB-dislocation interaction mechanisms, i.e. dislocation absorption at GBs and dislocation re-emission from GBs, are considered. By using the "coarse-graining" method, we can deal with the process of dislocation absorption and re-emission for arbitrary GB types.

SIMULATION MODEL

The gradient nano-grained (GNG) polycrystalline model with three grain sizes for multiscale DDD simulations is shown in Figure 1. The bottom surface of the sample is totally constrained and the top surface is uniaxially compressed along X-axis in a displacement-controlled mode.



(a) (b)

Figure 1. (a) Gradient nano-grained (GNG) polycrystalline model with three grain sizes; (b) initial dislocation network.

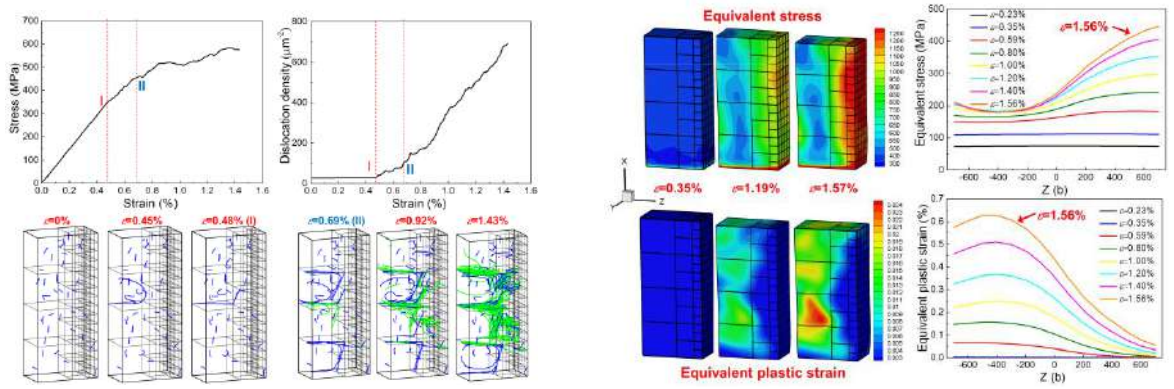
RESULTS AND DISCUSSION

From the dislocation structures evolution shown in Figure 2a, we can see that the dislocations initially activate and multiplicate in the larger grains, then gradually propagating to the smaller grains. Besides, as shown in the stress-strain curve in Figure 2a, the apparent yield point (point II in the figure) does not occur until the amount of dislocation movement in the grain interior is large enough, which is different from that of single crystals. Figure 2b presents the distributions of equivalent stress and plastic strain along gradient orientation at various strains. It can be observed that the equivalent stress in the larger gains is lower than that of smaller ones, while the equivalent plastic strain has an opposite trend in relative to equivalent stress. Figure 3a shows the variations of stress and dislocation density as a function of strain for GNG material and three polycrystals with homogeneous grains, the flow stress calculated by the rule of mixtures is also shown in the figure. It can be seen that the flow stress and strain hardening rate of the GNG samples are higher than the value obtained by the rule of mixtures.

Furthermore, we also conduct compressive simulation on the GNG material with four grain sizes. Figure 3b displays the geometrically necessary dislocation (GND) density along gradient orientation. It shows that the GND density

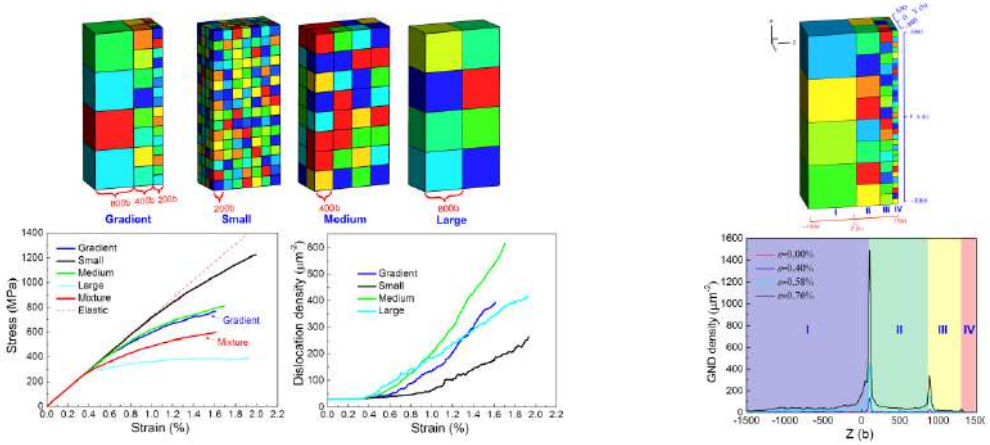
*Corresponding author. E-mail: xzhang@swjtu.edu.cn

increases as the strain increases. Besides, it also can be seen that there are significant GND pile-ups between grains with different sizes. The extra hardening of GNG material shown in Figure 3a may come from the back stress induced by GNDs accumulation in front of GBs.



(a) (b)

Figure 2. (a) A representative result of compressive GNG aluminum, including stress-strain curve, dislocation density versus strain and dislocation structures at various strains (blue lines represent the dislocations in the grain interior, while the green ones are the dislocations emitted from GBs). (b) Equivalent stress and plastic strain distribute along gradient orientation at various strains, note that this result is obtained by averaging five realizations.



(a) (b)

Figure 3. (a) Stress-strain and dislocation density-strain curves of GNG material and corresponding homogenous grain material, the flow stress obtained by the rule of mixtures is also shown in the figure; (b) the geometrically necessary dislocation density along Z-axis for the GNG model with four different grain sizes. Note the above results are obtained by averaging five realizations.

CONCLUSIONS

The main conclusions for present study can be summarized as follows: (1) A GB model that can describe the interaction between dislocations for any GB types has been proposed and implemented in the multiscale DDD framework to conduct simulations on GNG material under uniaxial compression; (2) the dislocations initially activate and multiplicate in the larger grains, then gradually propagating to the smaller grains; (3) the extra hardening of GNG materials may come from the back stress induced by GNDs accumulation in front of GBs.

COMPUTATIONAL MODELING OF SIZE-EFFECTS IN POLYMER NANO-COMPOSITES

Paras Kumar*[1,2] and Julia Mergheim[1]
[1]Institute of Applied Mechanics, Friedrich-Alexander Universität Erlangen-Nürnberg (FAU), Germany
[2]Central Institute for Scientific Computing, Friedrich-Alexander Universität Erlangen-Nürnberg (FAU), Germany

Summary Nano-sized filler particles have been found to be much efficient reinforcements for improving the mechanical properties of polymers in comparison to their micro-sized counterparts. Standard first-order computational homogenization lacks the length scale necessary to capture this size effect. An enhanced computation homogenization scheme based on the concept of *interface energetics* has been considered in this work and a thorough evaluation of its suitability for modeling polymer nano-composites has been carried out by means of systematic numerical experimentation. The method is more suited for modeling size effects in case of weaker inclusions in a stiff matrix than stiffer filler particles in a weak matrix.

INTRODUCTION

The positive impact of reduced filler particle size in terms of improvement of the overall mechanical behavior of polymer composites has been extensively corroborated by experimental studies [2]. This *smaller is stronger* size-effect is usually attributed to the formation of an *interphase layer* around the filler particles, which is pronounced in case of nano-sized reinforcements owing to their much higher specific surface area (SSA) [3]. The standard first-order computational homogenization scheme, commonly employed for modeling overall behavior of heterogeneous materials, by virtue of lack of necessary length scale, is unable to encapsulate the aforementioned size effect.

This work explores the Interface-Energetics-Enhanced Computational Homogenization (IECH) approach, wherein the standard scheme is enhanced by means of equipping the material interface with its own energetic structure. For details about the underlying formulations and other relevant aspects we refer the reader to [1] and the references therein.

NUMERICAL EXPERIMENTATION & DISCUSSION

In order to conduct a thorough evaluation of the IECH approach, we consider a series of representative volume elements (RVEs) such as one shown in Figure 1. Furthermore, two different filler materials, i.e. silica ($\mu_S = 34\,188\,\text{MPa}, \nu_S = 0.17$) and rubber ($\mu_R = 0.67\,\text{MPa}, \nu_R = 0.49$) are considered in an epoxy matrix ($\mu_E = 1185\,\text{MPa}, \nu_E = 0.35$). The model is tested for three different loading conditions: (i) uni-axial tension, (ii) shear and (iii) volumetric loading.

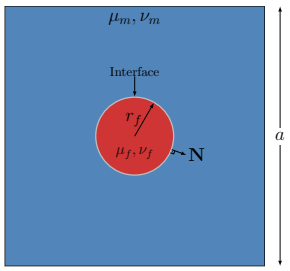

Figure 1: A 2D RVE consisting of a circular filler particle (red) of radius r_f embedded in a matrix material (blue). The subscripts m and f here refer to the matrix and the filler regions, respectively.

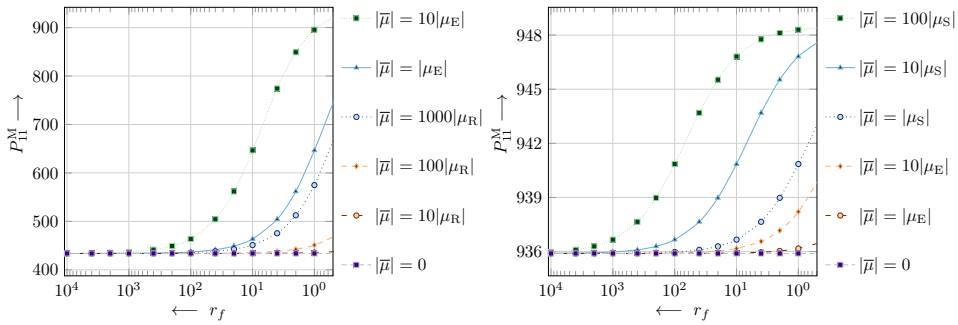


(a) Rubber inclusions in epoxy matrix.

(b) Silica inclusions in epoxy matrix.

Figure 2: Variation of the macroscopic Piola stress with filler particle radius for volumetric loading scenario.

Let the RVE having a given edge length a and filler particle radius r_f, cf. Figure 1, be scaled down by given factor K such that the particle size reduces while the filler volume fraction is left unchanged. Figure 2 depicts the variation of the macroscopic Piola stress w.r.t the filler particle radius r_f for different values of the interface shear modulus $\overline{\mu}$[1]. For the sake of brevity, only the results for volumetric loading have been presented here. A similar pattern has been observed for other loading scenarios as well. The curves for $|\overline{\mu}| = 0$ represent a *perfect interface*, which is observed in case of standard homogenization approach.

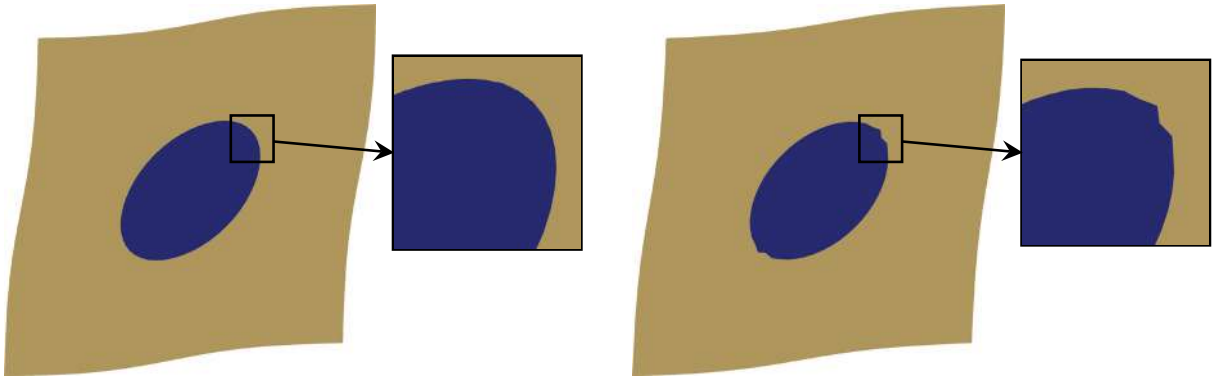
The overall response of the RVE becomes stiffer as the filler particles become smaller, especially, with increasing stiffness of the interface, cf. Figure 2a for instance. The observed size effect becomes pre-eminent for the cases where

*Corresponding author. E-mail: paras.kumar@fau.de.

[1]For a 2D RVE, the interface is actually a curve, i.e. a one-dimensional entity, thus a single material parameter suffices for the interface

$|\overline{\mu}| \geq \max\{|\mu_{\mathrm{m}}|, |\mu_{\mathrm{f}}|\}$. A saturation of the size effect w.r.t. the reducing filler particle radius is observed, particularly for the case of silica inclusions as shown in Figure 2b. The degree of stiffening achieved by means of the energetic interface is highly sensitive to the relative stiffness between the matrix and the filler material, cf. Figure 2a and Figure 2b respectively. In contrast to the softer rubber particles, a minimal improvement in the overall stiffness is achieved with much stiffer silica particles. This behavior can be attributed to the fact that, for the elastic interface considered in this study, the deformation of the interface depends on that of the particle. The appropriateness of the current approach is thereby restricted to the case of weaker filler particles in a stiffer matrix.

The applicability of the IECH approach to weaker filler particles is partially limited due to the occurrence of instabilities in the form of *kinks*, under shear loading conditions as depicted in Figure 3. Such behavior is more prominent for smaller particle sizes and higher interface stiffness. It is noteworthy that the instabilities are not of numerical nature, and are therefore observed for different finite element meshes. These instabilities are indeed caused due to the buckling of the stiff interface under excessive compression, which is observed on the top-right and bottom-left corners of the RVE during shear loading, cf. 3b. This bucking of the interface could be attributed to the lack of resistance from the surrounding filler material having almost negligible stiffness in comparison to the interface. On the contrary, no such instabilities are observed in the case of silica particles owing to the much larger stiffness of the filler particles. Thus, an energetic elastic interface can only sustain limited compressive loads.



(a) Deformation contour for perfect interface($|\overline{\mu}| = 0$). (b) Deformation contour for active interface ($|\overline{\mu}| = 10|\overline{\mu}|$).

Figure 3: Comparison of deformation contours for rubber filler case with fixed RVE size under the shear loading scenario

OUTLOOK

The above discussion reveals the limitation of the interface energetics based approach in modeling size effects in case of polymer nano-composites containing stiffer filler particles in a weak matrix. An alternative approach involving explicit modeling of a finite thickness *interphase* around the filler particles is being developed. Herein, a continuously graded interphase region with material properties varying between those of the filler and the matrix is modeled.

EXTENSION OF ANISOTROPIC CORE-SHELL MODEL TO HCP NANOCRYSTALLINE METALS

Katarzyna Kowalczyk-Gajewska*[1] and Marcin Maździarz[1]
[1]Institute of Fundamental Technological Research, Polish Academy of Sciences, Warsaw, Poland

Summary Anisotropic core-shell model of a nano-grained polycrystal is extended to estimate the effective elastic stiffness of several metals of hexagonal crystal lattice symmetry. In the approach the bulk nanocrystalline metal is described as a two-phase medium with different properties for a grain boundary zone and a grain core. While the grain core is anisotropic, the boundary zone is isotropic andthe shell has a thickness defined by the *cutoff radius* of a corresponding atomistic potential for the considered metal. The predictions of the proposed mean-field model are verified with respect to simulations performed with the use of the Large-scale Atomic/Molecular Massively Parallel Simulator, the Embedded Atom Model, and the molecular statics method. The effect of the grain size on the overall elastic moduli of nanocrystalline material with random distribution of orientations is analysed.

INTRODUCTION

A class of nanostructured material is considered that is composed of equiaxed nanometre-sized building blocks - crystallites of the same chemical composition and with a characteristic dimension smaller than 100 nm, which differ only by the crystallographic orientation. In such nanostructured material two main phases are distinguished: the grain core and the grain boundaries. The effect of grain boundary zone on the overall properties of a bulk polycrystal is the more significant the smaller is a grain size. Usually at the macroscale level the stress-strain response of nanocrystalline metals is governed by the continuum mechanics theory, and the mean-field estimates are still in use for assessing the bulk properties of nanocrystalline metals. Because of different properties of a grain boundary zone and the grain core, for nano-grained polycrystals two-phase or multi-phase mean-field frameworks are formulated (see [1] for an extensive review).

MODEL FORMULATION

In [1] a two-phase model of elastic nanocrystalline material was formulated in two variants called the Mori-Tanaka(MT) and self-consistent (SC) core-shell model, respectively. As inspired by earlier works [2], an additional phase that forms an *isotropic* coating around the *anisotropic* grain core is introduced. The smaller is the grain this transient zone influences more on the effective properties of polycrystal (Fig. 1). The estimates of overall stiffness by a two-phase model presented in the next section are obtained under the assumption that representative volume element contains infinite set of orientations of random uniform distribution. Under such assumption the overall stiffness tensor $\bar{\mathbf{C}}$ is isotropic and specified by an overall bulk modulus $\bar{K}$ and a shear modulus $\bar{G}$. The effective stiffness $\bar{\mathbf{C}}$ is calculated by embedding the coated grain in the infinite medium of the stiffness $\mathbf{C}_\mathrm{m}$ and next using the procedure of the double-inclusion model, namely

$$\bar{\mathbf{C}} = \left[f_0\mathbf{C}_\mathrm{s}\mathbf{A}_\mathrm{s} + (1-f_0)\left\langle \mathbf{C}(\phi^c)\mathbf{A}(\phi^c)\right\rangle_{\mathcal{O}}\right]\left[f_0\mathbf{A}_\mathrm{s} + (1-f_0)\left\langle \mathbf{A}(\phi^c)\right\rangle_{\mathcal{O}}\right]^{-1} \tag{1}$$

where

$$\mathbf{A}(\phi^c) = (\mathbf{C}(\phi^c) + \mathbf{C}_*(\mathbf{C}_\mathrm{m}))^{-1}(\mathbf{C}_\mathrm{m} + \mathbf{C}_*(\mathbf{C}_\mathrm{m}))\,, \quad \mathbf{A}_\mathrm{s} = (\mathbf{C}_\mathrm{s} + \mathbf{C}_*(\mathbf{C}_\mathrm{m}))^{-1}(\mathbf{C}_\mathrm{m} + \mathbf{C}_*(\mathbf{C}_\mathrm{m}))\,, \tag{2}$$

$\langle . \rangle_{\mathcal{O}}$ denotes averaging over the orientation space and $\mathbf{C}_*(\mathbf{C}_\mathrm{m})$ is the Hill tensor depending on the stiffness $\mathbf{C}_\mathrm{m}$ of infinite matrix and the shape of the coated grain, which is assumed as spherical in the present study. For the MT variant of the core-shell model $\mathbf{C}_\mathrm{m} = \mathbf{C}_\mathrm{s}$ is assumed, while for the SC variant $\mathbf{C}_\mathrm{m} = \bar{\mathbf{C}}$. In formula (1) f_0 is the volume fraction of the transient zone. Assuming the spherical shape of coated grains and denoting by Δ the coating thickness, f_0 is calculated by the formula

$$f_0 = 1 - \left(1 - \frac{2\Delta}{d}\right)^3\,, \tag{3}$$

where d is an averaged grain diameter. The parameter Δ introduces the size effect to the model. In [1] it was demonstrated that Δ can be taken as equal to the *cutoff radius* of the atomistic potential valid for the considered metal. Tensor $\mathbf{C}(\phi^c)$ is the anisotropic local elastic stiffness tensor for the single and depends on the crystal orientation. For cubic crystals studied in [1, 3] it is given by three material parameters For the considered hcp crystals it exhibits transverse isotropy and is specified by 5 independent components, which are the material-specific constants.

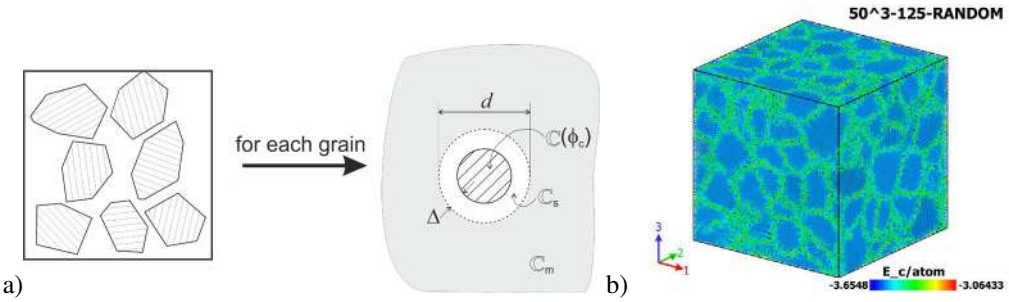

Figure 1: (a) Schematic of a core-shell model, (b) the example of a nanocrystalline sample considered in atomistic simulations.

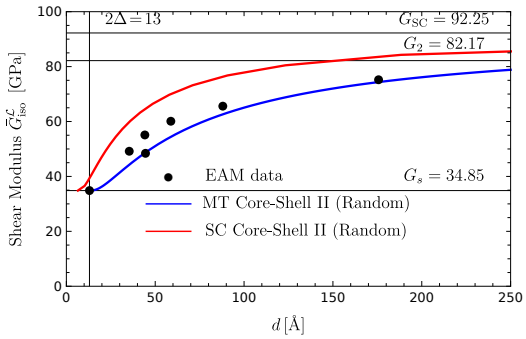

Figure 2: Effective shear modulus - $\bar{G}^{\mathcal{L}}_{\text{iso}}$ as a function of the average grain diameter d obtained by the two variants of the core-shell model - comparison with the results of atomistic simulations for Co.

RESULTS

Predictions of the mean field core-shell model will be compared with the results of atomistic simulations for 6 metals of hexagonal (hcp) lattice symmetry: Co, Zr, Mg, Re, Ti and Ru. The results are obtained by molecular statics using the corresponding EAM potentials taken from the literature [4] and then are analysed and visualized with the Open Visualization Tool OVITO [5]. The methodology for generating polycrystal samples by the Voronoi tessellation method, their pre-relaxation and numerical simulations were described in [1]. In particular, the samples with a different number of atoms per grain are generated, enabling to study the effect of grain size on the elastic stiffness. 21 components of stiffness tensor, of all pre-relaxed structures were computed by the stress-strain method with the maximum strain amplitude set to be 10^{-4}. Using the Log-Euclidean norm the closest isotropic approximation of the obtained tensor is found [1].

There is a known problem at the nano level with how to assume local effective material parameters for the boundary zone between atomistic layers in the local continuum approach (here, K_s and G_s values). Following [3], it is here proposed that elastic properties for the shells themselves are obtained by reducing the size of some generated polycrystal samples, so that the fraction of transient shell atoms is close to unity, $f_0 \to 1$.

Fig. 2 presents the preliminary results obtained for Co nanocrystalline bulk material. Elastic shear moduli obtained by the atomistic simulations and the core-shell model are compared. Good accordance of both predictions, especially fo rthe MT variant, is seen.

CONCLUSIONS

The two-phase core-shell model could provide reliable predictions of elastic properties of nanorystalline metals of hexagonal lattice symmetry. Variation of elastic bulk and shear modulus of polycrystals with random orientation distribution with a grain size is well reproduced as compared to the results of atomistic simulations.

COMPOSITE MATERIALS WITH HEXAGONAL MICROSTRUCTURE ANALYZED WITH A MICROPOLAR MODEL

Nicholas Fantuzzi*[1] and Patrizia Trovalusci[2]
[1]Department of Civil, Chemical, Environmental and Materials Engineering, University of Bologna, Bologna, Italy
[2]Department of Structural and Geotechnical Engineering, Sapienza University of Rome, Rome, Italy

Summary The present work demonstrate the advantages of micropolar model with respect to classical continuum (e.g. Cauchy of Grade 1) and nonlocal couple stress model (continua with internal constraints) in studying composite materials with an internal microstructure. In particular, composite materials with hexagonal microstructure will be modeled and investigated when concentrated loads are applied to a sample structure. Homogenized material properties have different behavior according to the selected particle geometry such as orthotetragonal, auxetic and chiral. It is shown that when chiral and auxetic material behavior are considered a micropolar model allows to predict features that are unpredictable by other material models.

INTRODUCTION

Composite materials can be studied by modeling interactions among their constituents or by homogenizing an equivalent continuum. Homogenization is an efficient approach but its effectiveness is strongly related to the continuum theory used and the homogenization method adopted to convert the physical particle/matrix system into an equivalent continuum (see [1]). When classical kinematics is enriched with extra degrees of freedom, homogenization procedures have been shown to provide more reliable models than in the case of classical local continua. In particular, micropolar theory introduces as degree of freedom the microrotation, that is an additional kinematic feature of the material point, different from the local rigid rotation (the classical macrorotation), the rotational feature of the infinitesimal neighborhood, and their effects have been widely investigated by [2, 3, 4] for masonry–like materials. Note that these rotations coincide in the couple–stress theory, as well as in the classical theory (see [5], Appendix). Micro-polar effects widely analyzed in the literature [1] as have been recently compared to other non-local effects analyzed in [6, 7] in the presence of geometrical or load singularities, such as concentrated loads, voids or material inclusions. In the present work three particular assemblies of regular and irregular hexagonal particles are considered as RVE material models. Discussion on material behavior made of these assemblies is throughly discussed when solids are subjected to concentrated loads.

MICROPOLAR CONTINUUM

In the present theory, a microrotation is considered as independent kinematic parameter. In a 2D framework there are two displacements and one rotation so that $\{u\}^T = \{u_1\ u_2\ \omega\}$ applies. The strain displacement vector is represented as: $\{\varepsilon\}^T = \{\{\varepsilon_{11}\ \varepsilon_{22}\ k_1\ k_2\}\ \{\varepsilon_{12}\ \varepsilon_{21}\}\}$, where ε_{ij}, for $i,j = 1,2$ are the in-plane normal and shear strains and k_1, k_2 are the micropolar curvatures. Note that the strain components are not reciprocal, $\varepsilon_{12} \neq \varepsilon_{21}$, The kinematic compatibility relations can be written as: $\{\varepsilon_1\} = [D_1]\{u\}$ and $\{\varepsilon_2\} = [D_2]\{u\}$ where $[D_1]$ and $[D_2]$ can be found in [8]. As strain measure of the micropolar model we have the relative rotation, defined as the difference between the microrotation ω and the skew-symmetric part of the gradient of displacement, θ. The focus of this work is on such a peculiar strain measure $\theta - \omega$ of the micropolarity of the model under study. Analogously, the work-conjugated stress measures of the micropolar model are represented in the vector: $\{\sigma\}^T = \{\{\sigma_{11}\ \sigma_{22}\ \mu_1\ \mu_2\}\ \{\sigma_{12}\ \sigma_{21}\}\}$ where σ_{ij} for $i,j = 1,2$ represent the classical normal and shear stress components, and μ_1, μ_2 are the microcouples. From the virtual work principle without introducing the constitutive equations, described below, equilibrium equations in terms of stresses and microcouples can be carried out as $\delta U + \delta V = 0$. So that:

$$\delta U + \delta V = \{\delta u\}^T \left\{ h \int_{\mathcal{A}} \left([D_1]^T \{\sigma_1\} + [D_2]^T \{\sigma_2\} \right) d\mathcal{A} - \left(\int_{\mathcal{V}} \{f\} d\mathcal{V} + \int_{\mathcal{S}} \{p\} d\mathcal{S} \right) \right\} = 0 \tag{1}$$

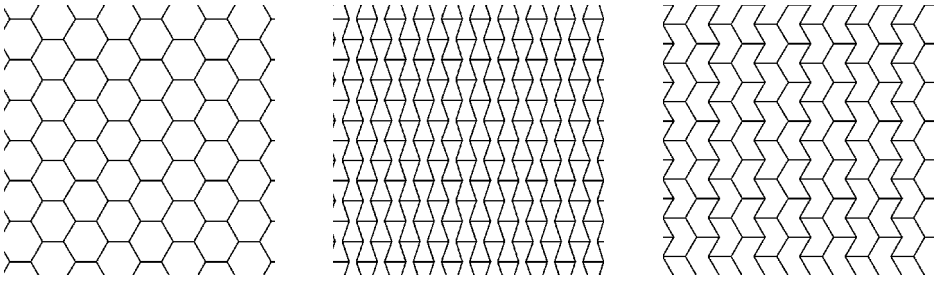

Figure 1: Hexagonal patterns given by geometric parameters $\alpha_1 = 0°$, $l_r = \frac{100}{1/\sqrt{3}+1}$: regular $\alpha_2 = \alpha_3 = 30°$, auxetic $\alpha_2 = \alpha_3 = -20°$ and asymmetric $-\alpha_2 = \alpha_3 = 30°$, from left to right.

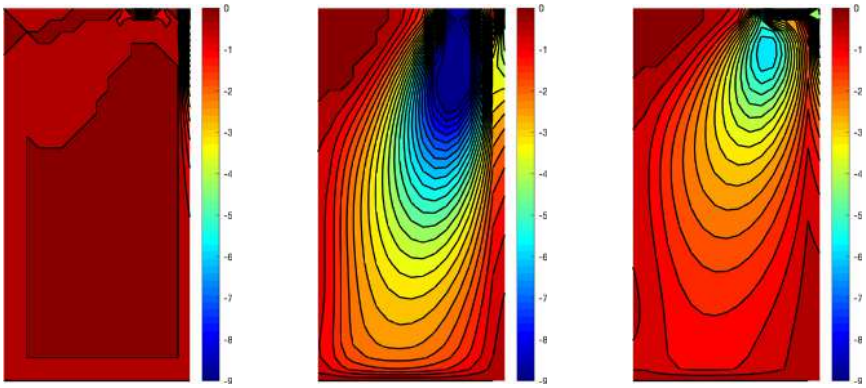

Figure 2: Relative rotation $\theta - \omega$ for regular, auxetic and chiral hexagonal patterns from left to right respectively.

h being the thickness of the 2D domain which can be considered as unitary for plane strain case. $\{f\}$ and $\{p\}$ are the vectors of body forces and boundary tractions, respectively. The micropolar constitutive equations take the form $\{\sigma\} = \mathbb{C}\{\varepsilon\}$ where $\mathbb{C}$ can be found in [8]. In the following, the finite element approximation will be applied directly to the variational principle in order to carry out the approximate solution of the problem.

RESULTS

The present irregular hexagonal geometry is defined by four parameters: three angles α_1, α_2, α_3, relative length, l_r. Using simple geometric formulae the RVE can be defined by translations and mirroring of tiles [8]. By changing the geometric parameters listed above several patterns can be obtained as the ones depicted in Figure 1 which are termed for future reference: regular, hourglass and asymmetric, respectively. They have been obtained by setting a equilateral geometry (all the sides have the same length) with $\alpha_1 = 0°$, $l_r = \frac{100}{1/\sqrt{3}+1} \cong 63.3975$ and by varying α_2 and α_3 angles as listed in Figure 1 caption. The solution of the problem is carried out using a finite element implementation [8]. A comparison in terms of relative rotation $\theta - \omega$ is shown in Figure 2 where it is clear that regular hexagons have a very small micropolar effect, whereas the other configurations have strong effect due to the present micropolar modelling.

CONCLUSIONS

The three selected patterns show peculiarities and outcomes related to the micropolar behavior. Assemblies of regular hexagons have an orthotetragonal behavior and it has been shown that their homogenized behavior is close to the behavior of classical elastic bodies. On the contrary, the other configurations showed strong nonlocal effects, related to the internal material size, which brought a larger stress diffusion within the body and reduced displacements. All these aspects could be underlined mostly because a micropolar continuum has extra rotational degrees of freedom with respect to classical continuum.

MODELLING THE CYCLIC TORSION OF POLYCRYSTALLINE MICRON-SIZED COPPER WIRES BY DISTORTION GRADIENT PLASTICITY

Lorenzo Bardella*[1] and Andrea Panteghini[1]
[1]Department of Civil, Environmental, Architectural Engineering and Mathematics, University of Brescia, Brescia, Italy

Summary Towards the modelling of the irreversible behaviour of micron-scale metals under non-proportional loading, we demonstrate that the distortion gradient plasticity recently proposed by our group [1] can predict the experimental data of Liu et al. [2] on the cyclic torsion of copper wires of diameter ranging from 18 to 42 micrometres. To reach our goal we plug the constitutive proposal of [1] in the model that we have previously developed for the torsion problem [3], which is based on the pivotal higher-order framework established by Gurtin [4], relying on Nye's dislocation density tensor to describe size effects in micron-scale metal plasticity. We implement the new model in a finite element (FE) code and identify its parameters by resorting to the Coliny evolutionary algorithm implemented in Dakota [5].

INTRODUCTION

This contribution focuses on modelling typical size effects in micron-scale metal plasticity [6, 7] by using a phenomenological theory of strain gradient plasticity. Here, the adjective phenomenological denotes theories neglecting metal crystallography. Specifically, we build on the 2004 Gurtin theory [4], here referred to as a distortion gradient plasticity (DGP) theory because it constitutively prescribes laws for the evolution of both the plastic strain and the plastic spin, i.e., the symmetric and skew-symmetric parts of the plastic distortion, respectively. This natural need ensues from the comparison with strain gradient *crystal* plasticity [8] along with the fundamental hypothesis that the primal higher-order (HO) kinematic variable characterising the theory is Nye's dislocation density tensor $\boldsymbol{\alpha}$ [9], that is the curl of the plastic distortion. Hence, $\boldsymbol{\alpha}$ is work-conjugate to a HO stress that, in the purely recoverable HO contribution proposed by Gurtin [4], is denoted as the defect stress, whose potential is the so-called defect energy, the latter being a function of $\boldsymbol{\alpha}$ entering the Helmholtz free energy density.

In particular, we consider the torsion of thin metal wires, for which, in [3], we have established that Gurtin theory [4] can accurately predict the experimental data under *monotonic* loading of Fleck et al. [6]. This is possible if one defines the defect energy as the sum of two regularised logarithmic contributions, each being a function of a distinct invariant of $\boldsymbol{\alpha}$, namely its trace (which represents the overall amount of pure densities of geometrically necessary screw dislocations) and the second invariant of its deviatoric part. Here, there are two crucial aspects that deserve to be briefly underlined. First, the logarithmic defect energy [10], beside resulting from statistical dislocation mechanics [11], is a *less-than-quadratic* defect energy, thus delivering some (energetic) strengthening with diminishing size, which is an increase in the yield point that characterises the experimental data in torsion [6, 2]. Second, in the torsion problem the first invariant of $\boldsymbol{\alpha}$ (i.e., its trace) depends on the plastic spin only [3] and its use as independent kinematic variable offers a natural and much richer description of the problem than that provided by the many phenomenological theories neglecting the plastic spin.

Unfortunately, the use of less-than-quadratic defect energies has a noticeable drawback, as highlighted in [3]: the predictions under cyclic loading are unreliable within polycrystal plasticity, as they exhibit questionable changes of concavity in the normalised stress-strain curves that are absent in experimental data [2]. In order to address this issue, in [1] we have proposed the use of a HO plastic potential, involving both recoverable and dissipative contributions, in the place of Gurtin's defect energy. Specifically, such HO plastic potential is the sum of M quadratic functions of the chosen primal HO variable (here, $\boldsymbol{\alpha}$), each of these M quadratic contributions being characterised by a different length scale parameter and being limited by a *pseudo*-yield surface of suitable size. Each contribution participates to dissipation when $\boldsymbol{\alpha}$ is larger than its maximum recoverable value, as governed by the *pseudo*-yield surface of the contribution. This technique is inspired by established laws within conventional nonlinear kinematic hardening [12]. This HO potential is particularly useful in the modelling as it can approximate (under monotonic loading) any less-than-quadratic defect energy, by suitably identifying the length scale parameters and the *pseudo*-yield surface limits of a relatively small number of quadratic contributions [1]. In passing, we note that this proposal, by establishing a thermodynamically consistent HO dissipation for HO strain gradient plasticity in general, also offers a way to address the issue concerned with the so-called "elastic gaps" affecting the predictions of *non-incremental* dissipative strain gradient plasticity theories under non-proportional loading [13].

Hence, the objective of this work is the accurate modelling of the experimental data on the cyclic torsion of thin metal wires by using the new HO potential proposed in [1] within the DGP applied to the torsion problem presented in [3]. To this purpose, we focus on the experimental results of Liu et al. [2] on polycrystalline copper wires of diameter ranging from 18 to 42 micrometres, whose grains have size variable from 5 to 9 micrometres, almost independently of the wire diameter.

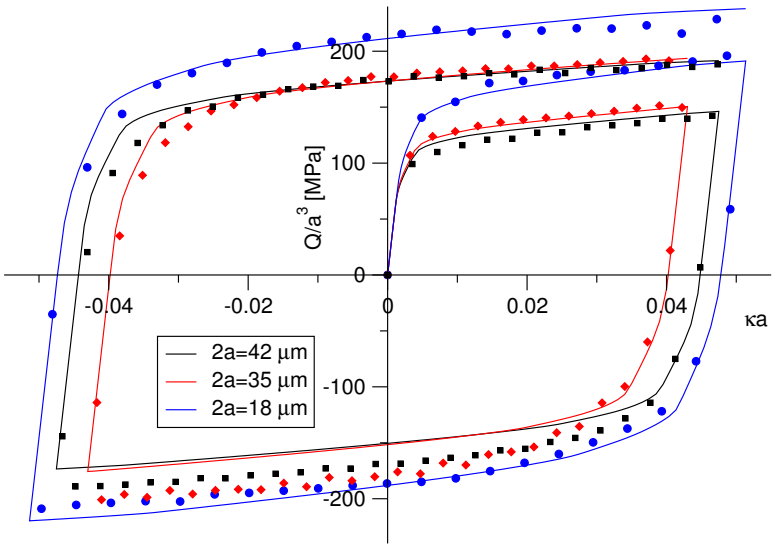

Figure 1: Comparison between the experimental data of Liu et al. [2] (discrete symbols) and theoretical predictions (continuous curves): normalised torque vs. nondimensional twist per unit length (from [15]).

METHOD, RESULTS, AND PERSPECTIVES

The DGP model for torsion is implemented in a user element subroutine for the FE code ABAQUS as detailed in [3], except that the constitutive laws of [3] concerned with the HO contributions are substituted with the HO potential proposed in [1], whose implementation straightforwardly follows the algorithm provided in [1]. Moreover, with respect to the model presented in [3], we have added a conventional kinematic hardening needed, in our phenomenological framework, to account for the polycrystalline microstructure, whereby the grain size is almost independent of the wire diameter (such that, the Hall-Petch size effect should be negligible).

The material parameters are identified by implementing a literature procedure originally developed for nonlinear kinematic hardening [14] and by resorting to the Coliny evolutionary algorithm implemented in Dakota [5]. The results, summarised in Fig. 1, show unprecedented good agreement between experimental data and model predictions [15].

We further demonstrate that once one selects a less-than quadratic defect energy predicting a certain behaviour under proportional loading, the number M of quadratic contributions in the new HO potential is only a matter of discretisation, as, for not-too-small M, it does not influence the results under any loading histories. This ensues from an analytical convergence result, by the way establishing that the parameters to be identified are solely those of a reference defect energy.

To assess our results, more experimental data should be analysed, such as the very recent ones of Guo et al. [16].

SIZE SCALING OF YIELD STRENGTH IN COPPER THIN LAYERS UNDERGOING SIMPLE SHEAR: A DISCRETE DISLOCATION DYNAMICS ANALYSIS BY THE METHOD OF MONOPOLES

Pilar Ariza*[1] and Michael Ortiz[2]
[1]Escuela Técnica Superior de Ingeniería, Universidad de Sevilla, Sevilla, Spain.
[2]Division of Engineering and Applied Science, California Institute of Technology, Pasadena, USA.

Summary We develop an approximation scheme for three-dimensional dislocation dynamics in which the dislocation line density is concentrated at points, or *monopoles*. Every monopole carries a Burgers vector and an element of line. The monopoles move according to mobility kinetics driven by elastic and applied forces. The divergence constraint, expressing the requirement that the monopoles approximate a boundary, is enforced weakly. The fundamental difference with traditional approximation schemes based on segments is that in the present approach an explicit linear connectivity, or 'sequence', between the monopoles need not be defined. Instead, the monopoles move as an unstructured point set subject to the weak divergence constraint. In this sense, the new paradigm is 'line-free', i. e., it sidesteps the need to track dislocation lines. This attribute offers significant computational advantages in terms of simplicity, robustness and efficiency, as demonstrated by means of selected numerical examples. We specifically assess the ability of discrete dislocation dynamics to reproduce the scaling laws and size effects uncovered by the recent experiments of Mu *et al.* (2014, 2016, 2017) on copper thin layers undergoing plastically constrained simple shear.

SIZE-SCALING OF YIELD STRESS IN SIMPLE SHEAR

There is at present ample experimental evidence that plastic deformation is scale dependent. Generally, as some measure of size related to a plastically deforming material decreases, the strength increases. Since the pioneering work of Hall [4] and Petch [5], a large number of experiments have been reported that reveal a size dependence of the yield stress of the form

$$\sigma_{\rm y} = \sigma_0 \left[1 + \left(\frac{\ell}{h}\right)^{\alpha}\right], \tag{1}$$

where ℓ is a constant constitutive length scale, h is an appropriate measure of the size of the plastically deforming region and α is an scaling exponent. Recently, an experimental protocol has been developed by Mu *et al.* [1, 2, 3] consisting of a thin layer of ductile copper sandwiched between stiff and brittle ceramic coatings (CrN and Si). Simple shear conditions can be induced in the metal by means of micro-pillar compression of the layered ceramic/metal/ceramic with the layers oriented at 45 degrees to the load axis. As the thickness of the copper layer is decreased, the shear stress required for large-scale plastic flow is increased. When fitting the yield stress in shear to a power law function of the inverse layer thickness, Mu *et al.* [1, 2, 3] found exponents α of the order of 0.2 in the as-deposited state. Hutchinson *et al.* have noted [2, 3] that conventional strain-gradient plasticity [6, 7, 8] tends to predict an scaling exponent $\alpha = 1$ and thus is fundamentally at odds with experiment. In a phenomenological vein, Dahlberg and Ortiz [9] have shown that the discrepancy can be removed if the theory is relaxed to allow for fractional plastic-strain gradients, i. e., by recourse to fractional strain-gradient plasticity [11, 10, 12].

THE METHOD OF MONOPOLES IN DISCRETE DISLOCATION DYNAMICS

In this work, we investigate whether the size scaling of yield stress in simple shear arises from discrete dislocation dynamics effects, including boundary pile-ups and other dislocation structures. To that end, we employ an approximation scheme for three-dimensional dislocation dynamics in which the dislocation line density is concentrated at points, or monopoles [13]. Every monopole carries a Burgers vector and an element of line. The monopoles move according to mobility kinetics driven by elastic and applied forces. The divergence constraint, expressing the requirement that the monopoles approximate a boundary, is enforced weakly. The fundamental difference with traditional approximation schemes based on segments is that in the present approach an explicit linear connectivity, or 'sequence', between the monopoles need not be defined. Instead, the monopoles move as an unstructured point set subject to the weak divergence constraint. In this sense, the new paradigm is 'line-free', i.e., it sidesteps the need to track dislocation lines. This attribute offers significant computational advantages in terms of simplicity, robustness and efficiency. Following concepts from optimal transportation theory (cf. [14]), we discretize the dislocation transport problem in time by introducing incremental transport maps. These maps push forward the dislocation density from one configuration to the next. Further adapting concepts from optimal transportation theory [15], we formulate an incremental minimum principle for the transport map, that encodes the energetics and mobility kinetics of the system. In particular, the motion of the monopoles is the result of a competition between energy, which drives the monopoles to low-energy configurations, and mobility, which opposes motion. Finally, the requisite interpolation of the transport maps is effected by means of mesh-free max-ent interpolation. The satisfaction of the requisite null-divergence constraint is ensured by the geometric exactness of the incremental updates. In addition, the monopoles tend to align 'head-to-toe' spontaneously in order to minimize the elastic energy (Figure 1a).

CONCLUSIONS

Our calculations exhibit the expected size-scaling of the yield stress in simple shear and provide a physical explanation of the experimentally observed scaling relations [1, 2]. The calculations also attest to the remarkable robustness of the method of monopoles [13] and, in particular, to its ability to negotiate complex dislocation dynamics including nucleation, close-range interactions, pileups, intersections and other mechanisms (Figure 1b). Finally, the calculations shed light on possible phenomenological approaches to size-aware plasticity, including fractional strain-gradient plasticity.

ELECTRO-ELASTICITYFOR A MICROSTRETCHCONTINUUMMODEL AND ITS APPLICATION TO PLANE WAVES

Maurizio Romeo*
Department of Mathematics Università di Genova, Genova,Italy

Summary A general micromorphic model of a dielectric continuum is developed accounting for microrotation and microstretch of the material particle. The electro-elastic coupling is based on an effective connection of electric multipoles with the microdeformation tensor. The set of balance equations for this model is rewritten in a linearized form and applied to a plane wave problem. A set of dispersion equations for electro-acoustic modes are obtained where microstructural parameters as microinertia, electric susceptibility and electric quadrupole play a relevant role.

MICROMORPHIC ELECTRO-ELASTIC MODEL

The continuum models of electro-elastic coupling require the description of polarization effects connected to mechanical deformation. In classical continuum theories this is usually realized by including the electromagnetic field in the constitutive model, accounting for the Maxwell's equations.
The mechanical micromorphic continuum theory, introduced to model material responses characterized by its microstructure (see [1]), can be extended to electromagneto-elasticity by a constitutive approach similar to the classical one [1], [2]. An alternative analysis of this coupling is based on the connection of mass and charge microdensities so that polarization and magnetization are explicitly obtained from electric multipoles of the microstructure [3], coherently with the derivation of Maxwell's equations from its microscopic formulation [4]. Here we are interested in dielectric solids so that magnetization and conducting properties are not considered. A simple micromorphic model, the so-called "micropolar" theory, accounts for a rotational microdeformation. Its application to dielectric media, allows to describe electro-acoustic modes of wave propagation [5] comparable with polarization modes obtained from phenomenological theories of electroelasticity [6]. If in addition to microrotations we also consider micro-expansions/contractions, we deal with a "microstretch" theory.

In this presentation we consider a microstretch model where the microdeformation tensor is introduced as a polar decomposition into a rotation and a biaxial stretch along and orthogonal to the variable axis of rotation. Electric multipoles, up to the second order, are written in terms of the microdeformation to obtain the electric polarization. A similar representation is given for the microinertia tensor. The governing equations for the mechanical displacement, the electric field (referred to an electric potential) and the microvariables of stretch and rotation, include the balance laws of momentum and couple, together with the Gauss' law for a not conducting material. Then a set of linearized equations are obtained in both cases of compressible or incompressible dielectric materials [7].

APPLICATION TO PLANE WAVES

The successive step of this analysis concerns the study of plane wave solutions to the linearized problem. The dispersion equations within two geometrical configurations for the orientation of the axis of rotation, in presence of an applied electric field, are obtained. Beside classical longitudinal and transverse elastic modes, a set of coupled modes involving electro-microelastic fields are found for the two geometrical configurations. These results show that microstructural parameters such as microinertia, electric susceptibility and quadrupoles, together with the orientational configuration and the applied electric field, modulate the wavenumber range for the existence of modes, the frequency band gaps of some modes and the asymptotic behaviour of phase speed.

SIZE-SCALE EFFECTS ON MECHANICAL PROPERTIES OF AN ALUMINUM ALLOY

Vagish D. Mishra[1], Balkrishna C. Rao[2], and H. Murthy [*1]
[1]Dept. of Aerospace Engg., Indian Institute of Technology Madras, Chennai, 600036, India
[2]Engineering Design, Indian Institute of Technology Madras, Chennai, 600036, India

Summary: Aluminum and its alloys are widely used in many sectors to produce lightweight components for aircrafts, ships, satellites, etc. Moreover, such parts are also getting smaller by the day to address environmental issues while ensuring accuracy and working range. Size of some components is smaller than mentioned in the standard for experiments necessary to understand material behavior. Prior researches show size-effect below a critical size. In the present effort, uniaxial tension tests were conducted on Al6061 alloy samples, where size of the samples is ranging from ASTM standard to substandard size. Digital image correlation, a non-contact strain measurement method, was used to measure full-field strains during tests. Tests were conducted for samples of varying gauge lengths and it was found that strengths and ductility decrease with increasing gauge length in contrast to Young's modulus.

INTRODUCTION

Machines are designed and subsequently made-up of large and miniature parts of various materials for some functionality within safe working limits. Accurate mechanical properties of these miniature parts are accordingly required which can be measured by suitable testing procedures and by considering possible size scale-effects. ASTM standard [1] is created for relatively large sized samples and cannot be used for miniature ones thereby necessitating standards for miniature samples. Prior researches [2-4] have reported on the size scale-effects of mechanical properties of miniature samples with accurate measurements of properties being achieved by conducting experiments on nearly same size samples.

Standard and miniature sized dog-bone samples were prepared from Al6061 alloy plates by varying gauge length and cross-sectional dimensions. An appropriate universal testing machine (UTM), Zwick/Roell Z0.5, having a capacity of 500N was used for miniature samples while Zwick/Roell Z100 of capacity 100kN was used for standard sized samples. In the present effort, two-dimensional digital image correlation (2-D DIC) which is suitable for miniature samples [4, 5], was used to determine full-field strains for standard and miniature samples during uniaxial tension tests.

EXPERIMENTAL DETAILS

Standard and miniature samples were prepared where miniature samples are a scaled-down version of standard samples mentioned in ASTM [1]. The cross-sectional dimensions of the standard sized samples and smallest samples were 12.7mm x 7mm and 0.85mm x 0.85mm respectively but the gauge length of samples was kept in multiples of sample width (w) ranging from 6 to 20 times of width. The standard and miniature dog-bone samples for uniaxial tension tests were prepared by cutting by wire *electrical discharge machining* (EDM) with brass coated copper wire (diameter = 0.25 mm) to achieve accurate dimensions and minimal material wastage. Spark erosion marks on sample surface during EDM cutting created a gray colored surface texture, which was used as natural speckles for DIC to avoid any alteration of results of miniature samples [4]. Dog-bone shaped samples were tested at a displacement rate of 0.5 mm/minute at room temperature (25ºC). A pair of *high definition charged coupled device* (HD CCD) cameras i.e., Prosilica GX 1910 (2 Megapixel), were used to capture images by using the image capturing software called Vic-Snap-2010, Correlated Solutions at 20 frames per second and post-processing software, Vic-2D-2009 by Correlated Solutions, was used to determine full-field strains for tested samples. Samples were examined before conducting uniaxial tension tests and five samples of all dimensions were tested and the average value with standard deviation is reported in the present report**.**

RESULTS

ASTM standard-sized samples of cross-sectional dimensions 12.7mm x 7mm, 6.34mm x 6.34mm with gauge lengths of 4w (where w = sample gauge width) were tested and results are as follows: Young's modulus (E) = 68.8 ± 0.7 GPa, yield strength = 293 ± 3 MPa, ultimate tensile strength (UTS) = 321 ± 2 MPa, and ductility = 15 ± 0.7%. All miniature samples of square and rectangle cross-section with gauge length varying from 6w to 20w were tested and results were compared. Uniaxial tension test results of rectangular cross-section dimension (1mm x 0.4mm, 0.81mm x 0.44mm) and square cross-section (0.85mm x 0.85mm) samples are reported in Fig. 1. The mechanical properties (Young's modulus (E), yield strength, UTS, and ductility) for the miniature samples having rectangular and square cross-section are reduced when compared to standard-sized samples. Young's modulus of 1mm x 0.4mm sample with gauge length 20w was decreased by ~ 5% when compared to the one with gauge length of 6w, which can be seen in Fig. 1(a). Yield strength, ultimate tensile strength (UTS), and ductility for 1mm x 0.4mm sample were increased by

~10%, 11%, and 115% respectively by decreasing the gauge length from 20w to 6w which can be seen in Fig. 1(b, c, & d). Other miniature samples of the cross-section of 0.81mm x 0.44 and 0.85mm x 0.85mm show the same variation of mechanical properties as 1mm x 0.4mm, see Fig. 1.

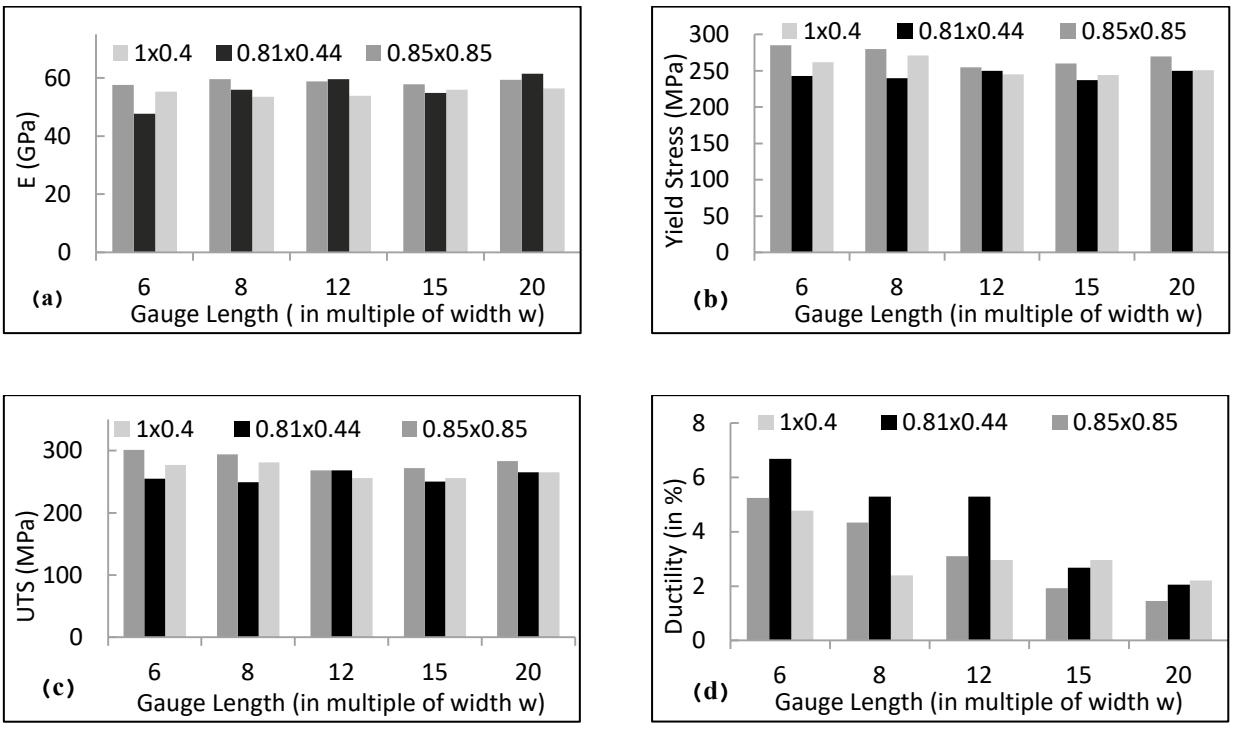

Figure 1: Variation of (a) Young's modulus (E, in GPa), (b) Yield strength (in MPa), (c) Ultimate tensile strength (UTS, in MPa), and (d) Ductility (in %), with gauge length for rectangle and square cross-sectional samples. E decreased with decrease in gauge length but other mechanical properties increased with decrease in gauge length for all the tested samples. (All dimensions are in mm)

CONCLUSIONS

Comparison of uniaxial tension test results for standard sized and miniature samples show reduced values of mechanical properties i.e. Young's modulus (E), yield strength, ultimate tensile strength, and ductility for miniature samples, which indicate presence of size-scale effects. Results of uniaxial tension tests of miniature samples with varying gauge length show a decreasing length resulting in increasing yield strength, ultimate tensile strength, and ductility for both rectangular and square cross-sections except for the Young's modulus. Further studies are required to find reason and relationship between sample geometry and mechanical properties for miniature samples.

ATOMISTIC SIMULATIONS OF PRECIPITATE/TWIN INTERACTIONS IN MG-AL-ZN ALLOYS

Anxin Ma*[1], Esteban Manzanares, Gustavo[1], and Javier Llorca[1]
[1]IMDEA materials institute, Tecnogetafe, Calle Eric Kandel, 2, 28906 Getafe, Madrid, Spain

Summary: Precipitate strengthening on twin migration is critical for controlling the mechanical properties and formability of Mg alloys, while our knowledge about this mechanism is not enough. In order to understand the twin-precipitate interaction, it is urgently needed to use molecular dynamics simulations with well validated Mg-Al-Zn potential to study the details of twin propagation and growth, when β-$Mg_{17}Al_{12}$ precipitate or Laves phase $MgZn_2$ precipitate exists inside a Mg matrix. This presentation reports the current MD simulations of the twin-precipitate interaction. At first, based on the Dickel-2019 MEAM potential for Mg-Al-Zn alloys, a strategy was developed to insert precipitates, e.g. lozenge-shaped $Mg_{17}Al_{12}$ precipitate with Burgers orientation relationship, or rode-shaped $MgZn_2$ precipitate with elliptical-cross-section obeying $(11\text{-}20)_{MgZn2}$ // $(0001)_{Mg}$ and $(1\text{-}100)_{MgZn2}$ // $(1\text{-}100)_{Mg}$, into a Mg matrix containing a (1-102) flat twin. The current approach ensures that the matrix/precipitate interfaces are close to the minimum energy configurations. In the next step, the influences of precipitate crystal lattice structure, precipitate geometry and orientation relation as well as temperature on the motion of (1-102) twin are investigated. It was found that the twin motion is mainly controlled by the formation of 2-atom-layer-steps, or twin dislocations. Depends on the temperatures and microstructures, the precipitate-matrix interface may retard or stimulate twin dislocation formation, see Figure 1. For both of Mg-Al and Mg-Zn alloys, precipitate produces pronounced hardening on twin migration at high temperature (>400K). Additionally, the Lavas phase precipitate, $MgZn_2$, produces better hardening than $Mg_{17}Al_{12}$ in the wide temperature region.

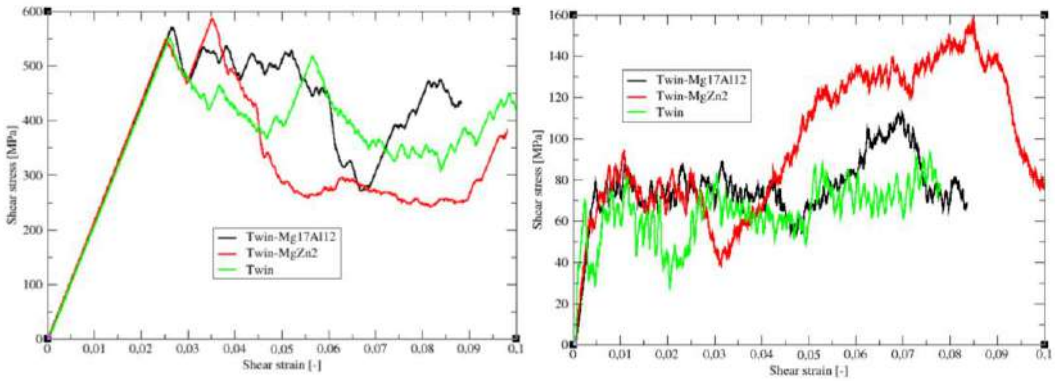

Figure 1. Stress strain curves as a (1,0,-1,2) twin passing a precipitate at 100K, left, and at 400K, right. The stress strain curve of a pure twin was also shown for comparison.

SIZE-DEPENDENT FRACTURE TOUGHNESS AND ITS EFFACT ON DAMAGE OF COATINGS

Lihong Liang*[1], H Long[2], and Y Wei [2]
[1]Department College of Mechanical and Electrical Engineering, Beijing University of Chemical Technology, Beijing, China
[2]College of Engineering, Peking University, Beijing 100871, China

Summary Size effect of mechanical properties of nanomaterials attract great attention, especially toughness and strength affect mechanical behaviour of materials. Fracture toughness on the damage of coatings bonded on substrates is studied based on finite element methods by applying a four-point bending loading and introducing cohesive elements in the coatings. The simulation results show that the damage, defined by crack length evolution, is slower for the coatings with larger toughness. Furthermore, size effect of fracture toughness of nanocrystalline coatings is estimated theoretically, and the fracture toughness of nanocrytalline coatings was found to decrease compared with those of conventional coatings. Combining the theory with the simulation results, it can be deduced that the damage of nanocrystalline coatings is faster, agreeing with the previous experimental results.

INTRODUCTION

Nanomaterials, including nanoparticles, nanowires, nanofilms, and nanostructured materials, often show different mechanical properties from the corresponding bulk materials. For example, elastic modulus of nanofilms is size-dependent when the thickness of films is thinner than about 20 nm [1], yield strength of nanocrystals obeys the Hall-Petch relation [2], etc. Size effect of fracture toughness has still to be discovered.

Recently, the experimental study on damage rate (reflected by crack evolution) of thin ceramic coatings, bonded on the alloy substrates under three-point tests, found that average damage rate of nanostructured coatings is larger than that of conventional coatings with the microstructure in micron scale [3], i.e., the evolution rate of transverse cracks in nanostructured coatings is faster. According to the theoretical expression of damage rate [4], damage rate is inversely proportional to fracture toughness of the coatings. Combining with the experiments and the theory, it can be predicted that the fracture toughness of nanostructured coatings is different from that of the conventional coating. To understand size effect of fracture toughness and its effect on damage and fracture behaviour, fracture toughness effect on damage of coatings is studied systematically based on finite element method by adjusting toughness parameter, and the corresponding size-dependent fracture toughness is proposed to compare with the experimental results.

FINITE ELEMENT SIMULATION OF COATING CRACKING

Methods

Ceramic coating/alloy substrate models are considered in order to compare with and understand the previous experiments, and the models are assumed to be under the plane strain condition and the 2D FEM analysis is carried out using the commercial software ABAQUS. The model includes two layers: the substrate with thickness h_s of 1.2 mm and the ceramic coating with thickness h_c of 400 μm. The span length is 24 mm. The vertical loading displacement w is applied on the substrate. The ceramic coating is considered as the linear elastic material with Young's modulus E_c and Poisson's ratio v_c [5]. The alloy substrate is assumed to be the elastic-plastic material with Young's modulus E_s, Poisson's ratio v_s and yield strength σ_Y, and its constitutive relation can be referred to Ref. [5]. The four-node plane strain reduced integration elements (CPE4R) are selected to mesh substrates and coatings.

Cohesive elements, based on interface cohesive zone model, are inserted regularly into the coating, the mesh is dense enough between two neighbor cohesive elements. The four-node cohesive elements (COH2D4) are applied. The strength σ^0 and toughness Γ of the cohesive elements refer to actual coating strength and fracture toughness, respectively, the detailed forms of strength and toughness, as functions of the crack displacement δ, and the damage and fracture criterion can be referred to Ref. [5]. Coating strength σ^0_n is 80 MPa here with the subscript n represent normal direction. Fracture toughness Γ_n are about 20 J/m^2, and the toughness of cohesive elements varies in the range while others remain unchanged to consider influence of fracture toughness.

Results

The cracking mode of ceramic coating is showed in Fig. 1(a), the failure mode is naturally coating transverse cracking, agreeing with the experimental results [6] as showed in Fig. 1(b). The fracture toughness effects on damage behavior of coatings are summarized as Table 1. It can be seen that the crack length decreases with increasing coating toughness and cracking occurs later, too, i.e., damage defined by a total crack length is slower for coatings with higher toughness, which is consistent with the theory that damage rate is inversely proportional to the fracture toughness [4]. On the other hand, the displacement at crack initial and total crack length was observed for different coating thicknesses. The results show that crack initiates earlier and crack length is longer for the thicker coatings. At the same time, the crack length of thick coatings increases faster, which implies that the damage of the thick coatings is faster, agreeing with the experimental results [3].

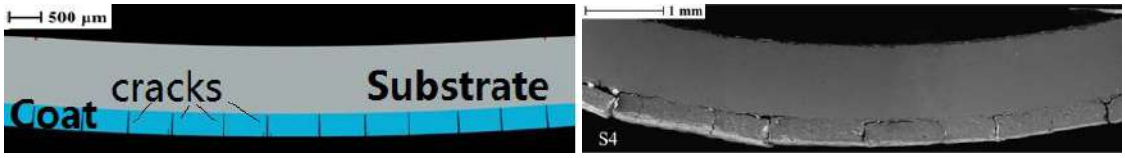

Figure 1. (a) Transverse cracks occur in the coat bonded on the substrate under 4-point bending simulation and (b) similar experimental results [6].

Table 1. Toughness effect on damage (crack length) of coatings.

Γ (J/m^2)	10	20	50
Crack initial displacement (mm)	0.36	0.5	1.27
Crack length at same displacement (mm)	5.89	4.8	1.72

SIZE EFFECT OF INTERFACE FRACTURE ENERGY

Table 1 indicates that the lower fracture toughness corresponds the larger damage rate, as demonstrated in the experiments for nanostructured coatings [3], which implies a size effect of intrinsic fracture energy of coatings. The studies have shown that both cohesive energy and surface energy decrease for nanocrystalline materials compared to corresponding bulk materials [7-8], the fracture energy of materials should also be size-dependent since it equals two times of surface energy [8] when interface energy of the same material is neglected. Therefore, size-dependent fracture toughness can be expressed as $\frac{\Gamma_n(d)}{\Gamma_b} = \exp\left(-\frac{Sl}{3Rd}\right)$ when the grain diameter d of nanocrystalline coatings is much larger than a critical size of the corresponding crystals related to the average bond length l, where $\Gamma_n(d)$ and Γ_b denote size-dependent fracture toughness of nanocrystalline coatings and the corresponding bulk value, respectively. $S = U/T_0$ is the entropy of solid-vapor transition with the cohesive energy U and boiling point T_0 of the corresponding crystals, and R is the ideal gas constant.

For zirconium oxide coatings, Γ_n/Γ_b is about 1/3 based on above expression with the parameter referring to the previous work [8]. According to the experimental results [3], the ratio of average damage coefficient of conventional coatings to that of nanostructured ones is about 0.7, which is roughly in agreement with the above discussion that damage rate is inversely proportional to the fracture toughness.

CONCLUSIONS

In summary, toughness effect of damage coatings was studied based on finite element method by introducing interface cohesive zone model. The results indicate that cracking is later and damage is slow for coating with large fracture toughness, agreeing with the theoretical prediction and experimental results. Size-dependent toughness is calculated and it is effective to characterize fracture behavior of nanocrystalline coatings.

ATOMISTIC STUDY OF EQUILIBRIUM PRESSURE OF HELIUM BUBBLE IN FCC IRRADIATED COPPER AND ITS ABNORMAL SIZE EFFECT

Lv Chenyangtao, Huang Xinlong, Chu Haijian*
School of Mechanics and Engineering Science, Shanghai University, Shanghai, China

Summary Helium management is of prime concern for materials in future fusion and fast fission reactors. The helium density inside helium bubble and its corresponding internal pressure have a significant influence on the mechanical properties of materials with radiation-induced helium bubble. In this work, the equilibrium pressure, size effect, temperature effect and stress field of FCC copper containing helium bubble are systematically explored by means of molecular simulations in this paper. Based on energy principle and stress criterion, the method to determine the equilibrium internal pressure is proposed and applied. An abnormal effect of the bubble size on the equilibrium pressure is found. In addition, a method to reduce the effect of thermal disturbance or fluctuation on the stress field is proposed by means of the superposition of time-domain average and regional average.

EQUILIBRIUM PRESSURE OF THE HELIUM BUBBLE AND SIZE EFFECT

When the bubble is vacuum or its internal pressure is quite small, radial tensile stress can be generated in the matrix due to the contribution of the surface tension, whereas a radial compressive stress will be generated when the bubble pressure is large enough. Therefore, there must be a critical equilibrium pressure that generates the minimum stress in the matrix. In terms of energy, the system is in the minimum energy state under the effect of equilibrium pressure. Therefore, the equilibrium pressures of He bubbles are analyzed based on the criterion of energy equilibrium and mechanical equilibrium in this work. Configurations of helium bubble with different size and its surrounding atoms under equilibrium internal pressure are shown in Fig. 1(left). The size effect of bubbles on the equilibrium pressure at different temperatures is given in Fig. 1(right).

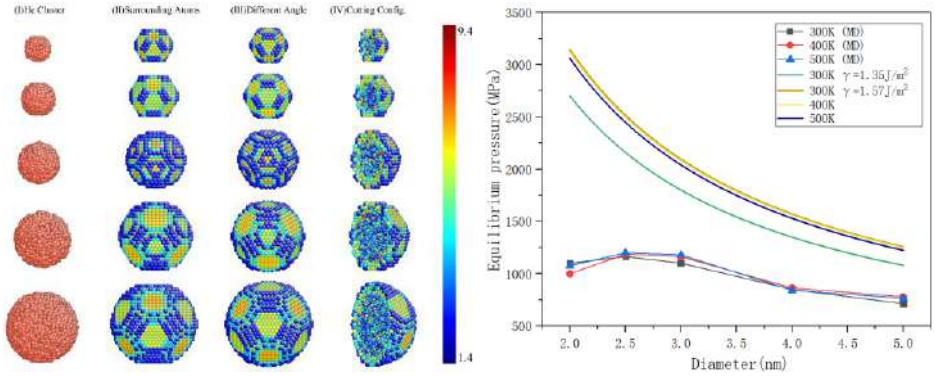

Fig.1 Configurations of helium bubble with different size under balance pressure after relaxation (from the top to bottom, bubble size 2, 2.5, 3, 4, 5nm) (left), and equilibrium internal pressure of the He bubble versus its diameter under different temperatures (right)

STRESS FIELD INTRODUCED BY HE BUBBLE

The atomic Virial stress tensors are processed by the method of time average and region average, Fig 2. shows the stress distribution on {111} plane due to the action of internal pressure of the bubble with respect to different bubble sizes. Stress concentrations at the Cu-He interface region are revealed on both contours of Mises equivalent stress and Shear stress. Fig. 3 shows the radial stress distribution along the $[1\bar{1}0]$ direction in helium bubble model.

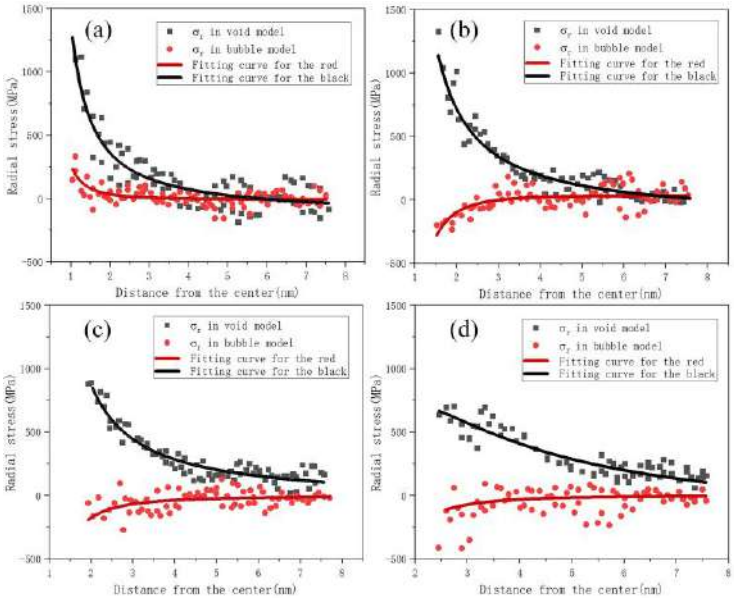

Fig.3 Helium bubble induced radial stress under equilibrium pressure along [$1\bar{1}0$]. (a) 2nm; (b) 3nm; (c) 4nm; (d) 5nm

CONCLUSION AND DISCUSSION

As a summary, the equilibrium pressure of He bubbles in FCC copper and its size effect are studied. The major contributions are included as follows:

1) The equilibrium pressures of the bubble obtained by means of the criterion of the minimum energy principle and stress criterion are self-consistent. Compared with simulation results of molecular simulation, the traditional theoretical formula based on spherical holes to estimate the equilibrium pressure seriously overestimates the results of helium bubbles, and the error increases significantly with the decrease of the size of helium bubbles. For instance, when the aperture is 3nm, the error exceeds 63%.

2) A critical size is firstly found. When the size of He bubble less than the critical one, the abnormal size effect arises, i.e. when the helium bubble diameter is less than 3 nm, the pressure does not increase obviously with the decrease of the aperture, whereas even reduce.

3) Due to the characteristics of the microscopic polyhedron of the hole and the anisotropy of the material, even under the action of the equilibrium pressure of helium bubble, there is still a certain stress in the surrounding copper matrix, which demonstrates a local feature and decreases rapidly as the increase of the distance from the center of the bubble.

HIGHER-GRADE ELASTIC BEAMS TO PROBE SCALING EFFECTS IN SOLIDS

Fabien Amiot*[1]
[1]Department of Applied Mechanics,Univ. Bourgogne Franche-Comté,Institut FEMTO-ST,CNRS/UFC/ENSMM/UTBM,Besançon,France

Summary The mechanical behavior of micrometer-sized structures differs from that of usual macroscopic objects. Their surface plays a key role in the overall behavior of the structure. Higher-grade elasticity, and especially second-strain gradient elasticity seems particularly suited to describe the observed size effects, and in particular the strong surface couplings at stake. These frameworks however involve a large number of constitutive parameters whose experimental identification seems today far from attainable. This contribution thus targets the development of robust beam equations for materials featuring higher-grade elasticity, which solve the deficiencies of the available theories, provides solutions involving on a limited number of parameters, and paves the way to the experimental identification of higher-grade elasticity parameters.

INTRODUCTION

Because of their high surface over volume ratio, the mechanical behavior of micrometer-sized structures differs from that of usual macroscopic objects. Two main families of mechanical size effects are observed for solids :

- a material parameter (for instance a stiffness) depends on the specimen size [1] ;
- strong surface couplings are observed. Their surface plays a key role, and this property has been proposed to devise micromechanical sensors of environmental changes [2]. In particular, a significant effort has been put on the development of biological sensors, based on cantilevers operated in static mode (see Fig. 1), and the published results are highlighting the need for a more basic understanding of coupled surface phenomena [3].

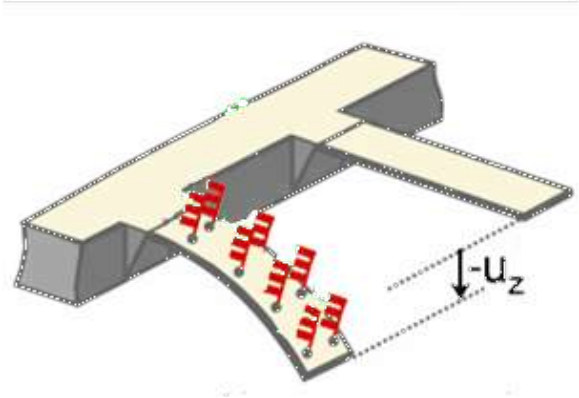

Figure 1: Principle of a cantilever-based sensor : a surface chemical modification induces a mechanical deformation (adapted from [2]).

It has been shown that the use of second strain gradient elasticity may provide a framework describing both these size effects, at the cost of additional modeling parameters which are yet to be identified [4]. Focusing on beams allows to simultaneously encompass most of the reported experimental results and to lower the complexity. The available higher-order beam theories are however only based on kinematic assumptions, so that they cannot render Poisson effect for instance [5]. The correct beam stiffness for vanishing higher-order elasticity parameters is sometimes recovered in a somehow arbitrary way, so that the consistency with the usual Cauchy material-based beam theory is questionable [6]. Refined higher-grade beam theories are therefore desirable, keeping their complexity as low as possible.

HIGHER-GRADE BEAM EQUATIONS

A method is proposed herein to build beam equations for materials featuring higher-grade elasticity. The proposed approach is based on the minimization of the constitutive equation gap in order to simultaneously satisfy kinematic and static conditions, including higher-order static admissibility conditions. It is shown that the resulting beam equations are consistent with the usual ones obtained with Cauchy materials when the dimensions are large enough and are yet tractable. The (few) driving parameters are obtained as closed-form expressions of the parameters of the three-dimensional constitutive law.

*Corresponding author. E-mail: fabien.amiot@femto-st.fr.

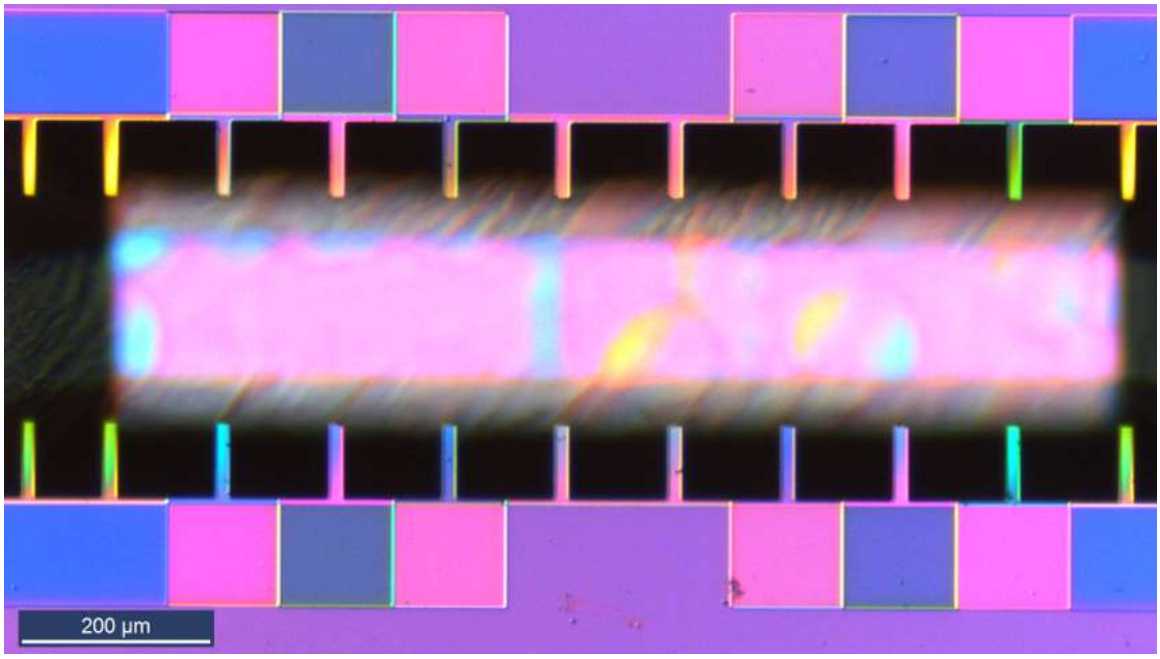

Figure 2: Optical view of a silicon nitride cantilevers array featuring different thicknesses (ranging from 230 to 550 nm).

For second-strain gradient elasticity, the resulting beam equations are found to be non-local : the non-local kernel results from the stationarity condition, and the involved length parameter is again expressed as a simple function of the parameters of the three-dimensional law. The differences with first-strain gradient theories and the usual (kinematic) second-strain gradient approach are highlighted for several representative load cases, so that the scale range such refined theory is required is identified. The obtained solutions can also be compared to those obtained from asymptotic analysis [7] or from a Gurtin-Murdoch like approach [8], and the obtained results are used to define bulk-driven and surface-driven (ecto-elastic) elasticity regimes.

Additionally spanning the range of thermodynamically admissible materials, the role of Mindlin's cohesion modulus is exemplified and it is shown that the predicted behaviors cluster in few, rather different, families, depending on the higher-grade elastic parameters. This could trigger the development of innovative MEMS devices and paves the way for the experimental approach of these higher-grade materials.

EXPERIMENTAL IDENTIFICATION

Based on the above-described framework and making use of arrays of silicon nitride cantilevers featuring different thicknesses (see Fig. 2), indications for the robust experimental identification of the involved higher-grade elastic parameters will be given.

LOW ORDER NON-STANDARD CONTINUALIZATION OF A BEAM LATTICE. ENHANCED PREDICTION OF DISPERSIVE BEHAVIOUR

F. Gómez-Silva*[1] and R. Zaera[1]
[1]Department of Continuum Mechanics and Structural Analysis, University Carlos III of Madrid, Avda. de la Universidad,30.28911Leganés,Madrid,Spain

Summary In this work, standard and non-standard continualization techniques are applied to a beam lattice, consisting of a chain of masses and linear rotational springs. The study focuses on the reliability of the new continuous equations when capturing the dispersive behaviour of the discrete system, considered as a reference. Besides, their physical consistency is examined, and low order continuous equations are pursued, in order to avoid the need of extra boundary conditions when finite solids problems are solved. The performance of the new equations is evaluated through vibration analyses with the best performance being shown by the new novel models, obtained by means of techniques, applied here for the first time to a discrete system such as the one considered in this work.

INTRODUCTION

The formulation of classical continuum models fails when size effects are present, due to the discreteness of the matter. To eliminate this problem, Molecular Dynamics and Lattice Dynamics approaches appear as an alternative to these models. Although these approaches enable to capture scale effects in a precise way, they imply high computational costs. This is why, since the 19th century, great efforts have been focused on the development of non-classical continuum models, which accurately reproduce the dispersive behaviour of discrete media. The first attempts date back to the 1960s with works by Mindlin or Eringen, among others. These models are considered axiomatic and depend on non-classical parameters, which require experimental results to be calibrated. Therefore, as an alternative, models based on the continualization of discrete systems appear. These systems are made up of cells which repeat periodically. In this way, it is possible to relate the scale parameters of the new non-classical models to the mechanical and geometric characteristics of the system.

In this work, the dynamic behaviour of a linear beam lattice, made up of masses and linear rotational springs, is studied. Different continualization methods are proposed (both standard and non-standard), some of which have been applied here for the first time to this kind of system. The different non-standard continuum models obtained are evaluated by comparing their dispersion relations with those of the discrete one. The new continuous governing equations are intended to be of low order, to avoid the need of extra boundary conditions when applied to bounded solids. The regularization approach proposed by Baigalupo and Gambarotta [1], and applied by them to lattice systems different from the one presented in this paper, is the one showing the best performance. In short, this work presents an in-depth study on the appropriateness of the different non-standard continuity methods to be implemented, and on their ability to reflect the dynamic behaviour of a beam lattice.

DISCRETE MODEL

The discrete beam model (Fig. 1), which is taken as a reference, consists of a chain of length L, made up of N straight segments of length $d = L/N$, regarded as a characteristic length. These segments are joined by linear rotational elastic springs of rigidity C. This model also includes $N + 1$ particles with mass m, connected by the segments. The horizontal position of an arbitrary particle n is described by $x_n = nd, n = 0, ..., N$ and the vertical position is described by its vertical displacement $v_n(t)$, $n = 0, ..., N$.

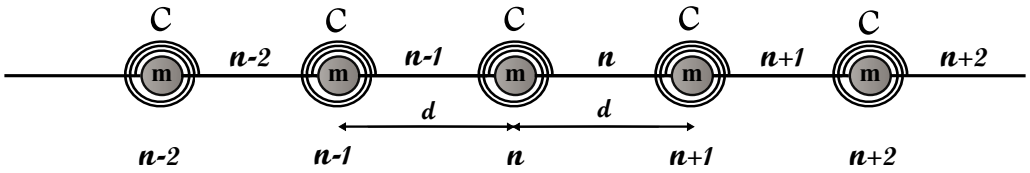

Figure 1: Discrete beam model.

*Corresponding author. E-mail: frgomezs@ing.uc3m.es.

NON-CLASSICAL CONTINUUM MODELS

As mentioned above, standard and non-standard continualization methods are applied to the discrete model in this work. Two standard continualization methods, using Taylor's series, are employed. One of them consists in expanding displacements in the governing equation of the discrete model, while in the other, displacements are expanded in the Lagrangian. Moreover, different non-standard procedures (employing pseudo-differential operators) are presented. The first one applies the pseudo-differential operator in the discrete governing equation, latter using Taylor's series and Padé approximants to expand it, as proposed by Hache et al. in [2]. This method is used also to obtain a new governing equation, including one additional scale parameter. In the second one, the shift operator is also introduced in the discrete governing equation, but in this case, only Padé approximants are used to expand it. Thirdly, a model with Enriched Kinetic Energy (EKE) is proposed, the shift operator applying to the Lagrangian of the system. Finally, the Regularization method is applied to the discrete governing equation. The last four procedures mentioned are applied here for the first time to this kind of system, leading to original governing equations. To summarise the results obtained, the following dimensionless general governing equation is derived

$$\overline{v}_{\overline{xxxx}} - a_1 \overline{v}_{\overline{xxxxxx}} + \overline{v}_{\overline{tt}} - a_2 \overline{v}_{\overline{xxtt}} + a_3 \overline{v}_{\overline{xxxxtt}} = 0, \tag{1}$$

which depends on the scale parameters a_1, a_2 and a_3, shown for each model in Table 1.

Table 1: Values of the parameters for the continuum models.

	Classic	Standard I	Standard II	Taylor-Padé I	Taylor-Padé II	Padé	EKE	Regularization
$\mathbf{a_1}$	0	-1/6	1/2	0	0	0	0	0
$\mathbf{a_2}$	0	0	0	1/6	1/6	1/6	1/12	1/6
$\mathbf{a_3}$	0	0	0	0	1/144	11/720	49/720	7/360

RESULTS AND MAIN CONCLUSION

In order to present some of the results obtained, the dimensionless dispersion curves of all models are shown near their corresponding errors in the Fig. 2. As can be proved, the four novel models show the best performance, the Regularization method having the smallest error. Furthermore, this model has no physical inconsistencies and does not require extra boundary conditions to be solved.

LOAD DEPENDENT STRUCTURE BORNE SOUND EXCITATION IN RAIL VEHICLE DRIVE TRAINS: SIMULATION APPROACH AND EXPERIMENTAL INSIGHT

Johannes Woller, Sascha Noack and Michael Beitelschmidt
Professorship of dynamics and mechanism design, Technische Universität Dresden

Summary The structure-borne noise input from the drive system largely characterizes the perceived interior noise of modern rail vehicles. In the development process, this sound component is still difficult to predict. In the present work, a simulation methodology based on the elastic multi-body simulation in the time-domain is outlined, which is suitable to enable a prediction of the drive-related (gearing excitation) structure-borne noise component in a frequency range up to 1 kHz. For the verification of the developed calculation methodology, vibration measurements on a test rig are evaluated over the operating field of the powertrain. A comparison with measurement data shows, that the model is able to reproduce the load dependency of the modelled drive and calculate comparable vibration levels and resonances.

INTRODUCTION

The acoustic requirements of new railway vehicles are rising steadily. Not only the exterior noise but also the interior sound is an important target for the development process. On this basis a research project, funded by BOMBARDIER TRANSPORTATION, deals with computational models of drive trains for rail vehicles. The objective of the project is the development of a calculation methodology for the source mechanisms and the transmission of structure borne (SB) sound in a driven running gear of a rail vehicle. A new approach for SB sound calculations is the use of elastic multi-body simulation (EMBS) in the acoustic frequency range. In railway industry, EMBS models are commonly used for calculation of the vehicle dynamics, dealing with safety against derailment, track loading calculations and ride comfort. The frequencies of interest are therefore in a range up to 20 Hz. In this publication, the modelling approach for the extension of that frequency range is outlined and first results of an experimental validation are shown. The investigation was carried out using a currently developed regional train built by BOMBARDIER TRANSPORTATION. Similar approaches can be found in literature e.g. for the passenger cars and wind energy systems [1].

EXPERIMENTAL INVESTIGATIONS

Measuring the interior sound in the vehicle, the tooth meshing frequencies of the gearboxes as well as the excitation due to the time-variant electromagnetic field of the traction motor were identified as dominant SB sound sources. In the interior, the traction-based noise components are of great importance, especially during acceleration and braking. The measurements reveal that the highest interior sound levels are dominated by SB noise transmission, especially in the range below 1000 Hz. A second measurement campaign was carried out on a powertrain test rig. Rotational speed and torque of the output shaft were measured. In addition, accelerations on the surfaces of powertrain components were recorded. From the known mechanical performance parameters of the powertrain, 98 representative performance points were selected and measured in stationary runs of 20 sec. Using the measured operating points, an operation map can be created (Figure 1) to determine the vibrational critical points. Detailed results from the experimental investigations at the test rig are published in [2].

MODELLING APPROACH

The powertrain model is built in the commercial software environment SIMPACK using a bottom-up methodology. To extend the validity to the acoustic frequency range, the structural dynamic behaviour of components involved into the transmission of SB noise must be considered. This is done by integrating flexible bodies. In SIMPACK the floating frame of reference (FFRF) method is used for this purpose. In the FFRF the deformation is made up of a large non-linear rigid body motion and a small linearized elastic local deformation. To reduce the high degree of freedom of elastic bodies, which are built by the finite element method (FEM), a Model Order Reduction (Component Mode Synthesis) is performed. Following the recommendation in [3], no constraint equation is used for the assembly of the system. All bodies are free, and the kinematics are handled via binding force elements (e.g. roller bearings, tooth contact etc.). The structure of the EMBS thus corresponds to a dynamically substructured system with an assembly on the right side of the equation of motion. The upper frequency limit for the validity of the model was set to 1000 Hz. All bodies have modal coordinates in a frequency range up to 2000 Hz. The housing of the powertrain, as the main elastic body, was validated by an experimental modal analysis. All shafts are modeled by means of beam elements (Timoshenko approach). For the elastomer bearings a linear stiffness approximation was used. The rolling bearings are modeled via point to point force law (3D including torque) using the ROLLERBEARING algorithm of SIMPACK consisting of nonlinear analytical formula. The gear contact and the related stiffness is calculated using the GEARPAIR 225 algorithm of SIMPACK [4]. This algorithm performs an analytical contact calculation and uses gear stiffness definitions according to DIN 3990. The model can calculate the dynamic tooth contact problem in the time domain even at high rotational speeds. The gear geometries include flank shape corrections. To take dynamic changes in the contact pattern into account, a width (115mm) discretization of the tooth is carried out. The tooth contact calculation takes place at 100 slices across the tooth width.

NONLINEAR SYSTEM BEHAVIOUR

Excitation mechanisms in gears are influenced by the relative position of the gear wheels. Consequently, the deformations of the gear wheels, the shafts, the bearings and the surrounding housing under load are of great importance for the gearing excitation. As the load torque increases, the stiffness of the tooth contacts varies due to changes in the contact pattern and the stiffness of the roller bearings changes. This leads to significant changes in system response across the operating field. Since the investigated drive is used in both directions of travel, two fundamental different excitation behaviors can be seen by changing the direction of rotation (positive and negative acting torque).

COMPARISON OF MEASUREMENT AND SIMULATION

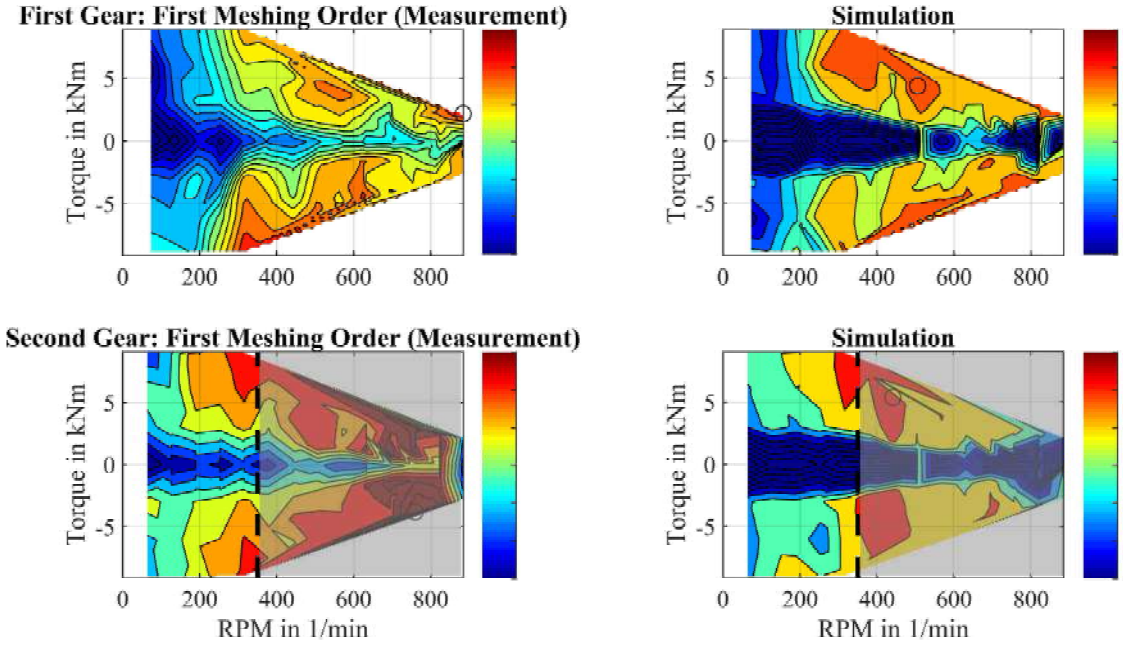

Figure 1: Linear interpolation surface based on the acceleration level (RMS) of the gear-related excitation frequencies at an important measuring point (MP2 in the Z direction) for measurement and simulation. The circle marks the highest level in each diagram. The dashed line indicates the frequency range > 1000 Hz based on the excitation order shown. Areas in gray exceed the model validity.

Figure 1 shows the comparison between measurement and simulation for the stationary acceleration levels at an important connection point of the powertrain. Similar resonance phenomena can be identified in measurement and simulation but not always at the same rotation velocity. The vibration level is comparable in wide speed ranges. The difference between traction and braking operation is clearly recognizable in both measurement and simulation. However, there are significant qualitative and quantitative deviations especially above 1000 Hz (thus outside the intended frequency scope). To calculate this operating field (98 stationary points), a calculation time of approx. 30 h was required on a standard workstation.

CONCLUSION

In this article, a calculation model for structure-borne noise from a rail vehicle powertrain was outlined. A systematic comparison between measurement and calculation is achieved by evaluating the entire operating field. The comparison of the gear-related orders between measurement and calculation reveals a globally qualitative and quantitative agreement at the shown measurement point. Nevertheless, there are significant deviations in detail and for individual operating points. Better agreement can potentially be achieved by eliminating model uncertainties in terms of parameters and a more suitable representation of modeling elements (e.g. bearing model, gear contact model).

TRANSFER MATRIX METHOD FORMULATION FOR ELASTIC BODY DYNAMICS WITH LARGE MOTION

Qinbo Zhou*[1,2], Jörg Fehr[1], Peter Eberhard[1], and Xiaoting Rui[2]
[1]Institute of Engineering and Computational Mechanics, University of Stuttgart, Stuttgart, Germany
[2]School of Energy and Power Engineering, Nanjing University of Science and Technology, PR China

Summary The transfer matrix method for multibody systems (MSTMM) is a multibody dynamics method developed in the last 25 years. It has been widely used in both science research and engineering and is capable of performing very fast calculations of the dynamics of complex multibody systems. This work extends the theory of MSTMM by formulating the transfer equation of an elastic body of general shape. The favorable ideas from the floating frame of reference method that (i) the overall motion is split into a large rigid body motion and a small elastic deformation, (ii) use of general shape are possible by calculating the standard input data, are transfered into the MSTMM formulation.

INTRODUCTION

The *transfer matrix method for multibody systems* (MSTMM) [1] is used for time-variant multibody dynamics with large nonlinear described overall motion. In the MSTMM, a system is decomposed into elements, including bodies and hinges. Kinematic and kinetic quantities at joint definition points are summarized as *state vectors* that are related by the characteristic of the element in between. This characteristic is described by linear *transfer equations* from one joint definition point to the other, which are called the *input and output points* I and O of the element, see Figure 1. For a specific system, by simple matrix operations, the element transfer equations are assembled into the *overall transfer equation*, which can be solved for given boundary states at the endpoints of the system.

The MSTMM has shown its strength in fast computation without establishing the global dynamics equation of the system and always keeping low order of system matrices independently from the degree of freedom, which makes MSTMM especially interesting in real-time applications or usage in embedded systems. With high-performance and high-precision demands on complex mechanical systems, high flexibility and large scale have emerged as essential trends to be covered by appropriate multibody simulation tools. However, the element transfer equation for elastic bodies has not been developed so far for the MSTMM. This work aims to bridge this gap by showing the framework of developing the transfer equation of a single elastic body described in the *floating frame of reference formulation* (FFRF).

DYNAMICS OF AN ELASTIC BODY

To model flexible bodies with elastic deformation and large rigid body motion, the FFRF is chosen. In this formulation, the motion of a free flexible body is separated into a nonlinear described overall motion of the reference frame K_R, see Figure 1, and a linear elastic deformation with respect to K_R. The small elastic deformations are further discretized using the Ritz approach ${}^R\boldsymbol{u}_P({}^R\boldsymbol{R}_{RP}, t) = \boldsymbol{\Phi}_P({}^R\boldsymbol{R}_{RP})\boldsymbol{q}(t)$ which is often handled by the finite element method. The dynamics equation of a flexible body is represented by a second order differential equation [2]

$$\boldsymbol{M}\dot{\boldsymbol{\eta}} = \boldsymbol{h}_a \quad \text{with} \quad \boldsymbol{\eta} = \left[{}^I\dot{\boldsymbol{r}}_{IR}^{\mathrm{T}} \quad {}^I\boldsymbol{\omega}_{IR}^{\mathrm{T}} \quad \dot{\boldsymbol{q}}^{\mathrm{T}}\right]^{\mathrm{T}}, \tag{1}$$

where $\boldsymbol{M}$ is the time-variant mass matrix, $\boldsymbol{\eta}$ is the generalized velocity and $\boldsymbol{h}_a$ is the generalized force. It is important to mention that the velocity ${}^I\dot{\boldsymbol{r}}_{IR}$ and angular velocity ${}^I\boldsymbol{\omega}_{IR}$ of K_R are herein expressed in the global inertial frame K_I. Consider two adjacent elements by connecting output O of an element j with input I of another element k. Then, in the MSTMM, it will greatly facilitate the transfer of state vectors from O of j to I of k, if these state vectors are projected onto a common coordinate system that is K_I.

One essential step for an efficient simulation is, to reduce the linear, time-invariant part corresponding to the linear FE model embedded in the nonlinear ODE (1). This is achieved by approximating elastic coordinates $\boldsymbol{q} \in \mathbb{R}^{n_q}$ using $\boldsymbol{q} \approx \boldsymbol{V}\bar{\boldsymbol{q}}$ with reduced elastic coordinates $\bar{\boldsymbol{q}} \in \mathbb{R}^{n_{\bar{q}}}$ ($n_{\bar{q}} \ll n_q$) and the projection matrix $\boldsymbol{V} \in \mathbb{R}^{n_q \times n_{\bar{q}}}$. Further, a second projection matrix $\boldsymbol{W} \in \mathbb{R}^{n_q \times n_{\bar{q}}}$ is selected such that $\mathcal{W} = \mathrm{span}(\boldsymbol{W})$ is orthogonal to the residual corresponding to the linear FE model. Finally, using the reduced ansatz space $\mathcal{V} = \mathrm{span}(\boldsymbol{V})$ and $\mathcal{W} = \mathrm{span}(\boldsymbol{W})$, Eq. (1) becomes

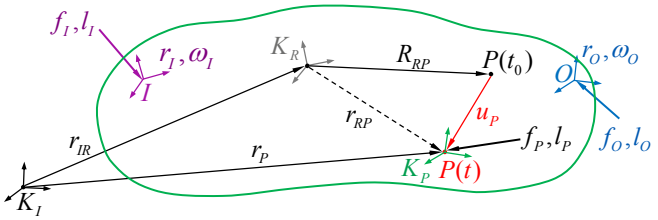

Figure 1: A single flexible body

$$\bar{\boldsymbol{M}}\dot{\bar{\boldsymbol{\eta}}} = \bar{\boldsymbol{h}}_a \quad \text{with} \quad \bar{\boldsymbol{\eta}} = \left[{}^I\dot{\boldsymbol{r}}_{IR}^{\mathrm{T}} \quad {}^I\boldsymbol{\omega}_{IR}^{\mathrm{T}} \quad \dot{\bar{\boldsymbol{q}}}^{\mathrm{T}}\right]^{\mathrm{T}}. \tag{2}$$

One can find the meaning of $\bar{\boldsymbol{M}}$ and $\bar{\boldsymbol{h}}_a$ in [3].

TRANSFER EQUATION OF AN ELASTIC BODY

The classical way of handling an elastic body can be now transferred into the MSTMM concept. In Figure 1, the kinematics on acceleration level for the translation and rotation at I and O can be expressed using $\dot{\hat{\boldsymbol{\eta}}}$ as

$$ {}^{I}\ddot{\boldsymbol{r}}_I = {}^{v}\boldsymbol{L}_{TI}\dot{\hat{\boldsymbol{\eta}}} + \boldsymbol{\zeta}_{TI}, \quad {}^{I}\ddot{\boldsymbol{r}}_O = {}^{v}\boldsymbol{L}_{TO}\dot{\hat{\boldsymbol{\eta}}} + \boldsymbol{\zeta}_{TO}, \quad {}^{I}\dot{\boldsymbol{\omega}}_I = {}^{v}\boldsymbol{L}_{RI}\dot{\hat{\boldsymbol{\eta}}} + \boldsymbol{\zeta}_{RI}, \quad {}^{I}\dot{\boldsymbol{\omega}}_O = {}^{v}\boldsymbol{L}_{RO}\dot{\hat{\boldsymbol{\eta}}} + \boldsymbol{\zeta}_{RO}, \tag{3} $$

respectively, where for point $P \in \{I, O\}$ there is

$$ \begin{aligned} {}^{v}\boldsymbol{L}_{TP} &= \begin{bmatrix} \boldsymbol{I}_3 & -{}^{I}\tilde{\boldsymbol{r}}_{RP} & \boldsymbol{A}^{IR}\boldsymbol{\Phi}_P\boldsymbol{V} \end{bmatrix}, \qquad {}^{v}\boldsymbol{L}_{RP} = \begin{bmatrix} \boldsymbol{O}_{3\times3} & \boldsymbol{I}_3 & \boldsymbol{A}^{IR}\boldsymbol{\Psi}_P\boldsymbol{V} \end{bmatrix}, \\ \boldsymbol{\zeta}_{TP} &= {}^{I}\tilde{\boldsymbol{\omega}}_{IR}{}^{I}\tilde{\boldsymbol{\omega}}_{IR}{}^{I}\boldsymbol{r}_{RP} + 2{}^{I}\tilde{\boldsymbol{\omega}}_{IR}\boldsymbol{A}^{IRR}\dot{\boldsymbol{u}}_P, \quad \boldsymbol{\zeta}_{RP} = {}^{I}\tilde{\boldsymbol{\omega}}_{IR}\boldsymbol{A}^{IRR}\boldsymbol{\omega}_{RP}. \end{aligned} \tag{4} $$

It should be mentioned that $\boldsymbol{\Psi}_P$ in Eq. (4) is the rotational shape function such that the infinitesimal rotation vector at point P is ${}^{R}\boldsymbol{\theta}_P({}^{R}\boldsymbol{R}_{RP}, t) = \boldsymbol{\Psi}_P({}^{R}\boldsymbol{R}_{RP})\boldsymbol{q}(t)$. The reconstruction of $\boldsymbol{\Psi}_P$ from $\boldsymbol{\Phi}_P$ can be found in [4].

To consider reaction forces $\vec{f}_I$, $\vec{f}_O$ and torques $\vec{l}_I$, $\vec{l}_O$ acting on I and O, see Figure 1, they are purposely extracted from the generalized force $\bar{\boldsymbol{h}}_a$ in Eq. (2). This yields the re-written equation of motion

$$ \bar{\boldsymbol{M}}\dot{\hat{\boldsymbol{\eta}}} = \bar{\boldsymbol{h}}_a + {}^{w}\boldsymbol{L}_{TI}^{\mathrm{T}}{}^{I}\boldsymbol{f}_I + {}^{w}\boldsymbol{L}_{TO}^{\mathrm{T}}{}^{I}\boldsymbol{f}_O + {}^{w}\boldsymbol{L}_{RI}^{\mathrm{T}}{}^{I}\boldsymbol{l}_I + {}^{w}\boldsymbol{L}_{RO}^{\mathrm{T}}{}^{I}\boldsymbol{l}_O, \tag{5} $$

where for point $P \in \{I, O\}$ there is ${}^{w}\boldsymbol{L}_{TP} = \begin{bmatrix} \boldsymbol{I}_3 & -{}^{I}\tilde{\boldsymbol{r}}_{RP} & \boldsymbol{A}^{IR}\boldsymbol{\Phi}_P\boldsymbol{W} \end{bmatrix}$ and ${}^{w}\boldsymbol{L}_{RP} = \begin{bmatrix} \boldsymbol{O}_{3\times3} & \boldsymbol{I}_3 & \boldsymbol{A}^{IR}\boldsymbol{\Psi}_P\boldsymbol{W} \end{bmatrix}$.

Then, the transfer equation of an elastic body can be deduced by relating O quantities ${}^{I}\ddot{\boldsymbol{r}}_O$, ${}^{I}\dot{\omega}_O$, ${}^{I}\boldsymbol{l}_O$, ${}^{I}\boldsymbol{f}_O$ (blue in Figure 1) with I quantities ${}^{I}\ddot{\boldsymbol{r}}_I$, ${}^{I}\dot{\omega}_I$, ${}^{I}\boldsymbol{l}_I$, ${}^{I}\boldsymbol{f}_I$ (purple in Figure 1). This can be achieved by eliminating $\dot{\hat{\boldsymbol{\eta}}}$ in Eq. (3) according to Eq. (5) where the generalized velocity $\dot{\hat{\boldsymbol{\eta}}}$ can be explicitly expressed as

$$ \dot{\hat{\boldsymbol{\eta}}} = \bar{\boldsymbol{M}}^{-1}\bar{\boldsymbol{h}}_a + \bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{TI}^{\mathrm{T}}{}^{I}\boldsymbol{f}_I + \bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{TO}^{\mathrm{T}}{}^{I}\boldsymbol{f}_O + \bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{RI}^{\mathrm{T}}{}^{I}\boldsymbol{l}_I + \bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{RO}^{\mathrm{T}}{}^{I}\boldsymbol{l}_O. \tag{6} $$

Equation (6) is substituted into Eq. (3) so that $\dot{\hat{\boldsymbol{\eta}}}$ vanishes, yielding the following equation in matrix form

$$ \begin{aligned} &\underbrace{\begin{bmatrix} \boldsymbol{I}_3 & \boldsymbol{O}_{3\times3} & {}^{v}\boldsymbol{L}_{TO}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{RO}^{\mathrm{T}} & {}^{v}\boldsymbol{L}_{TO}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{TO}^{\mathrm{T}} & \boldsymbol{0}_{3\times1} \\ \boldsymbol{O}_{3\times3} & \boldsymbol{I}_3 & {}^{v}\boldsymbol{L}_{RO}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{RO}^{\mathrm{T}} & {}^{v}\boldsymbol{L}_{RO}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{TO}^{\mathrm{T}} & \boldsymbol{0}_{3\times1} \\ \boldsymbol{O}_{3\times3} & \boldsymbol{O}_{3\times3} & {}^{v}\boldsymbol{L}_{TI}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{RO}^{\mathrm{T}} & {}^{v}\boldsymbol{L}_{TI}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{TO}^{\mathrm{T}} & \boldsymbol{0}_{3\times1} \\ \boldsymbol{O}_{3\times3} & \boldsymbol{O}_{3\times3} & {}^{v}\boldsymbol{L}_{RI}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{RO}^{\mathrm{T}} & {}^{v}\boldsymbol{L}_{RI}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{TO}^{\mathrm{T}} & \boldsymbol{0}_{3\times1} \\ \boldsymbol{0}_{1\times3} & \boldsymbol{0}_{1\times3} & \boldsymbol{0}_{1\times3} & \boldsymbol{0}_{1\times3} & 1 \end{bmatrix}}_{\boldsymbol{E}_1} \underbrace{\begin{bmatrix} {}^{I}\ddot{\boldsymbol{r}}_O \\ {}^{I}\dot{\boldsymbol{\omega}}_O \\ -{}^{I}\boldsymbol{l}_O \\ -{}^{I}\boldsymbol{f}_O \\ 1 \end{bmatrix}}_{\boldsymbol{z}_O} \\ &= \underbrace{\begin{bmatrix} \boldsymbol{O}_{3\times3} & \boldsymbol{O}_{3\times3} & {}^{v}\boldsymbol{L}_{TO}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{RI}^{\mathrm{T}} & {}^{v}\boldsymbol{L}_{TO}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{TI}^{\mathrm{T}} & {}^{v}\boldsymbol{L}_{TO}\bar{\boldsymbol{M}}^{-1}\bar{\boldsymbol{h}}_a + \boldsymbol{\zeta}_{TO} \\ \boldsymbol{O}_{3\times3} & \boldsymbol{O}_{3\times3} & {}^{v}\boldsymbol{L}_{RO}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{RI}^{\mathrm{T}} & {}^{v}\boldsymbol{L}_{RO}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{TI}^{\mathrm{T}} & {}^{v}\boldsymbol{L}_{RO}\bar{\boldsymbol{M}}^{-1}\bar{\boldsymbol{h}}_a + \boldsymbol{\zeta}_{RO} \\ -\boldsymbol{I}_3 & \boldsymbol{O}_{3\times3} & {}^{v}\boldsymbol{L}_{TI}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{RI}^{\mathrm{T}} & {}^{v}\boldsymbol{L}_{TI}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{TI}^{\mathrm{T}} & {}^{v}\boldsymbol{L}_{TI}\bar{\boldsymbol{M}}^{-1}\bar{\boldsymbol{h}}_a + \boldsymbol{\zeta}_{TI} \\ \boldsymbol{O}_{3\times3} & -\boldsymbol{I}_3 & {}^{v}\boldsymbol{L}_{RI}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{RI}^{\mathrm{T}} & {}^{v}\boldsymbol{L}_{RI}\bar{\boldsymbol{M}}^{-1}{}^{w}\boldsymbol{L}_{TI}^{\mathrm{T}} & {}^{v}\boldsymbol{L}_{RI}\bar{\boldsymbol{M}}^{-1}\bar{\boldsymbol{h}}_a + \boldsymbol{\zeta}_{RI} \\ \boldsymbol{0}_{1\times3} & \boldsymbol{0}_{1\times3} & \boldsymbol{0}_{1\times3} & \boldsymbol{0}_{1\times3} & 1 \end{bmatrix}}_{\boldsymbol{E}_2} \underbrace{\begin{bmatrix} {}^{I}\ddot{\boldsymbol{r}}_I \\ {}^{I}\dot{\boldsymbol{\omega}}_I \\ {}^{I}\boldsymbol{l}_I \\ {}^{I}\boldsymbol{f}_I \\ 1 \end{bmatrix}}_{\boldsymbol{z}_I}, \end{aligned} \tag{7} $$

where O and I quantities are summarized as state vectors $\boldsymbol{z}_O$ and $\boldsymbol{z}_I$ of output and input ends of the elastic body, respectively. The transfer equation of an elastic body is then obtained as

$$ \boldsymbol{z}_O = \boldsymbol{E}_1^{-1}\boldsymbol{E}_2\boldsymbol{z}_I =: \boldsymbol{U}\boldsymbol{z}_I, \tag{8} $$

where $\boldsymbol{U} = \boldsymbol{E}_1^{-1}\boldsymbol{E}_2$ is the transfer matrix. The deduced transfer matrix is also validated by simulation and compared with classical methods in the proposed talk.

CONCLUSIONS

The transfer matrix of an elastic body with a single input and a single output end moving in 3D space is derived. The deduced transfer matrix can be used as a building block plugged into a multibody system composed of other bodies and hinges in the context of the MSTMM. Note that there is no limitation of the meshing during the discretization process, the method is applicable for an elastic body with irregular shape. This is a major improvement compared to the previous investigations on flexible members using the transfer matrix method, which are restricted to strip-like meshing only.

THE DYNAMICS OF A MOBILE ROBOT WITH FOUR MECANUM WHEELS AS A PROBLEM OF NON-HOLONOMIC MECHANICS

Igor Zeidis*[1] and Klaus Zimmermann[1]
[1]Department of Mechanical Engineering, Technische Universität Ilmenau, Thuringia, Germany

Summary For a mobile robot with four Mecanum wheels the kinematical rolling conditions lead to non-holonomic constraints. By solving the constraint equations for a part of generalized velocities by using a pseudoinverse matrix, the mechanical system is transformed to another system that is not equivalent to the original system. For certain special types of motions, e.g., translational motion of the robot or its rotation relative to the center of mass, with appropriate constraints being imposed on the torques applied to the wheels, the solution obtained by means of the pseudoinverse matrix coincides with the exact solution. In these cases, the constraints imposed on the system become holonomic constraints, which justifies using Lagrange's equations of the second kind. Using the methods of non-holonomic mechanics, a broader class of trajectories can be covered.

INTRODUCTION

This paper relates to mechanics of wheeled locomotion. Along with biologically inspired forms of locomotion like crawling, flying or swimming, the wheeled locomotion is still in the focus of research. The demand of mobile platforms working in complex environments or personal robots with high maneuverability for handicapped people has led to the invention of new kinds of wheels, especially in the last fifty years. A key issue of an efficient application of these wheels and an optimal control of the whole mobile system is the understanding of the physical interaction between the wheels and the environment. For this reason, mechanics of wheeled locomotion draws attention of mechanical engineers, see, e.g., [1], [2]. The authors of the cited papers mainly use methods of analytical mechanics to obtain the equations of motion. In many cases, Lagrange's equations of second kind are selected, which is correct, in general, for holonomic systems, see e.g. [3]. In this article, we consider the classical kinematic constraint implying point contact and rolling without slipping. The purpose of the present work is to analyze the method that is widely used in robotics. This method involves the approximate solution of the constraint equations with respect to part of the generalized velocities using a pseudoinverse matrix and subsequent derivation of Lagrange's equations of the second kind. We call this method approximate method. These equations are compared with the equations obtained by using non-holonomic mechanics methods. We will call the non-holonomic mechanics methods exact methods.

FORMULATION OF THE MECHANICAL PROBLEM

The dynamics of a four-wheeled robot with Mecanum wheels arranged on two parallel axles (Fig. 1) are studied. The robot moves so that all its wheels have permanent contact with the underlying plane. The body of the robot has a mass of m_0, its center of mass lies on the longitudinal axis of symmetry of the body. The distance from the center of mass C of the robot to each of its wheel axles is ρ, the distance between the centers of the wheels is $2l$. The coordinates of the center of mass in a fixed coordinate system XOY are x_c, y_c , the angle formed by the longitudinal axis of symmetry of the body with axis OX is ψ, each wheel has a mass of m_1. The angles of rotation of the wheels relative to the axes that are perpendicular to the planes of the respective wheels and pass through their centers are φ_i, and the torques applied to the wheels are M_i $(i = 1, \dots, 4)$.

A Mecanum wheel is a wheel with rollers fixed on its outer rim. The axis of each of the rollers forms the same angle δ $(0^\circ < \delta \leq 90^\circ)$ with the plane of the wheel. As a rule, the angle δ_i $(i = 1, \dots, 4)$ is equal to 45°. Each roller may rotate freely about its axis, while the wheel may roll on the roller. We will model a Mecanum wheel by a thin disk of radius R ; the velocity of the point of contact of the disk with the supporting plane is orthogonal to the axis of the roller. Such a design provides additional kinematic advantages for the Mecanum wheels in comparison with the conventional wheels and leads to non-holonomic constraints. For this reason, a full non-holonomic approach is used to describe the dynamics of a mobile robot with four Mecanum wheels.

Introduce a robot-attached coordinate system $\xi\eta\zeta$ with origin at the center of mass C of the cart. We point axis $C\xi$ along the longitudinal symmetry axis of the cart, axis $C\eta$ along the lateral symmetry axis, and axis $C\zeta$ vertically upward. Denote by $V_{C\xi}$ and $V_{C\eta}$ the projections of the velocity of the center of mass onto the movable axes $C\xi$ and $C\eta$, respectively. From four kinematic constraint equations two are non-holonomic:

$$V_{C\xi} = \frac{R}{2}(\dot\varphi_1 + \dot\varphi_2), \qquad V_{C\eta} = \frac{R}{2}(\dot\varphi_3 - \dot\varphi_1). \tag{1}$$

The other two equations are holonomic and can be integrated

$$\psi = \frac{R}{2(\rho + l)}(\varphi_2 - \varphi_3) + C_1, \qquad \varphi_4 = \varphi_1 + \varphi_2 - \varphi_3 + C_2, \tag{2}$$

where C_1, and C_2 are constants.

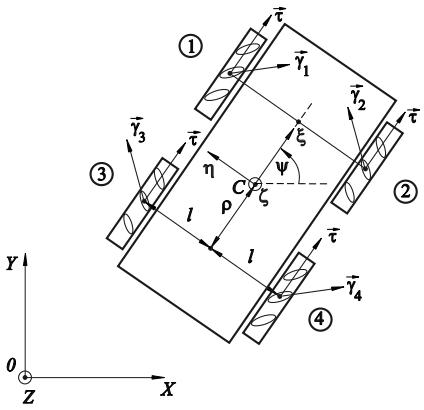

Figure 1: Four wheeled mobile robot with Mecanum wheels.

EQUATIONS OF MOTION OF THE SYSTEM

The system under consideration is called Chaplygin system, it can be described by Chaplygin's equations for non-holonomic systems. The equations of motion for such a mechanical system can be represented as follows [4]:

$$\frac{d}{dt}\left(\frac{\partial T^*}{\partial \dot{\varphi}_s}\right) - \frac{\partial T^*}{\partial \varphi_s} + P_s = Q_s, \quad s = 1, 2, 3. \tag{3}$$

Here, T^* is the function of the kinetic energy of the system from which the velocities $V_{C\xi}$, $V_{C\eta}$ have been eliminated using equations for non-holonomic constrains, Q_s are the generalized forces. The additional (as compared with Lagrange's equations of the second kind) terms P_s are accounted for by non-holonomic constraints and vanish if the constraints are holonomic.

In robotics, researchers often consider kinematic constraints as a system of four linear equations for three unknowns, $V_{C\xi}$, V_{C_η}, and $\dot{\psi}$. This system is overdetermined and does not have a solution for arbitrary values of $\dot{\varphi}_1$, $\dot{\varphi}_2$, $\dot{\varphi}_3$, and $\dot{\varphi}_4$. This system may have a solution only if the equations are linearly dependent. In this case, an approximate solution is obtained by means of the pseudoinverse matrix. The solution found in such a way do not satisfy the system of constraint equations for arbitrary $\dot{\varphi}_1$, $\dot{\varphi}_2$, $\dot{\varphi}_3$, $\dot{\varphi}_4$. However, of all possible triples of quantities $V_{C\xi}$, $V_{C\eta}$, $\dot{\psi}$, this triple provides a minimum for the sum of the squared discrepancies, i.e., the sum of the squared differences of the left-hand and right-hand sides of the equations.

CONCLUSIONS

To describe the dynamics of a robot with four Mecanum wheels one should use the equations of motion that are appropriate for mechanical systems with non-holonomic constraints. Apparently, for Chaplygin systems, Chaplygin's equations should be preferred, since in this case, the dynamic equations form a closed system with respect to the generalized velocities treated as independent variables. In the general case, solving the constraint equations for a part of the generalized velocities by using the pseudoinverse matrix reduces the mechanical system under consideration to a system that is not equivalent to the original system, because the number of degrees of freedom of the reduced system is larger than the number of degrees of freedom of the original system. However, if we confine our consideration to certain special types of motions, e.g., translational motion of the robot or its rotation relative to the center of mass, and impose appropriate constraints on the torques applied to the wheels, the solution obtained by means of the pseudoinverse matrix will coincide with the exact solution. In these cases, the constraints imposed on the system become holonomic constraints, which justifies using Lagrange's equations of the second kind. In the general case, the mathematical methods of non-holonomic mechanics should be used.

INVESTIGATIONS INTO MODEL TUNING OF FLEXIBLE MULTI-BODY SYSTEMS WITHIN THE UDWADIA-KALABA FRAMEWORK

Edward J. H. Yap, D. Rezgui, M.H. Lowenberg, S.A. Neild and K. Rahman
CAME School, University of Bristol, Queens Building, Bristol, BS8 1TR, UK BAE Systems, Rochester, Kent, ME1 2XX, UK

Summary: The study of Multi-Body Dynamic (MBD) modelling approaches is integral to the analysis of mechanical systems that feature joints which govern the range of kinematic motion and display large displacements and geometric non-linearities. Further complexity is introduced if one or more system components is considered deformable due to inherent flexibility. This paper presents an investigation into modelling a flexible crank-slider mechanism within the Udwadia-Kalaba MBD framework by idealising the flexible links using a lumped parameter approach. Through time history simulations, frequency response characteristics are obtained which are compared against those from an alternative flexible mechanism model produced within MATLAB's MBD toolkit Simscape. Tuning studies are conducted to explore the capabilities and limitations of the lumped parameter approach for flexibility within the Udwadia-Kalaba framework whilst also assessing the feasibility of scaling this approach to larger systems of increased complexity.

THE UDWADIA-KALABA MBD MODELLING APPROACH

The Udwadia-Kalaba[1] equations of motion as presented in Eq.(1) are proposed for use in this work as they specifically address the modelling of multibody mechanical systems subjected to kinematical constraints. The formulations reduce the system to a corresponding system of rigid bodies with the system's physical geometrical constraints included as a separate entity.

$$\ddot{\mathbf{x}} = \mathbf{a} + \boldsymbol{M}^{-\frac{1}{2}}\left(\boldsymbol{A}\boldsymbol{M}^{-\frac{1}{2}}\right)^{+}(\boldsymbol{b} - \boldsymbol{A}\mathbf{a}) \tag{1}$$

$\ddot{\mathbf{x}}$ refers to the vector of true accelerations of the multibody system under the influence of geometric constraints. $\mathbf{a}$ refers to the vector of external accelerations due to impressed forces acting on the system. $\boldsymbol{M}$ is the mass matrix of the system and with $\boldsymbol{A}$ and $\boldsymbol{b}$ being matrices both arising from the differentiation of the system's geometric constraints twice with respect to time. The + symbol represents the Moore-Penrose generalized pseudoinverse function[2]. This dynamic modelling approach has also previously been investigated by Nielson et al[3], Li et al[4] and Xu et al[5] who all found convincing agreement of simulated system dynamic results with reference data. In these studies, the application of the Udwadia-Kalaba modelling approach was restrained to rigid-body systems. The scope of this paper is to further explore the application of this modelling approach to consider the inherent flexibility of multibody systems. In a comparison with alternative modelling methodologies, Udwadia and Phohomsiri[6] observed that this modelling approach provided for the first time an explicit set of equations for general constrained systems. The equations of motion obtained may be numerically solved; requiring only the system's mass matrix, acceleration vector due to impressed forces and geometric constraint equations expressed as differential algebraic equations,

In 2019, Yap *et al*[7] provided an application study of the Udwadia-Kalaba modelling approach to a rigid nonlinear planar crank-slider linkage mechanism (Figure 1). The dynamic behaviour of this mechanism under the influence of an externally applied sinusoidal force was assessed with results shown to match responses from alternatively-formulated models produced within MATLAB's MBD toolkit Simscape[8] and a reduced coordinate Lagrangian method. Results from the study validated the system responses produced from the Udwadia-Kalaba modelling approach against the other modelling methods[7] and demonstrated the applicability of the Udwadia-Kalaba approach to dynamically model generic multibody systems subjected to kinematical constraints that may also display nonlinearity. Simscape provides a useful alternative modelling framework as physical system models are created through connections of components that are represented through block diagrams.

THE CRANK-SLIDER MECHANISM

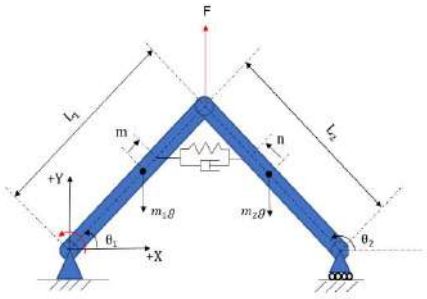

Figure 1: The crank-slider mechanism with rigid links

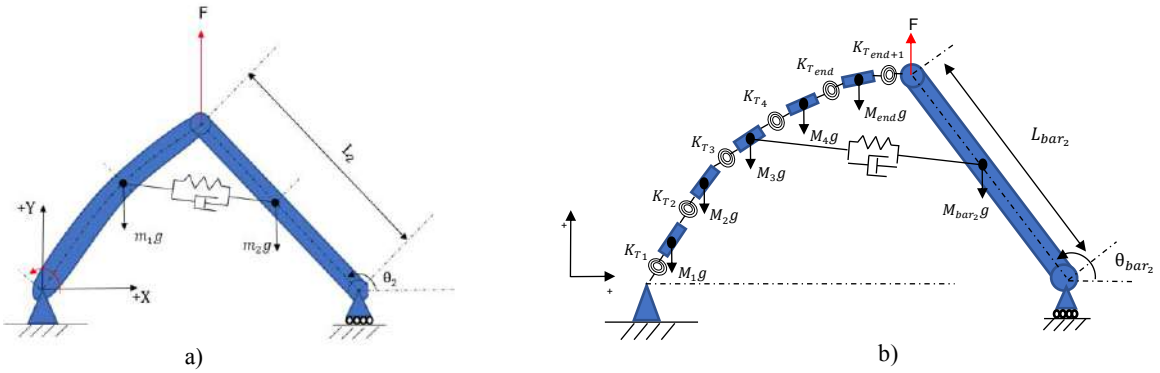
The crank-slider is a nonlinear planar mechanism consisting of two bars initially assumed to be rigid connected via a revolute joint as seen in Figure 1. One end of bar 1 is attached to the ground through a revolute joint whilst the end of bar 2 is attached to the ground via a translational/ revolute joint which permits horizontal translational displacement. A spring-dashpot connecting bars 1 and 2 provide means of translational resistance and energy dissipation.

The mechanism with both links initially assumed rigid can be described using six geometric positional states x_1, y_1, θ_1, x_2, y_2, θ_2 with subscripts 1 and 2 denoting the bars. x_i, y_i denote bar centre of gravity translations whilst θ_i represents bar rotations relative to the horizontal.

SCOPE OF THE FULL PAPER

The intended scope of this paper is to further develop the work on the crank-slider mechanism by now representing the dynamics of flexibility through the incorporation of linkage compliance. The flexibility is idealised by lumped masses and stiffnesses within the Udwadia-Kalaba framework, which has been shown to be applicable for generic multibody systems subjected to kinematical constraints. Frequency response characteristics are obtained which are compared against those from a a flexible crank-slider mechanism constructed within Simscape. The model tuning studies that ensue will explore the capabilities and limitations of adopting the lumped parameter approach for flexibility within the Udwadia-Kalaba framework whilst also assessing the feasibility to scale this approach to larger systems of increased complexity.

Since the underlying principle of the Udwadia-Kalaba formulation is to reduce the physical system to a corresponding system of rigid bodies, the flexible links are represented by a series of rigid elements connected by a set of springs. The determination of the appropriate mass and stiffness values is done through matching the dynamics of the discretised link to the original one. This approach is illustrated in Figure 2 where within the crank-slider mechanism, bar 1 which is now assumed to be deformable, is represented by a series of rigid elements connected with springs. M_i represents the mass of individual rigid elements and K_{T_i} represents individual spring stiffnesses where i is the number of rigid elements. Due to the planar motion of the mechanism in two-dimensional space, only three positional states x_i, y_i, θ_i, are required to describe the configuration of each rigid element.



a) b)

Figure 2: The crank-slider mechanism a) bar 1 replaced with a flexible link, b) idealisation of the flexible link as a series of rigid elements connected with springs under the lumped parameter approach.

CONCLUSIONS

The Udwadia-Kalaba modelling approach has previously been demonstrated to be applicable for modelling generic multibody systems subjected to kinematical constraints that also display nonlinear behaviour. An application study of this modelling approach was conducted on a rigid nonlinear crank-slider mechanism and validated. This paper tackles the increasing of complexity through representing the dynamics of deformable links through the incorporation of linkage flexibilities. For this a lumped-parameter approach is adopted within the Udwadia-Kalaba framework. Frequency response characteristics are obtained which are compared against those from a flexible crank-slider mechanism constructed within Simscape. The model tuning studies that ensue will explore the capabilities and limitations of adopting the lumped parameter flexibility approach within the Udwadia-Kalaba framework whilst also assessing the feasibility to scale this approach to larger systems of increased complexity.

SYMMETRY AND RELATIVE EQUILIBRIA OF A BICYCLE SYSTEM

Jiaming Xiong[1], Caishan Liu *[1]
[1]State Key Laboratory for Turbulence and Complex Systems, College of Engineering, Peking University, Beijing, China

Summary In this paper, we study the symmetries of a bicycle moving on a horizontal plane and a revolution surface, respectively. In each case, we obtain the reduced system on the reduced constraint space, i.e., the quotient manifold of the constraint distribution under the action of the symmetry group. We investigate the relative equilibria of the reduced system, which correspond to the bicycle's uniform upright straight motion, uniform circular motion or static equilibrium states. In general, these relative equilibria are not isolated, but rather form a series of one-parameter solution families. Finally, we analyze the Lyapunov stability of the relative equilibria and prove that they cannot be asymptotically stable, but may be stable under certain conditions.

INTRODUCTION

A bicycle is a typical nonholonomic system whose motion needs to be described using more coordinates than the dimensions of its velocity space [1]. Studies on bicycle dynamics started at the end of the 19th century. Since then the stability of the bicycle's upright straight motion and circular motion has been investigated widely [2-5], especially in the case of horizontal ground. However, the existing studies had little to say about the symmetry of the bicycle system, which is the key to reduction of bicycle dynamics. In this paper, we will systematically analyze the symmetries of a bicycle moving on a horizontal plane and a revolution surface, respectively. The connection between these two cases is that the symmetry group in the latter case is a Lie subgroup of that in the former case.

WHIPPLE BICYCLE AND ITS CONFIGURATION SPACE

As shown in Fig. 1, a Whipple bicycle consists of four rigid bodies including a rear wheel, a rear frame, a front frame and a front wheel [2]. The two frames have lateral symmetries in their shape and mass distributions. The two wheels are circular symmetric and make ideal knife-edge rolling contact with the ground. The effects of structural compliance, joint friction and rolling friction are assumed to be negligible.

The configuration space of the Whipple bicycle moving on the ground is a seven-dimensional manifold, $Q = S^1 \times S^1 \times S^1 \times \mathrm{SE}(2) \times S^1$ (strictly speaking, Q is an open submanifold of this manifold), whose components of product represent the lean motion of the rear frame, steer motion, rotation of the rear wheel, rigid body motion of the rear frame in the horizontal plane (including horizontal translation and yaw motion) and rotation of the front wheel, respectively. In addition, the bicycle is subjected to four nonholonomic constraints due to the non-slipping contact between its two wheels and the ground. Thus, at each point $q \in Q$, the set $\mathcal{D}_q$ of all possible velocities satisfying these constraints is a three-dimensional subspace of the tangent space T_qQ. The collection of these $\mathcal{D}_q$ form a constraint distribution on Q, $\mathcal{D} = \bigcup_{q\in Q} \mathcal{D}_q$, which is a ten-dimensional submanifold of the tangent bundle TQ.

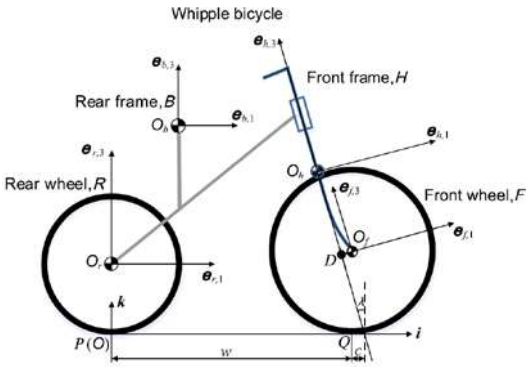

Figure 1. Whipple bicycle (in upright configuration).

BICYCLE SYSTEM ON A HORIZONTAL PLANE

Symmetry of the bicycle system

Denoting by $R = S^1 \times S^1$ the base space, and by $G = S^1 \times \mathrm{SE}(2) \times S^1$ the structure group, we know that the configuration space $Q = R \times G$ is a trivial principal fiber bundle. We introduce the left action of G on Q as follows, $hq = (r, hg), \forall h \in G, \forall q = (r, g) \in Q$. Under this action, the bicycle system has the following two invariances [1]:

(1) The Lagrangian is invariant, i.e., $L(q, \dot{q}) = L(gq, g\dot{q}), \forall (q, \dot{q}) \in TQ, \forall g \in G$.

*Corresponding author. E-mail: liucs@pku.edu.cn

(2) The constraint distribution is invariant, i.e., $g\mathcal{D}_q = \mathcal{D}_{gq}, \forall g \in G, \forall q \in Q$.

Therefore, the dynamic system on $\mathcal{D}$ induces a well-defined reduced system on the quotient manifold $\mathcal{D}/G$, which is called the reduced constraint space [1]. A local representative of this reduced system can be obtained using the Gibbs-Appell equations [4].

Relative equilibria

The equilibrium points of the reduced system on $\mathcal{D}/G$ are called relative equilibria [1]. We prove that these relative equilibria, under a regular condition, are not isolated, but rather form a series of one-parameter solution families. For the bicycle with benchmark parameters [2], we find that there a total of five one-parameter solution families of relative equilibria. Among them, one family corresponds to the uniform upright straight motion of the bicycle, and the other four families correspond to the bicycle's uniform circular motion.

The non-isolation property makes these relative equilibria non-hyperbolic. Thus, their Lyapunov stability cannot be directly determined via the linearized system around them [4]. To deal with this problem, we note that the conserved total energy of the bicycle system, under the Lagrangian and constraint distribution invariances, induces a well-defined reduced constrained energy on $\mathcal{D}/G$. It is a first integral of the reduced system, and equivalently, its level sets are invariant manifolds. Using these invariant manifolds, we prove that if all the eigenvalues of the linearized system, except a zero eigenvalue, have negative real parts, then a relative equilibrium is stable, but is not asymptotically stable. However, the restriction of the reduced system on an invariant manifold, may have an isolated asymptotically stable equilibrium point.

BICYCLE SYSTEM ON A REVOLUTION SURFACE

Symmetry of the bicycle system

When the bicycle moves on a revolution surface, its configuration space and constraint distribution take the same forms as those in the former case. However, a symmetry breaking occurs in this case since the ground no longer has horizontal translation symmetry. The symmetry group is $H = S^1 \times S^1 \times S^1$, where the three components of product represent the rotation of the rear wheel, rotation of the rear frame in the horizontal plane (i.e., yaw motion) and rotation of the front wheel, respectively. Clearly, H is a Lie subgroup of G. The quotient manifold $\mathcal{D}/H$ is a seven-dimensional manifold, and the reduced dynamic system induced on it can be implicitly obtained using the Lagrangian equations of the first type [5].

Relative equilibria

As in the case of horizontal ground, we prove that under a regular condition, the relative equilibria of the bicycle dynamics on the revolution surface also form a series of one-parameter solution families. We numerically investigate several cases where the grounds are specified as paraboloids of revolution. In each case, we find four solution families which correspond to the uniform circular motion of the bicycle, and one solution family corresponding to the bicycle's static equilibrium states. The Lyapunov stability of these relative equilibria can be analyzed in the same way as the case of horizontal ground. Under the condition that all the eigenvalues of the linearized system, except a zero eigenvalue, have negative real parts, a relative equilibrium is stable, but is not asymptotically stable.

CONCLUSIONS

In this paper, we study the symmetries of bicycle systems on the horizontal plane and revolution surface, respectively. Although the symmetry groups are different, the relative equilibria in these two cases have the same properties. Under a regular condition, these relative equilibria are not isolated, but rather form a series of one-parameter solution families. Furthermore, if all the eigenvalues of the linearized system around a relative equilibrium, except a zero eigenvalue, have negative real parts, then this relative equilibrium is Lyapunov stable, but is not asymptotically stable. However, the restriction of the reduced system on an invariant manifold, which is a level set of the reduced constrained energy, may have an isolated asymptotically stable equilibrium point.

EVOLUTION OF WHEEL-RAIL KINEMATIC COUPLING DUE TO RCF AND NATURAL & MAINTENANCE-INDUCED WEAR USING VEHICLE DYNAMIC SIMULATIONS

Visakh V Krishna*[1], Saeed Hossein-Nia[1], Carlos Casanueva[1], and Sebastian Stichel[1]
[1]Department of Engineering Mechanics, KTH Royal Institute of Technology, Stockholm, Sweden

Summary The wheel-rail interaction constitutes a complex kinematic coupling that evolves over time due to various factors such as wear, rolling contact fatigue and periodic maintenance activities, that determine the rail service life. The state of the rail surface after a specified traffic and tonnage passing reflects the track-friendliness of the vehicles. This is particularly helpful in guiding track access pricing strategies for different vehicle designs based on the amount of damage they cause to the track. A complex and highly non-linear multi-body simulation environment is set up and iterative vehicle dynamics calculations are performed, along with the implementation of recently developed wheel-rail contact models, damage models and maintenance procedures over a 100 MGT tonnage period.

INTRODUCTION

In a bid to increase the competitiveness of the European rail freight sector, there is a demand for increased rail freight traffic volumes with longer trains and heavier axle loads. Considering that 40% of the track-maintenance costs is accounted to rail surface damage in the form of wear and rolling contact fatigue, the long-term evolution of the rail surface can indicate the track-friendly nature of a given bogie-design. In this paper the authors utilize multi-body simulations to simulate the evolution of the wheel-rail kinematic coupling due to rolling contact fatigue on rails, the resulting maintenance-induced wear and the wear caused by the vehicles themselves.

FRAMEWORK

The overall framework is depicted in Figure 1. The methodology follows the iterative simulation framework described in [1] for wheel life prediction. A matrix of simulation inputs modelled according to the operation on the Swedish iron-ore line has been considered to simulate the rail surface over a tonnage passing corresponding to about 4 years of operation (100 MGT). The simulation module carries out three-dimensional multi-body simulations by generating wheel-rail geometry functions for the given set of profiles to provide the contact forces and creepages on the contact patch. The contact stresses are then calculated using the *Hertz* theory for normal contact and the recently developed *FaStrip* [1] for the tangential contact respectively. These are then implemented in a stress-based wear prediction model to calculate the vehicle-induced wear on the rail surface ($\mathbf{w_{nV}}$).

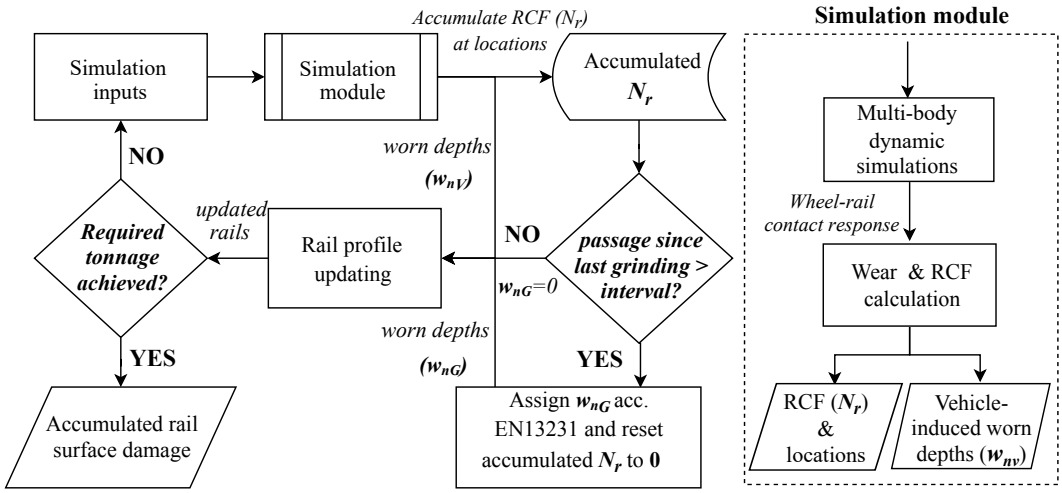

Figure 1: Simulation framework

In addition to wear, cracks arising due to RCF (Rolling Contact Fatigue) is a major driver of rail surface damage and can lead to fracture of the rail cross section if not mitigated on time. Based on the shakedown theory and the Tresca criterion for full slip, the RCF risk is calculated by counting the number of axle passes ($\mathbf{N_r}$) with a risk of exceeding the material yield limit in shear on individual mesh points on the contact patch. Further, to account for the effect of wear on RCF, an energy-dissipation based model that calculates local energy thresholds to scale $\mathbf{N_r}$ is implemented as described in [1].

Rolling Contact Fatigue and the mitigating maintenance interventions

Several works such as [2] and [3] recommend mitigation measures in the form of cyclic grinding actions removing surface cracks at regular intervals, modelled based on the principle of *gauge corner relief*. This alters the rail profile in such a way that the high RCF-prone gauge regions are relieved from wheel-rail contact, pushing the contact regions towards the centre of the rail. These actions drastically change the wheel-rail kinematic coupling and hence need to be considered while calculating long term evolution of rail profiles. A 15 MGT grinding interval and a moderate gauge corner relief has been considered in the methodology for curved track sections according to [3], corresponding to six maintenance interventions, each introducing an artifical grinding-induced wear ($\mathbf{w_{nG}}$). This depends on the location of cracks on the rail surface at the end of each grinding cycle and therefore for the ith grinding intervention, the grinding depths is calculated to

$$\mathbf{w_{nG_i}} = f\left(\sum_{\mathbf{i-1}}^{\mathbf{i}} \mathbf{N_r(y)}\right) \tag{1}$$

For each passing wearstep (loop), the rail head geometry is updated with the wear depths up to the required tonnage as:

$$\mathbf{W_n} = \sum_{j=0}^{100\ MGT} \mathbf{w_{nV_j}} + \mathbf{w_{nG_j}};\ \mathbf{w_{nG_j}} \neq 0 \in j \bmod 15\ \text{MGT} = 0 \tag{2}$$

For every instance of grinding intervention (i.e. j mod 15 MGT=0), the $\mathbf{N_r}$ concentrations are reset to zero, signifying the removal of cracks entirely on the affected regions.

EVOLUTION OF THE RAIL SURFACE

The evolution of the rail surface for the outer rail on a 600 m radius curve is depicted by Figure 2 for a standard Y25 bogie. Figure 2a depicts the evolving normal depths on the rail surface with the $\mathbf{w_{nV}}$ peaks along each wearstep marked by green squares. These are juxtaposed with the RCF ($\mathbf{N_r}$) concentrations for the tonnage passing in Figure 2b. There is a gradual shift and spread of vehicle-induced wear $\mathbf{w_{nV}}$ while the RCF concentrations become less dense after the first grinding intervention. This changes the wheel-rail kinematic coupling significantly since the contact point slides away from the gauge region with increasing tonnage. Also, this varies with vehicle suspension since it determines the radial steering performance of the wheelsets during curve negotiation.

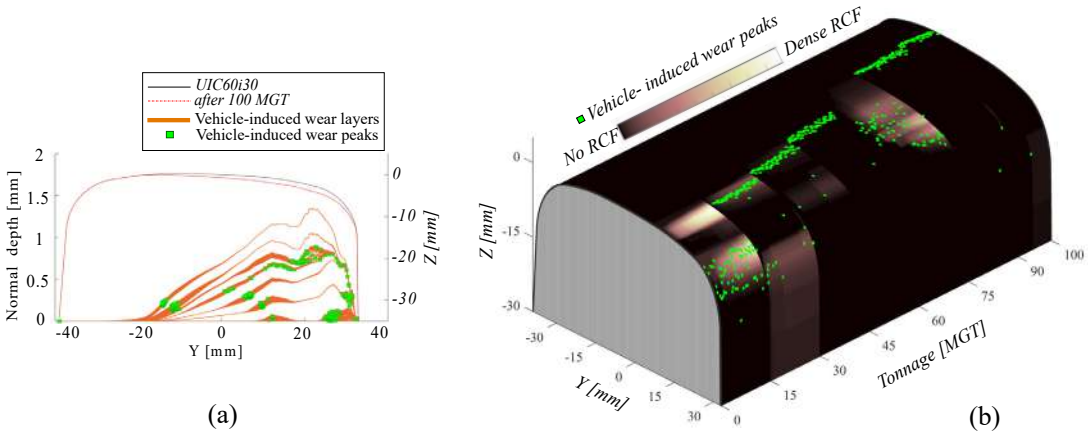

Figure 2: Mapping the evolving wheel-rail kinematic coupling and the associated migration of different damage regions over 100 MGT: (a) Normal wear- $\mathbf{W_n}$ (orange- $\mathbf{w_{nV}}$ and white- $\mathbf{w_{nG}}$) (b) RCF risk- $\mathbf{N_r}$; Radius= 600 m, Outer rail, Bogie: Standard Y25

CONCLUSIONS

The evolution of wheel-rail kinematic coupling over a long period of tonnage due to various damage modes and maintenance interventions has been modelled using an iterative multibody simulation framework and the migration of contacting points and the resulting damage regions is observed. This knowledge can be used to suggest predictive maintenance strategies w.r.t the vehicle dynamics of the train traffic on a given track section.

UPRIGHT PIANO ACTION: EXPERIMENTAL CHARACTERIZATION AND MULTIBODY MODELING

Sébastien Timmermans*[1], François Leroy[1], Anne-Emmanuelle Ceulemans[2], and Paul Fisette[1]
[1]Institute of Mechanics, Materials and Civil Engineering, Université catholique de Louvain, Belgium
[2]Faculté de philosophie, arts et lettres, Université catholique de Louvain, Belgium

Summary In this work, a multibody model of an upright piano action is presented, that has been experimentally validated via high speed camera. The model takes all the bodies into account as well as specific felt force laws and body geometries to deal with intermittent contacts. In addition, experimental tunings of model parameters have been undertaken. Simulations of the model allow, among others, to estimate the maximal playing frequency and a minimal input force on the key to produce a sound. More specifically, the bridle strap and butt spring usefulness are discussed, showing the interest of the multibody modeling approach for studying piano actions.

INTRODUCTION

In pianos, the sound is produced by the impact between the hammer and the strings. A mechanism – called piano action – propels the hammer according to the key motion which is controlled by the pianist. Upright pianos contain an action which differs from that of the grand piano. Both complex, these two actions can be modelled through multibody methods to analyse their behaviour over different impulses and to help understanding their functioning.

The multibody model is based on a demonstrator action, see Fig. 1. The latter has been used for both physical parameters estimation and experimental validation. An equivalent CAD replica of that action has been carried out.

PREVIOUS MODELS

Whereas many publications developed models of the grand piano action, very few focus on the upright piano ones. A first noticeable attempt by Oledzki presents a dynamic model containing only two masses and a nonlinear spring based on experimental observations [1]. After that, several publications of Ramin Masoudi, John McPhee and Stephen Birkett led to the most complete vertical action dynamic model so far. Using the graph theory, they modelled the physical interactions between the five main bodies of the action [2]. Their simulations already allowed to explore the model behaviour under different impulses. Five new features (bridle strap and butt spring, flexibility of some parts, new felt contact model, etc.) were introduced in [3] to enhance the model fidelity and an experimental validation is presented in [4].

In line with the upper modeling works, we propose to build an action multibody model, thanks to the symbolic Robotran multibody software [5], while going deeper in the parameters identification through well-targeted experimentations.

UPRIGHT MULTIBODY MODEL

Based on the action of Fig. 1, the model consists of five mobile bodies, several stops and springs shown in Fig. 2, all moving in a vertical plane. The model considers only rigid bodies, no backlash in the joints and simplified contact geometries: the corresponding bodies shapes are approximated by circular arcs or line segments to find the contact patch location and to compute the reaction forces resulting from felts laws characteristics. Fig. 3 illustrates the case of the hammer-jack contact geometry.

Figure 1: Upright piano action demonstrator and its equivalent CAD replica.

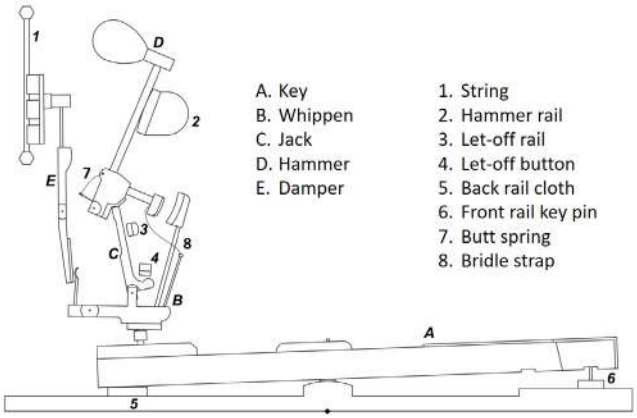

Figure 2: Multibody model main components: mobile bodies (resp. other elements) are indicated by letters (resp. numbers).

*Corresponding author. E-mail: sebastien.timmermans@uclouvain.be.

Parameters experimental characterization

Experimentations conducted on subparts of the model have allowed us to identify forces laws coefficients. For example, the friction of the hammer rotating joint has been characterized by identification between simulations and experiments, depicted in Fig. 4, using high speed camera tracking at 2000 fps. Whereas, with a 1-kg mass as input, the model reacts similarly as the demonstrator for the pre-impact phase [0;0.1] s, the imposed key motion causes the hammer to hit the string a bit too early, around 0.1 s in Fig. 5, but in a quite satisfactory manner, given the modeling parameters uncertainties.

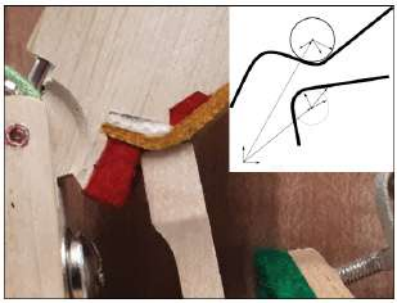

Figure 3: Modeling of the hammer-jack contact geometry.

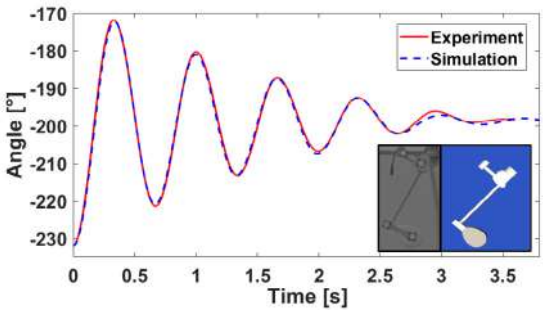

Figure 4: Hammer rotation time history: Sim. vs Exp.

Model advanced simulations

Exploration of the model response to an increasing frequency of key force inputs shows that the hammer is unable to hit the string from around 11 Hz. Therefore, 10 Hz can be considered as the maximal playability frequency of the model. Actuate experimentally the action with an external actuator provides a value between 11 and 12 Hz. The minimal force so that the hammer reaches the string and produce a sound is around 1.2 N, which correspond approximately to the experimentally measured values between 1.12 and 1.21 N. More importantly, the importance of the bridle strap and butt spring – see Fig. 2 – is illustrated in Fig. 6: they both help the hammer to travel back faster to its rest position so that key strokes can be repeated faster. This result is original since it refers to specific elements whose role is not clearly explained, even by piano tuners.

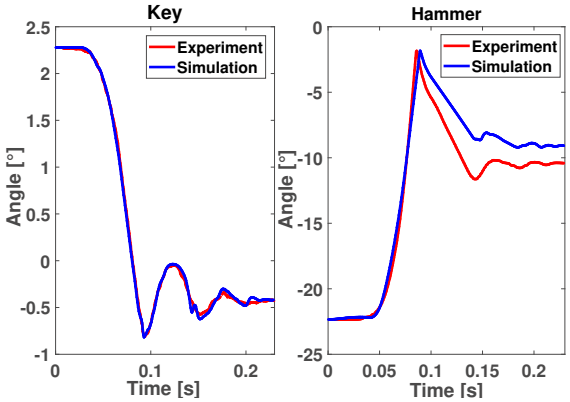

Figure 5: 1-kg input simulation.

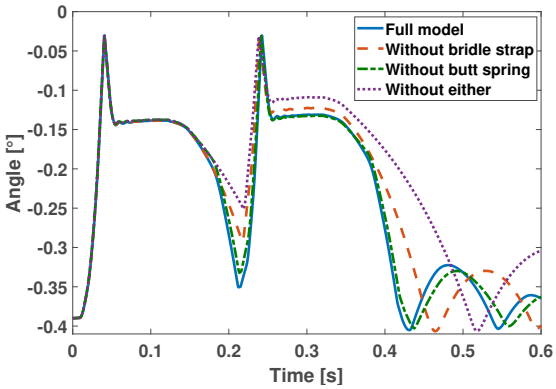

Figure 6: Hammer angular position for a double blow.

CONCLUSIONS

A multibody model of an upright piano has been carried out and has shown reasonable agreement with experimentations. Additional simulations have helped us to quantify and analyse the action performances, in particular for the bridle strap and butt spring whose role is important in fast dynamics. Improvement of the parameters identification would enhance the model fidelity for the next future, having in mind that it could be used in real-time to enhance the haptic feedback touch of numerical pianos, as we are currently developing for a grand piano action [6].

HYBRID THIN SHELL TRIANGLE ELEMENT FOR MULTI-FLEXIBLE-BODY DYNAMICS

Alessandro Tasora, Dario Mangoni, Simone Benatti, Dario Fusai
Department of Engineering and Architecture, University of Parma, Italy

Summary In this work we discuss an efficient finite element for thin shells to be used in multi-flexible-body simulations involving large displacements and material nonlinearities. The formulation is based on the BST element, from whom it inherits the idea of rotation-less nodes and the computation of curvature from the state of the neighbouring triangles; additionally, in sake of performance, we added the possibility of de-activating the tangent stiffness matrix for the bending components in case of extreme flexural compliance, thus leading to hybrid implicit-explicit integration schemes. The element has been implemented in our open-source ProjectChrono multi physics simulation library.

INTRODUCTION

Triangular shell finite elements have been studied extensively in literature because, if compared to their quadrilateral counterparts, they provide an immediate way to mesh complex CAD surfaces with arbitrary topology. In particular, among the various formulations, the DKT-CST shell element [1] proved to be efficient and reliable, although at the cost of introducing rotational degrees of freedom at each node. The BST element presented in [2] circumvents this complication by using only translational degrees at each node, hence leading to a very straightforward and robust implementation – although limited to Kirchhoff-Love thin shells. Further research showed that the BST element can handle complex kinked shells with large displacements, such as those studied in inflatable structures, crash tests, etc. [3]. Because of these attractive features we developed a triangle shell on the basis of the BST element and we added it to our ProjectChrono multibody library [4]. In this context the thin-shell assumption was not a major issue because the library already contains alternative finite elements for Mindlin–Reissner thick shells; on the other hand, the thin shell triangle proved to be very efficient for problems involving objects such as foldable tissues, sails, etc., where shear effects are negligible. In order to improve the computational efficiency with implicit integrators, we investigated the possibility of discarding the terms that, in the tangent stiffness matrix, account for the bending stiffness; this leads to hybrid implicit/explicit time stepping schemes where the bending forces are handled like in explicit integrators, and the membrane effects are dealt by the implicit part: since bending forces are way less stiff then membrane counterparts, this results in methods that are almost as stable as the original implicit methods, but with less overhead in solving the linear systems requested at each iteration. We performed benchmarks with both geometric and material non-linearity, showing the efficiency of the discussed implementation.

IMPLEMENTATION

The BST finite element uses six nodes, as shown in Fig.1, and each node has only three degrees of freedom, as node rotation is not needed. Curvature $\boldsymbol{\kappa}$ is computed from the tilting of the neighbouring triangles, subtracted initial bending if any, and strain $\boldsymbol{\varepsilon}$ is assumed constant through the triangle as in CST elements.

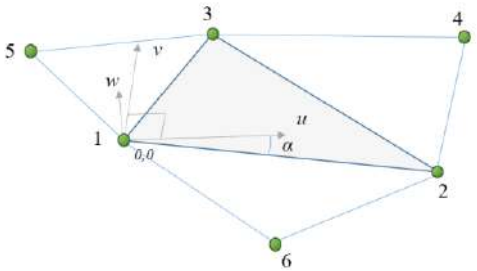

Figure 1. The six-node triangle shell element. Material coordinates can be rotated respect to the 2-1 direction via the α angle, for instance when using orthotropic layered materials. Nodes 4,5,6 are optional, if the triangle is on a boundary.

From the knowledge of $\boldsymbol{\kappa}$ and $\boldsymbol{\varepsilon}$, generalized stresses $\{\boldsymbol{m},\boldsymbol{n}\}$ are computed using through-the-thickness quadrature, thus supporting multi-layered materials via the Classical Laminate Theory. We exploited object oriented paradigms such as polymorphism and inheritance in order to provide an expandable material system; in this way one can reuse predefined constitutive equations for isotropic/orthotropic/generic elasticity at each layer, or one can provide its own custom material model using C++ programming, incurring in zero performance penalty.

After Gauss quadrature, internal forces and tangent stiffness matrices can be easily computed and inserted in the global system. Our multibody software supports systems made with arbitrary number of motors, constraints, parts, finite elements, even with frictional contact, as described in [5,6], resulting in a system of Differential Algebraic Equations (DAE) or a Differential Variational Inequality (DVI). The dynamical simulation is performed using an implicit integrator,

specifically an HHT method or, for faster and less precise tests, an implicit Euler with clamped iteration number. The latter also provide support for DVI non-smooth dynamics.

As in most implicit integrators, most CPU time is spent in solving a large system matrix that has the sparsity pattern of a KKT saddle-point matrix when constraints, contacts or motors are added. Aiming at higher performance, we provide the option of neglecting the bending components of the tangent stiffness matrices, resulting in a system matrix with higher sparsity and faster solution. This is possible only if the bending forces are not stiff compared to membrane forces, and this happens for example when simulating tissues and clothes.

NUMERICAL TESTS

For benchmarks where the shear effect is not relevant, the BST finite element provided comparable results with the two other shell elements implemented in our library (namely an ANCF shell quadrilateral element and a geometrically-exact quadrilateral element), but at a fraction of the computational overhead. It is fair to add that the quadrilateral elements are both capable of capturing Mindlin-Reissner thick shell effects, whereas the BST shell uses the Kirchhoff-Love hypothesis. Nevertheless, the thin shell assumption fits well with many engineering problems involving, for example, tissues or comparable materials, such as in the case of the simulation of sails, airbags, paper processing equipment, etc.

In Fig.2 we show a benchmark where a 1m x 1m sheet is dropped on a square support. Under the effect of the gravity, the sheet deforms and creates wrinkles. In Fig.1, left, Young modulus is $E=6\cdot10^4$, Poisson ratio is $\mu=0$, and thickness is 0.06m. In Fig.1, right, the thickness is 0.01m. In the latter case, given the fact that bending forces are not stiff from the integration point of view, we experienced that removing the bending components of the stiffness matrices decreased the computational effort for solving the linear system almost by a factor of two.

For solving the linear system in the HHT iterations we tested both the direct-parallel MKL Pardiso solver, and a GMRES Krylov solver with warm-starting and AVX vectorization.

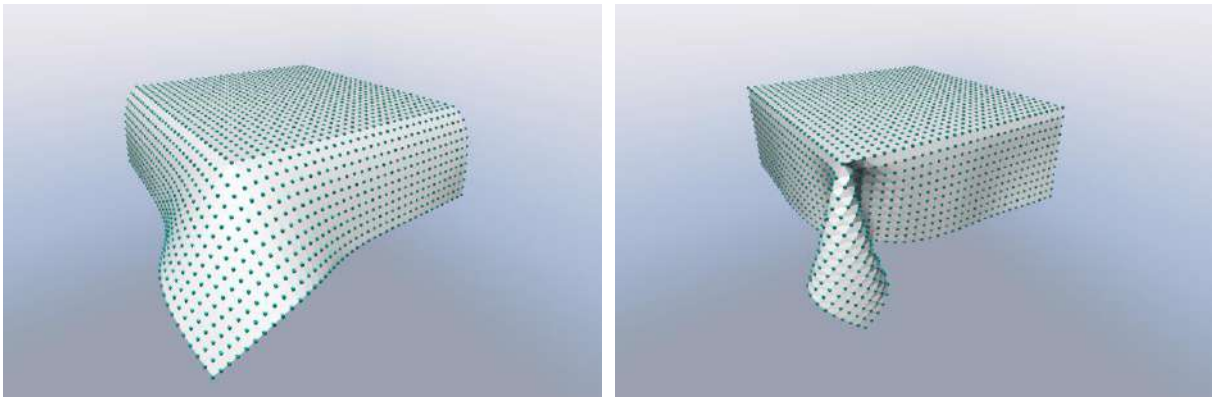

Figure 2. Left: a case where the bending component of tangent stiffness matrix is relevant, hence a conventional implicit integration is used. Right: for small bending stiffness, the tangent stiffness matrix can be simplified, for a hybrid implicit (membrane) / explicit (plate) integration scheme.

CONCLUSIONS

A rotation-free, triangular finite element for thin shells has been implemented within the ProjectChrono open source multibody library. Custom optimizations have been studied in order to increase the computational efficiency, in detail this element supports hybrid implicit/explicit integration in sake of coarser stiffness matrices. Object-oriented programming has been used in order to provide a modular and expandable material model; the predefined materials classes provide support for isotropic/orthotropic/generic elasticity, plasticity, structural damping, all reusable in a laminated multi-layer setting; further material models can be implemented by class inheritance and polymorphism.

BIOMECHANICS AND MECHATRONICS FOR THE DESIGN OF INTEGRAL VEHICLE SAFETY SYSTEMS

Jörg Fehr*[1], Fabian Kempter[1], Jan Riethmüller[1], and Werner Schiehlen[1]
[1]Institute of Engineering and Computational Mechanics, University of Stuttgart, Germany

Summary The risks of injury or fatality in traffic accidents have declined significantly in recent years. Increasing emphasis for achieving further improvements in vehicle safety will be placed on integral safety systems. Integral safety involves a concerted strategy of interlinking sensors and actuators of active and passive safety. After a review on vehicle safety systems the Driver-in-the-Loop (DiL) Simulator at the University of Stuttgart, Germany, will be presented. This DiL is used to validate active human body models. In a test series with 17 test persons and three different warning signs, each of the occupants' behavior is further analysed, i.e. looking at the muscle stiffness to show the possibilities of further reduction of severe casualties.

INTRODUCTION

Today's cars feature different active and passive safety components to protect the occupants and other road users. If one combines advanced driver assistance systems (ADAS) with passive safety, we speak about integral safety concepts. In integral safety concepts, the countermeasures for accident damage minimization can react before the actual crash, i.e. through occupant alarming, repositioning to more beneficial postures, airbag firing and belts tightening. In contrast to classical crash scenarios, the investigation of such integral safety concepts requires new simulation methods. Prior to the crash the accelerations are much lower, enabling the occupants to change their posture by muscle contraction. At those smaller loads, dummies (ATD) and passive human body models (HBM) no longer adequately represent human occupants, as muscle activity must be included in the surrogate models. Furthermore, only with virtual tests, the full range of possible impact scenarios can be tested without any risk for human lives.

Therefore, the active human body models (AHBM) are now essential engineering tools to provide further biomechanical knowledge about the effects of human behavior on injury risks and others in wide range of possible scenarios. Two types of muscle activated human body models are available: (i) costly nonlinear finite element models for injury mechanics research down to the tissue level, see e.g. [1], and (ii) multibody models well suited for rather long simulations of pre-crash maneuvers to predict the overall motions of the human in such situations. For the development of AHBM, validation and calibration processes of the simulation models with advanced mechatronic testing devices are uttermost important [2]. Different types of validation setups differing in complexity, data acquisition, transferability to real driving scenarios, adjustability, reproducibility and safety issues are reported in the literature. In this work, a DiL approach is used to study the influence of warning signals on the driver's action to prepare himself for the virtual impact by muscle stiffening, see [3]. Therefore, a user study based on the ethical requirements was conducted with our DiL Simulator.

DiL SIMULATOR

Advantages of Driver-in-the-Loop simulators are: (i) the safe and replicable environment, (ii) kinematic feedback in all six degrees of freedom reducing the risk of motion sickness, (iii) in addition to classical sled tests, multi-directional trajectories can be performed, (iv) the visual feedback of a virtual driving environment, e.g. by using head-mounted displays, (v) the excellent accessibility for measurements and, (vi) the fast application and testing of early alert systems. The DiL simulator is depicted in Figure 1 and explained in [4]. The system consists of a 6-DOF motion platform, a force-feedback wheel and a bass-shaker at the back of the driving seat. The work-flow is based on a Matlab-Simulink-model, provided by Prescan, with multibody vehicle models, visualization of the designed scenario and logical operations to ensure reproducible crash scenarios.

To analyze the driver's behavior in the simulator during Pre-Crash situations, motions as well as muscle activation can be monitored. The subjects are tracked by a motion capture system from Optitrack using computer stereo vision with reflexive infrared markers. Furthermore, a force sensor mounted at the steering wheel allows measuring the support of the driver applied on the steering wheel [5]. This force can be considered as an indication of the amount and timing of pre-stressing in an emergency braking situation.

Two separate PCs are used to coordinate the real-time simulation, control of the motion platform and the acquisition of measured data. The workflow of the mechatronic system is depicted in Figure 2. The simulation PC is in charge of running the simulation and providing visual feedback to the driver at the same time. A 10 degree of freedom vehicle dynamics model [6] is used to simulate in real-time the behavior of the vehicle. The measurement PC controls the motion of the platform with the software package SimCorDX. For a more realistic driving experience motion cueing algorithms-[7] are applied. This PC also ensures the synchronized data acquisition of the kinematic measurement via the Optitrack system, the signals from the force sensor recorded with a digital oscilloscope and signals of the virtual simulation, i.e. steering motion. Synchronization of the measurement is done using TCP/IP communication and a small Arduino system.

The motion of the head and the arms are tracked with 200 Hz, furthermore the driving wheel angle and braking pedal state is saved. It is important, that all measurement systems, e.g. motions, EMG signals and support force on the driving wheel, are synchronized, automatically labeled and semiautonomous evaluated. A kinematic resimulation of the experimental results can be used to compare different motions of test persons without violating the General Data Protection Regulation.

TEST SERIES WITH 17 PERSONS AND 2 WARNING SIGNALS

To get a better understanding of the human behavior in those pre-crash situations and understand the prestressing, a preliminary test series with 17 persons (age 49.5+- 31.5) with a driving experience of 32+-31 years was conducted. The participants were driving in the simulator for some time to get comfortable with the system and were asked to drive with a constant velocity of 50 km/h. After a specific time, the crash scenario was initiated once per subject. The vehicle “ego” controlled by the subject hits the opponent car “bullet” approaching from the left. The participants performed a manual emergency braking when realizing the need for an intervention. To invest the effects of different warning signals, two randomly selected groups of the participants received a warning signal 20 m, respectively 0.5 s before the crash. They received either an acoustic signal of the sound system of the DiL or haptic feedback in the form of vibrations performed by the force-feedback steering wheel. The third control group didn`t receive any warning signal. The results of this study are shown in [5] and summarized in the following.

Without a warning signal, data shows more variance. While some people hit the braking pedal quite early, some made substantial effort much later. Both warning signals decreased the (mean) reaction times of the drivers. Furthermore, the group of participants with haptic feedback applied larger braking forces and a more significant support force on the driving wheel than the other two groups. This indicates that the warning with haptic feedback is an excellent possibility to prepare occupants for a potential impact and is better suited than the audio warning system. The study showed that measurements of the support force on the driving wheel during braking events could serve as an indicator of the level of alertness of the driver.

CONCLUSIONS

On the way towards autonomous transport, virtual testing of automated driving functionalities is inevitable to proof the safety of these systems. To strive for a higher level of road safety and thus to work towards the goal of Vision Zero, more effort is needed and a greater variety of critical scenarios must be considered, see e.g. [8]. Such a large variety of critical situations can only be tested virtually; therefore, the development of reliable biofidelic simulation models is important. Active HBM, validated for Pre-Crash simulations, can serve as a tool for enhancing integral safety systems and clear the way for automated traffic with improved real-world safety. The validation of active human body models is difficult as volunteers are needed. The proposed Driver-in-the-Loop simulator allows investigations of driver behavior in Pre-Crash scenarios, with and without the interaction of driver assistance systems. In further studies, muscle activity is recorded to get a better understanding of which muscle control strategy in the models is better suited to represent human behavior in pre-crash scenarios. Due to the small number of participants and the number of possible influences, i.e. actual velocity, on the investigated signals, the results should be considered as trends, needed to be examined in more extensive studies on high-end driver simulators.

COLLISION DETECTION FOR RIGID SUPERELLIPSOIDS USING THE NORMAL PARAMETERIZATION

Ulrich J. Römer*[1]
[1]Institute of Engineering Mechanics, Karlsruhe Institute of Technology, Karlsruhe, Germany

Summary The normal parameterization as an approach to describe geometries is introduced. The advantages of this description – as compared to other parameterizations or implicit functions – in the context of collision detection are: the possibility to explicitly calculate axis aligned bounding boxes for any convex geometry, an efficient iterative algorithm for collision detection between objects with arbitrary geometry that does not require any (analytical) derivatives. A system of several rigid superellipsoids is used to demonstrate the application and performance of the proposed approach in a multibody simulation.

MOTIVATION

Collision detection is an essential task in multibody models with unilateral contacts. While the geometry of complicated objects can be approximated using mesh-based approaches, good approximations require a high number of vertices, which in turn increases the computational effort and computation times. These approaches are widely used because they are very flexible and efficient collision detection algorithms are available for mesh-based geometry descriptions [1].

Alternative approaches use smooth representations based on implicit functions or some parameterization. This typically requires far fewer parameters than high-accuracy mesh approximations, however, it is more difficult to describe or approximate arbitrary geometries. A possible remedy to mitigate this drawback is to use unions of several objects. In this context, ellipsoids, superellisoids and superovoids are popular geometries for the approximation of objects such as particles in granular media [2], rigid foot models [3], robot fingers or human teeth [4], to name but a few examples.

Collision detection for objects with smooth geometry representations can be performed based on the common normal concept: the outer normal vector at the (potential) contact points on the boundaries of two objects are (anti)parallel. There are few explicit solutions for this problem, e. g. detecting collisions between two spheres. In general, efficient algorithms based on Newton iterations are proposed in the literature [4, 5]. For these collision detection problems, significant improvements in computation times compared to mesh-based approaches with high-accuracy are reported [4].

The necessity for iterative methods arises from the geometry representation by the commonly used parameterizations or by implicit functions. Any representation based on implicit functions requires an iterative solution to even determine points on a boundary surface; the calculation of two points on opposing boundaries with parallel normal vectors must therefore also be solved iteratively. Parameterizations, on the other hand, are based on a formula for the explicit calculation of all points on the boundary surface of an object, which also allows an explicit calculation of the corresponding normals. However, the inverse relationship, the calculation of a point on the boundary for a given normal direction, generally yields an implicit relationship which again must be solved iteratively.

With the aims to improve current approaches for collision detection problem between smooth objects and to contribute to the derivation of explicit solutions, we propose a new parameterization for convex objects which we call the *normal parameterization* which is based on [6]. A useful property is the possibility to calculate axis aligned bounding boxes explicitly for any geometry described in this way. To illustrate further properties and the possible use in collision detection applications, we demonstrate its use by means of a simulation with several rigid superellipsoids. Two collision detection algorithms, one based on a Newton iteration with analytic Jacobian and one based on a fixed-point iteration without the need of any derivatives, are presented. A transient time simulation with several rigid superellipsoids and multiple collisions is used to compare these algorithms to approaches from literature.

METHOD

Given a normal direction $\mathbf{n}$ in spherical coordinates $(\varphi,\theta) \in \mathbb{S}^2$, the normal parameterization gives the position $\mathbf{r}(\varphi,\theta) : \mathbb{S}^2 \to \mathbb{R}^3$ of the corresponding point P on the object's boundary relative to a body-fixed point B. In general, the normal parameterization of a strictly convex object follows from the *generating potential* $g(\varphi,\theta) : \mathbb{S}^2 \to \mathbb{R}$ as

$$\mathbf{r}(\varphi,\theta) = \begin{cases} \frac{\partial g(\varphi,\theta)}{\partial \varphi}\mathbf{e}_\varphi + (\sin\varphi)^{-1}\frac{\partial g(\varphi,\theta)}{\partial \theta}\mathbf{e}_\theta + g(\varphi,\theta)\mathbf{e}_\mathrm{n}\,, & \text{if } \varphi \in (0,\pi)\,, \\ \frac{\partial g(\varphi,\theta)}{\partial \varphi}\mathbf{e}_\varphi + (\cos\varphi)^{-1}\frac{\partial^2 g(\varphi,\theta)}{\partial \varphi \partial \theta}\mathbf{e}_\theta + g(\varphi,\theta)\mathbf{e}_\mathrm{n}\,, & \text{if } \varphi \in \{0,\pi\}\,, \end{cases}$$

where the normal direction $\mathbf{e}_\mathrm{n} = \mathbf{n}$ and the tangent directions $\mathbf{e}_\varphi, \mathbf{e}_\theta$ are rotated with respect to a body-fixed reference frame $\{\mathbf{b}_\mathrm{x}, \mathbf{b}_\mathrm{y}, \mathbf{b}_\mathrm{z}\}$ by

$$\begin{aligned} \mathbf{e}_\varphi &= \cos\varphi\cos\theta\,\mathbf{b}_\mathrm{x} + \cos\varphi\sin\theta\,\mathbf{b}_\mathrm{y} - \sin\varphi\,\mathbf{b}_\mathrm{z}\,, \\ \mathbf{e}_\theta &= \quad -\sin\theta\,\mathbf{b}_\mathrm{x} + \quad \cos\theta\,\mathbf{b}_\mathrm{y}\,, \\ \mathbf{e}_\mathrm{n} &= \sin\varphi\cos\theta\,\mathbf{b}_\mathrm{x} + \sin\varphi\sin\theta\,\mathbf{b}_\mathrm{y} + \cos\varphi\,\mathbf{b}_\mathrm{z}\,, \end{aligned}$$

*Corresponding author. E-mail: ulrich.roemer@kit.edu.

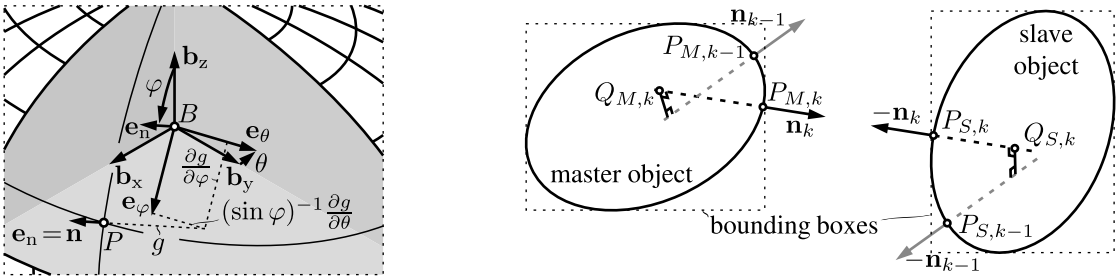

Figure 1: (a) Reference frames for the definition of the normal parameterization; (b) collision detection between two objects.

cf. figure 1a. Superellipsoids follow from the generating potential

$$g(\varphi,\theta) = \left(\left(\left(a^2 \sin^2\varphi \cos^2\theta\right)^{\frac{\delta}{2(\delta-1)}} + \left(b^2 \sin^2\varphi \sin^2\theta\right)^{\frac{\delta}{2(\delta-1)}} \right)^{\frac{\epsilon(\delta-1)}{\delta(\epsilon-1)}} \left(c^2\cos^2\varphi\right)^{\frac{\epsilon}{2(\epsilon-1)}} \right)^{\frac{\epsilon-1}{\epsilon}}$$

with $a, b, c, \delta, \epsilon \in \mathbb{R}$, $a, b, c > 0$ and $\delta, \epsilon > 1$. With this, the parameterization fulfills the implicit equation

$$\left(\left((x/a)^2\right)^{\delta/2} + \left((y/b)^2\right)^{\delta/2} \right)^{\epsilon/\delta} + \left((z/c)^2\right)^{\epsilon/2} = 1\,.$$

Collision detection is performed in two steps: first, axis aligned bounding boxes are used to quickly check whether two objects may overlap; if this test does not rule out a possible collision, one of two iterative procedures is employed for accurate collision detection. The calculation of an axis aligned bounding box for any object with arbitrary orientation with respect to an inertial frame $\{\mathbf{i}_x, \mathbf{i}_y, \mathbf{i}_z\}$ is simple. To determine the distance of the bounding box from the body-fixed point B in any direction $\{\pm\mathbf{i}_x, \pm\mathbf{i}_y, \pm\mathbf{i}_z\}$, calculate (φ, θ) from $\mathbf{e}_n$ for the respective direction and evaluate $g(\varphi, \theta)$. If the bounding boxes of two objects do not overlap, there can be no collision.

If there is an overlap of the bounding boxes, two iterative algorithms for accurate collision detection based on the common normal concept between two objects with arbitrary position and orientation are considered. For both algorithms, chose one object as master object with index M and the other as slave with index S. Let $\mathbf{n}_k = x_k\mathbf{i}_x + y_k\mathbf{i}_y + z_k\mathbf{i}_z$ with $x_k^2 + y_k^2 + z_k^2 = 1$ be the normal direction for the master object in the k-th iteration step. Determine the corresponding coordinates $(\varphi_{M,k}, \theta_{M,k})$ from $\mathbf{e}_{n,M,k} = \mathbf{n}_k$ and the coordinates $(\varphi_{S,k}, \theta_{S,k})$ from $\mathbf{e}_{n,S,k} = -\mathbf{n}_k$ due to the common normal concept. Evaluate the normal parameterization to determine the points $P_{M,k}$ and $P_{S,k}$ on the objects' boundaries, cf. figure 1b.

Algorithm I is based on a Newton iteration with analytic Jacobian and is adapted from [5]. Let $\mathbf{d}_{MS,k}$ be the vector from $P_{M,k}$ to $P_{S,k}$ and calculate a Newton step to zero the two tangential components $\mathbf{d}_{MS,k} \cdot \mathbf{e}_{\varphi,M,k}$ and $\mathbf{d}_{MS,k} \cdot \mathbf{e}_{\theta,M,k}$ and determine $\mathbf{n}_{k+1}$. Algorithm II is based on a fixed-point iteration for $\mathbf{n}$, which is designed such that no derivatives are required. Determine $Q_{M,k}$ as the point on the line given by $P_{M,k}$ and $\mathbf{e}_{n,M,k}$ which is closest to the same line from the previous iteration $k-1$ (cf. figure 1b). $Q_{M,k}$ is an approximation the center of curvature; $Q_{S,k}$ is determined analogously. The next iterate $\mathbf{n}_{k+1}$ is then taken as the unit vector pointing from $Q_{M,k}$ into the direction of $Q_{S,k}$.

RESULTS AND CONCLUSIONS

The collision detection approach is applied to a multibody system with several rigid superellipsoids. The investigated example systems show that the proposed approach works for rigid body simulations. Algorithm II which is based on a fixed-point iteration shows better robustness but slower convergence than algorithm I. The ability to explicitly calculate axis aligned bounding boxes is an advantage of the proposed normal parameterization, as is the possibility for an accurate and robust collision detection procedure which does not require any derivatives.

FLIPPING THE WALKING ROBOT TO THE WORKING POSITION

Yury Golubev[1,2], Victor Koryanov[2] and Elena Melkumova[*1]
[1]Moscow State University, Moscow, Russia
[2]Keldysh Institute of Applied Mathematics, RAS, Moscow, Russia

Summary It is shown that the autonomous rescue of a six-legged machine from an emergency position "upside down" is possible with the help of cyclic movement of the legs, if the body has an upper shell in the form of a truncated cylinder. A method is proposed of rocking the body, which provides a flipping of the body and the return of the robot to the operating position. An analytical study and computer simulation of the full dynamics of the robot were fulfilled which confirmed the effectiveness of the developed technique for restore the functional capability of the robot. The results of numerical experiments and corresponding video materials are presented. The work was supported by the Russian Foundation for Basic Research (grant No. 19-01-00123 A).

INTRODUCTION

Except for hardware failures, the worst of emergencies is the case when the robot turns out to be in the upside down position when its body lies on the supporting plane with its legs upwards. If the robot is equipped with sensors that help it get its bearings in space and determine the direction of gravitational force, the upside down position of the body can cause the robot to lose orientation in space. To find a way out in such an emergency situation, the robot should have means to recover the normal position of its body. To facilitate the execution of this task, resonance effects that occur at a certain shape of the body due to special motion of the legs can be used.

ROCKING THE BODY WHEN LYING ON THE BACK

To facilitate the overturn, the robot's body in the working position can have the shape of convex (upward) part of a cylinder cut by a plane parallel to the cylinder's axis. Consider the model problem. Assume that a homogeneous segment of a circle of mass M lies on the horizontal supporting straight line. The segment is bounded by an arc of the circle of radius R and a chord that is at the distance h from the circle center. The circle arc touches the supporting line at the point A. The segment can roll without slippage on the supporting line rotating about the circle center at the angle φ measured from the vertical radius connecting the circle center with the point A at which the segment touches the supporting line. If $\varphi = 0$, then the segment lies such that its chord is parallel to the supporting line (Fig. 1).

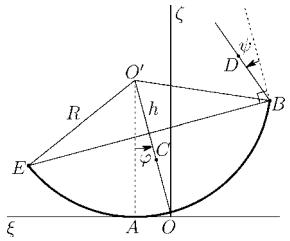

Figure 1. Upside down position of the robot.

To investigate the dynamic effects under the planar motion of the body and the legs that increase the oscillation amplitude as the body rocks itself in emergency situation, we assume that the parameters of the system are such that the upside down position of the robot is stable for all values of the angle ψ. Then, we can try to make the robot to turn over to normal position by cyclically varying ψ, thus making the robot's body to oscillate with increasing amplitude. To analytically describe the process of rocking, we use the theorem on changes of the system angular momentum about a moving point A [1, 2].

The robot design basically coincides with the one described in [3, 4]. The rigid body of the robot is composed of two truncated right cylinders put together by their common plane rectangular cut. Six identical two-link legs are symmetrically attached at the sides of the rectangular intersection of the cylinders. The leg attachment points on each side are equally spaced. In distinction from [3, 4], each part of the body and feet may touch the supporting surface and surrounding objects. The legs may not mutually cross during motion.

Suppose that as a result of an accident the robot turned over and lies on its back on the supporting horizontal plane with its legs up. It must choose the side of its body over which it will turn to the normal position with its back upwards (Fig. 3a). The rescue operations are performed in three phases.

Phase 1. The legs the attachment points of which are at the side chosen for turning over will be inactive. They must be straightened and arranged in such a way that they do not impede the turn over operation. The example of such arrangement is presented in figures with fragments of simulation of motion below.

*Corresponding author. E-mail: elena_v_m@mail.ru.

Phase 2. The legs on the other side of the body should be straightened, and they will be active. They start rocking the body due to direct control of their joint angles. All three legs move synchronously in the plane perpendicular to the longitudinal axis of the body at a fixed knee angle. For them, only the angles ψ between the leg and the body vary. To achieve unbounded body rocking, the function $\psi(t)$ cannot be periodic because the period of body oscillations depends on the amplitude. Fig. 2 contains the plot of the fragment of $\psi(t)$ corresponding to the typical oscillation.

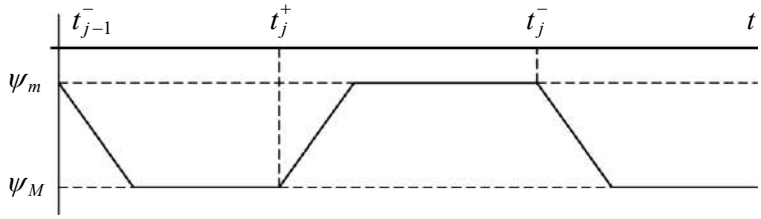

Figure 2. Control by angle ψ .

Here ψ_M, ψ_m are the values of ψ at which the active legs are closest to the attachment points of the passive legs (ψ_M), and at the greatest feasible deviation from these points (ψ_m) during the desired motion of the active legs. The sequence $\{t_j^+, t_j^-,\ j = 1, 2, \ldots\}$ marks time instants at which the height of the attachment points of the active (index +) and passive (index –) legs above the supporting plane is minimal. The time interval of transition from one constant value of ψ to the other is fixed. Fig. 3b, 3c shows the positions corresponding to time instants t_j^+, t_j^- of one of the oscillations.

Phase 3. After the turnover, the robot rests its active legs upon the supporting plane (Fig. 3d), and it must get on its feet. This can be done by sequentially transferring triples of legs with the leveling of the body [1, 2].

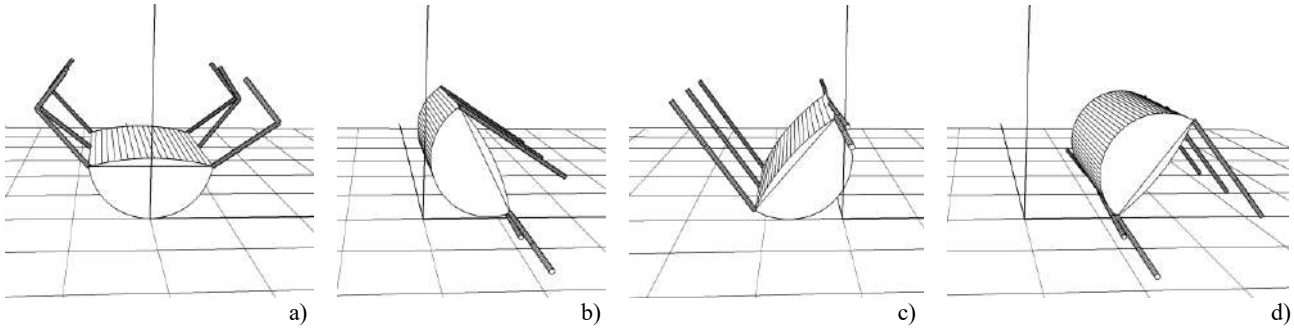

Figure 3. Initial position (a), typical swing in the direction of passive legs (b), its reverse swing (c), completion of rocking (d)

The computer simulation was performed by using the *Universal Mechanism* software package [5].

CONCLUSIONS

The new problem of rescuing an autonomous insectomorphic robot residing in the abnormal upside down position on the supporting plane is solved. To make the rescuing operation possible, a special shape of the robot's body consisting of two truncated right circular cylinders put together by their common plane rectangular cut is proposed. An algorithm for rocking the robot in the neighborhood of its emergency equilibrium position is developed. This algorithm uses the robot's kinematic and dynamic capabilities to bring the robot to normal position without outside assistance. The validity of the algorithm is proved analytically [1, 2]. A stable resonance motion of the system that turns the robot over to normal working position is designed.

TAPE SPRING MODELLING AND DYNAMICS

J. P. Meijaard *[1]
[1]Olton Engineering Consultancy, Enschede, The Netherlands

Summary A beam model for the large deflections of a tape spring, which may be accompanied by significant distortion of its cross-section, is proposed. Besides the variables that describe a classical thin-walled beam, additional variables are introduced that describe the variable shape of the cross-section. A finite element based on this model is developed, which uses assumed strain fields and discrete deformation quantities. The element is applied to some static and dynamic test problems.

PROBLEM STATEMENT

In classical beam theory, it is assumed that changes in the shape of the cross-section are negligible. In the absolute nodal coordinate formulation, some deformations of the cross-section can be taken into account, but the distortion remains small. This assumption may no longer hold for some beams with a thin-walled cross-section. In particular, tape springs, which have a cross-section in the shape of a shallow arch, can develop folds in which the cross-section becomes almost flat. Also end-effects such as the constrained anticlastic curvature at clamped ends can influence the overall stiffness, especially for beams that are short in comparison with their cross-sectional dimensions.

Tape springs have been modelled by simple analytical expressions, where several effects are neglected [1, 2] and dynamics is not included, or by detailed finite element models with shell or solid elements [3]. Here, a beam model with some additional degrees of freedom to model the deformation of the cross-section is proposed. A similar approach has been pursued in [4]. The main contribution here is that the cross-sectional quantities are formulated in terms of known quantities, such as the position of the shear centre and the warping constant, with a few additional quantities specific to the condition of a varying cross-section over the length of the beam. Furthermore, a finite element based on this theory is developed.

BEAM MODEL

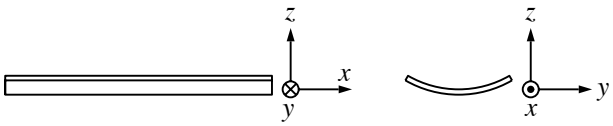

Figure 1: Beam with a shallow cross-section.

A prismatic beam with a thin-walled curved cross-section as shown in Fig. 1 is considered. The configuration and strains of the beam are related to the line of centroids. The axial strain and the shear strain in the xy-plane are included, but the shear strain in the xz-plane is neglected. The three curvatures, the torsion and the two bending curvatures, are defined in the usual way. The warping is connected to the torsion deformation, which can be constrained at clamped ends or give a contribution if variable torsion is present or the shape of the cross-section changes over the length of the beam. In addition to these classical aspects, the initial shape and the change of the shape of the cross-section is determined by two additional variables, which define a symmetric quartic curve. These changes of the shape make that the cross-sectional quantities such as the moments of inertia, the position of the shear centre and the warping function change over the length of the beam and in time. The difference between the centre of shear and the centroid of the cross-section gives rise to a contribution of the torsion to the shear measured at the line of centroids.

The shear stress in the cross-section is determined by the torsion and the shear force in the usual way. The axial stress distribution is more complicated and contains contributions due to the axial strain at the line of centroids, the bending in the two directions, the change in the torsion, large values of the torsion, the change in the warping function over the length of the beam and the change of the shape of the cross-section itself.

The mass distribution is modelled in a standard way with the distributed mass per unit of length and the moments of inertia of the cross-section. In addition, the change in the shape of the cross-section gives rise to mass coupled to the variables describing these changes. No additional mass has to be attached to the warping deformation of the cross-section.

*Corresponding author. E-mail: j.p.meijaard@olton.nl.

SOLUTION TECHNIQUES

Based on the above assumptions, a two-node beam element is developed based on assumed strains fields, the so-called generalized strains. The nodal coordinates are three displacements and rotations and also the value of the warping and the values of the two variables that describe the shape of the cross-section. The strain fields are linear for the bending, cubic for the torsion, and the shear is directly related to the bending and torsion strains. In addition, there are linearly varying variables for the shape of the cross-section. These assumptions on the strains give the elastic energy of the element, which determines its stiffness properties.

The mass properties are obtained from an interpolation of the position of the line of centroids with a distributed line mass. The mass moments of inertia are lumped to the nodes. The mass contribution from the variables for the shape of the cross-section is directly connected to these variables and coupling with the moments of inertia is neglected.

The element can be used in a multibody dynamics simulation context. Static problems, where a load path is followed by an arc continuation method, as well as dynamic simulations can be made, where explicit time integration methods are used.

SOME APPLICATIONS

A set of test problems for an initially flat strip is analysed. Large deflections caused by final bending moments are considered. Due to the suppression of the anticlastic curvature at large curvatures, the effective stiffness increases. The results compare well with the analytical solutions given by Ashwell [5]. Also the influence of the constrained anticlastic curvature at clamped ends can be fairly accurately described for the driving stiffness of a parallel leaf spring guidance [6]. In many cases, the static behaviour of a leaf spring can be modelled by a single element, with errors in the stiffness values below ten percent [7].

The bending of a tape spring in the xz-plane depends strongly on the direction of the bending moment. Loading a cantilevered beam in the positive z-direction, which gives rise to a mid-plane surface with a positive curvature, with increasing loads first leads to bending-torsional buckling with a stable post-buckling load path, which eventually becomes unstable in a snap-through instability. This contrasts with the behaviour of a tape spring loaded by end moments as reported in the literature [2]. Loading in the opposite direction gives rise to a snap-through instability.

The dynamic behaviour and the transfer of energy to modes with a higher frequency can be demonstrated by performing a simulation starting from an undeformed initial state.

Also the spatial behaviour if the cantilevered tape spring is loaded in the xy-plane can be described. There is no clear case of lateral buckling, because the shear centre and the centre of mass of the cross-section are not the same.

CONCLUSIONS

The proposed beam model for a tape spring can be used to make static and dynamic calculations in a multibody dynamics environment with fairly good accuracy of the results, which can be compared with experiments.

The approach is given in a general form, so more accurate models can easily be obtained by including more terms for the deformation of the cross-section and more elaborate interpolations of the strains in the finite element formulation.

CONSTRAINTS THAT CONNECT FINITE ELEMENTS AND MULTIBODY MODELS - A CASE OF A DOUBLE PENDULUM THAT SLIDES ON AN ELASTIC BEAM

Krzysztof Lipinski[1]
[1]Mechanical Department, Gdansk University of Technology, Gdańsk, Poland

Summary The paper focuses on constraints between a multibody system and a finite elements model. It combines a set of some structurally different relations. The multibody part is composed of non-deformable bodies and joints. Joints' relative displacements are taken as the generalised coordinates (considered as significant). Non-constant mass matrix (displacements dependent), as well as the centrifugal/Coriolis/gyroscopic effects, are considered. Finite elements are used for the beam. Displacements of their nodes are taken as the generalised coordinates (considered as small). For other points, shape functions and the nodal displacements are used. Resulting dynamics equations are linear to the kinematic parameters of the nodes'. Proposed constraint equations are holonomo/scleronomic. In dynamics, Lagrange multipliers are used and the generalised coordinates are partitioned on dependent and independent ones. Classical method [1] is modified to fit to the actual case. Finally, an exemplary system is introduced, and results of its numerical simulations are presented.

INTRODUCTION

The paper focuses on a point-contact constraint that is present between a multibody system and an elastic deformable structure. The non-homogenous form of the considered model implies a set of consequences critical in formulation of the contact equations, mainly as a set of multibody relations has to be joined with kinematics of the finite elements. In the paper, in case of the multibody part, classical multibody modelling [2, 3] is considered. The model is composed of non-deformable bodies and mobile joints. Joints' displacements are assumed as the generalised coordinates of this sub-model. Their magnitudes are significant. The body associated orientation matrices, $\boldsymbol{T}^i$, are calculated as dependent on joints' rotation, and vectors of the mass centres, $\vec{x}^i$, are calculated form lengths of the elements of the chin. When differentiated twice, they result in velocity and acceleration formulas. For dynamics, free body diagrams are constructed for all the bodies (the joints are cut and replaced by joint interactions). Next, the Newton/Euler equations of dynamics are used, combined with the kinematics formulas, and projected onto the joint mobility directions. Resulting formulas are written in the standard matrix form [2, 3, 5]:

$$\boldsymbol{M_b}(\boldsymbol{q_b})\cdot\ddot{\boldsymbol{q}}_b + \boldsymbol{F_b}(\dot{\boldsymbol{q}}_b,\boldsymbol{q_b}) = \boldsymbol{Q}(\dot{\boldsymbol{q}}_b,\boldsymbol{q_b},\boldsymbol{f_e},\boldsymbol{t_e},t)\ , \tag{1}$$

where: $\boldsymbol{M_b}$– mass matrix; $\boldsymbol{q_b}$ – vector of the sub-system's coordinates, $\boldsymbol{F_b}$ – vector of inertial effects; $\boldsymbol{Q_b}$ – vector of the sub-system generalized forces; $\boldsymbol{f_e}$, $\boldsymbol{t_e}$ – external forces and torques, t - time.

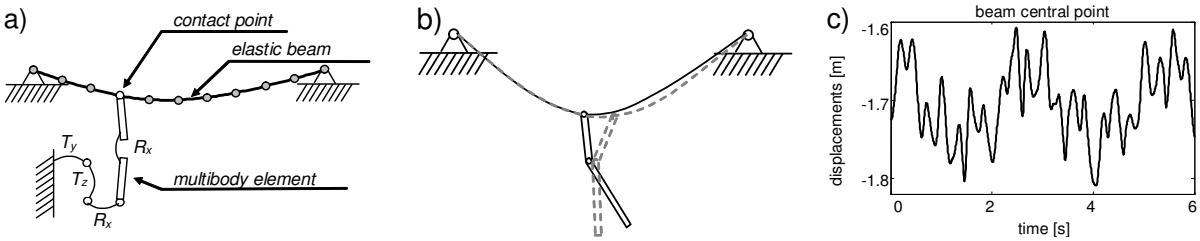

Figure 1: Draft of the system (a); selected slides of simulation (b); motion of the central node (c)

The matrix $\boldsymbol{M_b}$ depends on coordinates (i.e., it is a not constant one) and the vector $\boldsymbol{F_b}$ (understand as a column matrix) collects all the nonlinear inertial effects as: centrifugal accelerations, Coriolis accelerations, gyroscopic torques.

The finite elements part is composed of short segments, and it represents a stationary located elastic structure (its drift motion is absent). To express its pose, at a set of points is selected (called nodes) and displacements of these points are used (considered as the sub-system's coordinates and collected in $\boldsymbol{q_c}$ column matrix). Recalled displacements are assumed as small. When other point is considered, its displacements are described by so-called shape functions [4]:

$$\boldsymbol{q} = \boldsymbol{N_e}\cdot\boldsymbol{q_e}\ , \qquad \widehat{\boldsymbol{N}}_{be}(\zeta) = \begin{bmatrix} 2\zeta^3-3\zeta^2+1 & l_e(\zeta^3-2\zeta^2+\zeta) & -2\zeta^3+3\zeta^2 & l_e(\zeta^3-\zeta^2) \\ \dfrac{6(\zeta^2-\zeta)}{l_e} & 3\zeta^2-4\zeta+1 & \dfrac{6(-\zeta^2+\zeta)}{l_e} & 3\zeta^2-2\zeta \end{bmatrix}, \tag{2}$$

where: $\zeta = \hat{x}_1/l_e$ - relative position of the considered point in respect to its reference node.

To obtain equations of the model's dynamics, a method proposed in [4,5] is employed. Resulting equations are linear in respect to displacements, velocities and accelerations of the nodes, i.e. the mass, dissipation and stiffness matrices are considered as constant for this model. It can be expressed as [4]:

$$\boldsymbol{A_c}\cdot\ddot{\boldsymbol{q}}_c + \boldsymbol{B_c}\cdot\dot{\boldsymbol{q}}_c + \boldsymbol{C_c}\cdot\boldsymbol{q_c} = \boldsymbol{P_c}\ . \tag{3}$$

where: $\boldsymbol{M_c}$ – mass matrix; $\boldsymbol{D_c}$ - damping matrix; $\boldsymbol{K_c}$ - stiffness matrix; $\boldsymbol{P_c}$ - vector of nodal forces.

CONSTRAINTS FORMULAS AND DYNAMICS OF THE CONSTRAINED SYSTEM

The main zoom of the paper is set on the constraint equations. With the presence of the constraint, the previously obtained differential equations of dynamics of the sub-models are converted into a single set of differentially-algebraic equations (*DAE form*) [3,5]:

$$\begin{aligned} &\boldsymbol{M}_b(\boldsymbol{q}_b)\cdot\ddot{\boldsymbol{q}}_b+\boldsymbol{F}_b(\dot{\boldsymbol{q}}_b,\boldsymbol{q}_b)+\boldsymbol{J}_b^T(\boldsymbol{q}_b)\cdot\lambda=\boldsymbol{Q}_b(\dot{\boldsymbol{q}}_b,\boldsymbol{q}_b,\boldsymbol{f_e},\boldsymbol{t_e},t)\ ; \quad \boldsymbol{M}_c\cdot\ddot{\boldsymbol{q}}_c+\boldsymbol{D}_c\cdot\dot{\boldsymbol{q}}_c+\boldsymbol{K}_c\cdot\boldsymbol{q}_c+\boldsymbol{J}_c^T\cdot\lambda=\boldsymbol{P}_c\ ; \\ &\boldsymbol{\Phi}(\boldsymbol{q}_c,\boldsymbol{q}_b)=\boldsymbol{N}\cdot\boldsymbol{q}_c-p_n(\boldsymbol{q}_b)=0\ ; \quad \boldsymbol{J}_b=\tfrac{\partial}{\partial\boldsymbol{q}_b}\boldsymbol{\Phi}\ ; \quad \boldsymbol{J}_c=\tfrac{\partial}{\partial\boldsymbol{q}_c}\boldsymbol{\Phi}\ , \end{aligned} \tag{4}$$

where: $p_n(\boldsymbol{q_b})$ – vertical position of the contact point at the multibody sub-model.

To eliminate the dependent velocities and accelerations, derivatives of the constraint equations are necessary. Our intention is to write them as [3,5]:

$$\begin{aligned} &\boldsymbol{N}\cdot\dot{\boldsymbol{q}}_c+\dot{\xi}\cdot\boldsymbol{N}_\xi\cdot\boldsymbol{q}_c-\boldsymbol{J}\cdot\dot{\boldsymbol{q}}_b=0\ ; \quad \boldsymbol{N}\cdot\ddot{\boldsymbol{q}}_c+\ddot{\xi}\cdot\boldsymbol{N}_\xi\cdot\boldsymbol{q}_c+2\dot{\xi}\cdot\boldsymbol{N}_\xi\cdot\dot{\boldsymbol{q}}_c+\dot{\xi}^2\cdot\boldsymbol{N}_{\xi\xi}\cdot\boldsymbol{q}_c-\left(\boldsymbol{J}\cdot\dot{\boldsymbol{q}}_b\right)_q\cdot\dot{\boldsymbol{q}}_b-\boldsymbol{J}\cdot\ddot{\boldsymbol{q}}_b=0\ ; \\ &\boldsymbol{N}_\xi=\tfrac{\partial}{\partial\xi}\boldsymbol{N}\ ; \quad \boldsymbol{N}_{\xi\xi}=\tfrac{\partial^2}{\partial\xi^2}\boldsymbol{N}\ ; \quad \left(\boldsymbol{J}\cdot\dot{\boldsymbol{q}}_b\right)_q=\tfrac{\partial}{\partial\boldsymbol{q}_b}\left(\boldsymbol{J}\cdot\dot{\boldsymbol{q}}_b\right)\ ; \quad \boldsymbol{J}_c=\boldsymbol{N}\ ; \\ &\boldsymbol{J}=\tfrac{\partial}{\partial\boldsymbol{q}_b}p_n=-\boldsymbol{J}_b\ ; \quad \dot{\xi}=v_t(\dot{\boldsymbol{q}}_b,\boldsymbol{q}_b)/l\ ; \quad \ddot{\xi}=a_t(\ddot{\boldsymbol{q}}_b,\dot{\boldsymbol{q}}_b,\boldsymbol{q}_b)/l\ , \end{aligned} \tag{5}$$

where: v_t – horizontal speed of the contact point; a_t – horizontal acceleration of the contact point.

Of course, the horizontal kinematics of the contact point depends on the kinematics of the multibody part, thus [3,5]:

$$\begin{aligned} &\boldsymbol{N}\cdot\dot{\boldsymbol{q}}_c+\boldsymbol{J}_R\cdot\dot{\boldsymbol{q}}_b=0\ ; \quad \boldsymbol{N}\cdot\ddot{\boldsymbol{q}}_c+\boldsymbol{J}_R\cdot\ddot{\boldsymbol{q}}_b+2\dot{\xi}\cdot\boldsymbol{N}_\xi\cdot\dot{\boldsymbol{q}}_c+\dot{\xi}^2\cdot\boldsymbol{N}_{\xi\xi}\cdot\boldsymbol{q}_c+(1/l)\boldsymbol{N}_\xi\cdot\boldsymbol{q}_c\cdot\gamma_T-\gamma=0\ : \\ &\boldsymbol{J}_t=\tfrac{\partial}{\partial\boldsymbol{q}_b}p_t\ ; \quad \boldsymbol{J}_R=(1/l)\cdot\boldsymbol{N}_\xi\cdot\boldsymbol{q}_c\cdot\boldsymbol{J}_t-\boldsymbol{J}\ ; \quad \gamma_t=\left(\boldsymbol{J}_t\cdot\dot{\boldsymbol{q}}_b\right)_q\cdot\dot{\boldsymbol{q}}_b\ ; \quad \gamma=\left(\boldsymbol{J}\cdot\dot{\boldsymbol{q}}_b\right)_q\cdot\dot{\boldsymbol{q}}_b\ , \end{aligned} \tag{6}$$

where: $\boldsymbol{J}_t$ – matrix of partial derivatives of the horizontal position of the contact point.

Then, coordinates of the multibody structure, $\boldsymbol{q_b}$, are partitioned onto dependent, $\boldsymbol{v}$, and independent, $\boldsymbol{u}$, ones. As a consequence, the dynamic equation can be written, and $\boldsymbol{\lambda}$ can be evaluated:

$$\begin{aligned} &\boldsymbol{M}_{buu}\cdot\ddot{\boldsymbol{u}}+\boldsymbol{M}_{buv}\cdot\ddot{\boldsymbol{v}}+\boldsymbol{F}_{bu}+\boldsymbol{J}_{bu}^T\cdot\boldsymbol{\lambda}=\boldsymbol{Q}_{bu} \quad\Rightarrow\quad \boldsymbol{\lambda}=-\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{M}_{buu}\cdot\ddot{\boldsymbol{u}}-\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{M}_{buv}\cdot\ddot{\boldsymbol{v}}-\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{F}_{bu}+\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{Q}_{bu} \\ &\boldsymbol{M}_{bvu}\cdot\ddot{\boldsymbol{u}}+\boldsymbol{M}_{bvv}\cdot\ddot{\boldsymbol{v}}+\boldsymbol{F}_{bv}+\boldsymbol{J}_{bv}^T\cdot\boldsymbol{\lambda}=\boldsymbol{Q}_{bv}\ . \end{aligned} \tag{7}$$

Obtained $\boldsymbol{\lambda}$ is eliminated from the dynamics. Next, the constraint equations (at the acceleration level) are partitioned also, and the dependent accelerations are eliminated from the dynamics. They can be written in the standard way [3,5]:

$$\begin{aligned} &\boldsymbol{M}_{11}\cdot\ddot{\boldsymbol{u}}+\boldsymbol{M}_{11}\cdot\ddot{\boldsymbol{q}}_c+\boldsymbol{F}_1=\boldsymbol{Q}_1 \\ &\boldsymbol{M}_{21}\cdot\ddot{\boldsymbol{u}}+\boldsymbol{M}_{22}\cdot\ddot{\boldsymbol{q}}_c+\boldsymbol{D}_2\cdot\dot{\boldsymbol{q}}_c+\boldsymbol{K}_2\cdot\boldsymbol{q}_c+\boldsymbol{F}_2=\boldsymbol{P}_2 \end{aligned} \tag{8}$$

where:

$$\begin{aligned} &\boldsymbol{M}_{11}=\boldsymbol{M}_{bvu}-\boldsymbol{J}_{bv}^T\cdot\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{M}_{buu}-\boldsymbol{M}_{bvv}\cdot\boldsymbol{J}_{Rv}^{-1}\cdot\boldsymbol{J}_{Ru}+\boldsymbol{J}_{bv}^T\cdot\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{M}_{buv}\cdot\boldsymbol{J}_{Rv}^{-1}\cdot\boldsymbol{J}_{Ru} \\ &\boldsymbol{M}_{12}=-\boldsymbol{M}_{bvv}\cdot\boldsymbol{J}_{Rv}^{-1}\cdot\boldsymbol{N}+\boldsymbol{J}_{bv}^T\cdot\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{M}_{buv}\cdot\boldsymbol{J}_{Rv}^{-1}\cdot\boldsymbol{N}\ ; \qquad \boldsymbol{Q}_1=\boldsymbol{Q}_{bv}-\boldsymbol{J}_{bv}^T\cdot\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{Q}_{bu} \\ &\boldsymbol{F}_1=\boldsymbol{F}_{bv}-\boldsymbol{J}_{bv}^T\cdot\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{F}_{bu}-\left(\boldsymbol{M}_{bvv}-\boldsymbol{J}_{bv}^T\cdot\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{M}_{buv}\right)\cdot\boldsymbol{J}_{Rv}^{-1}\cdot\left(2\dot{\xi}\cdot\boldsymbol{N}_\xi\cdot\dot{\boldsymbol{q}}_c+\dot{\xi}^2\cdot\boldsymbol{N}_{\xi\xi}\cdot\boldsymbol{q}_c+(1/l)\cdot\boldsymbol{N}_\xi\cdot\boldsymbol{q}_c\cdot\gamma_T-\gamma\right) \\ &\boldsymbol{M}_{21}=-\boldsymbol{J}_c^T\cdot\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{M}_{buu}+\boldsymbol{J}_c^T\cdot\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{M}_{buv}\cdot\boldsymbol{J}_{Rv}^{-1}\cdot\boldsymbol{J}_{Ru}\ ; \qquad \boldsymbol{M}_{21}=\boldsymbol{M}_c+\boldsymbol{J}_c^T\cdot\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{M}_{buv}\cdot\boldsymbol{J}_{Rv}^{-1}\cdot\boldsymbol{N} \\ &\boldsymbol{D}_2=\boldsymbol{D}_c+\boldsymbol{J}_c^T\cdot\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{M}_{buv}\cdot\boldsymbol{J}_{Rv}^{-1}\cdot2\dot{\xi}\cdot\boldsymbol{N}_\xi\ ; \qquad \boldsymbol{K}_2=\boldsymbol{K}_c+\boldsymbol{J}_c^T\cdot\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{M}_{buv}\cdot\boldsymbol{J}_{Rv}^{-1}\cdot\dot{\xi}^2\cdot\boldsymbol{N}_{\xi\xi}+ \\ &\boldsymbol{F}_2=-\boldsymbol{J}_c^T\cdot\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{F}_{bu}+\boldsymbol{J}_c^T\cdot\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{M}_{buv}\cdot\boldsymbol{J}_{Rv}^{-1}\cdot\left((1/l)\cdot\boldsymbol{N}_\xi\cdot\boldsymbol{q}_c\cdot\gamma_T-\gamma\right)\ ; \qquad \boldsymbol{P}_2=\boldsymbol{P}_c-\boldsymbol{J}_c^T\cdot\boldsymbol{J}_{bu}^{-T}\cdot\boldsymbol{Q}_{bu} \end{aligned} \tag{9}$$

CONSIDERED SYSTEM

The used exemplary model corresponds to a planar beam connected with a double pendulum that oscillates and slides on the beam (Fig.1a). The beam is modeled with use of 50 finite elements. Corresponding constraint equations are introduced as they are presented in the work, as well as the above method is used for the coordinate partitioning and for the elimination. Finally, obtained equations are tested numerically (Fig. 1bc).

ORBITAL MOTION DYNAMICS FOR ASTEROID APOPHIS ARTIFICIAL SATELLITE

Vyacheslav V. Ivashkin*[1,2], Anqi Lang [2,3], Peng Guo [1]

Summary Orbital motion of the satellite of the asteroid Apophis is studied taking into account main perturbations - from the attraction of main celestial bodies - the Sun, Earth, Moon, Venus, Jupiter, the non-sphericity of the asteroid and the solar radiation pressure. Two asteroid models are considered - a prolate spheroid and a triaxial ellipsoid. It is found the existence of stable orbits of the asteroid satellite, allowing for several years before the approach of the asteroid to the Earth in 2029 to realize the spacecraft motion near the asteroid. This makes it possible, in principle, to carry out radio measurements of satellite motion parameters from ground-based stations and to improve significantly our knowledge of the Apophis orbit.

INTRODUCTION. STATEMENT OF THE PROBLEM

The organization of an expedition to asteroids, in particular, to the Near-Earth ones, is an important problem of modern cosmonautics. In the paper, in frame of analysis of the characteristics of a possible expedition to the asteroid Apophis, the investigation of the orbital motion of the spacecraft (SC) around the asteroid is performed. In accordance with the considered mission scheme [1], we believe that after the main spacecraft arrives to the asteroid, a special mini-spacecraft is inserted in some orbit of the asteroid satellite, so that after the main spacecraft departs to the Earth, the mini-spacecraft will for a long time, ~ several years, continue to fly near the asteroid and some ground-based stations will measure the satellite motion parameters and it gives the possibility to know better the Apophis orbit. The purpose of the study is to investigate whether it is possible to choose the orbit of this mini-spacecraft so that it will passively move around the Apophis for several years without corrections. The analysis showed that we can create the stable mini-satellite orbit with motion of the satellite near the asteroid for several years till the close approach of the asteroid to the Earth in 2029.

MODEL OF SPACECRAFT MOTION. MODEL OF ASTEROID

In an investigation of the spacecraft motion relative to the asteroid Apophis, we took into account three types of perturbations: the attraction of distant celestial bodies (the Sun, Earth, Moon, Venus, Jupiter, etc.), the non-sphericity of the Apophis, and the solar radiation pressure (SRP). For this complicated field, we used a numerical method of the analysis based on the numerical integration of the equations of the spacecraft motion relative to the asteroid:

$$d\mathbf{r}/dt = \mathbf{V}; d\mathbf{V}/dt = \mathbf{a}_0 + \mathbf{a}_1 + \mathbf{a}_2 + \mathbf{a}_3.$$

Here: $\mathbf{r}$ (x, y, z), $\mathbf{V}$ (V_x, V_y, V_z) is the position vector and velocity vector of the spacecraft in the asteroid-centric non-rotating rectangular coordinate system OXYZ, $\mathbf{a}_0 = -\mu_A \mathbf{r}/r^3$ is the central acceleration, $r = |\mathbf{r}|$; μ_A is the gravitational parameter of the asteroid Apophis; $\mathbf{a}_1$, $\mathbf{a}_2$, $\mathbf{a}_3$ – perturbation accelerations: from the attraction of distant celestial bodies, from the non-sphericity of Apophis and from the solar radiation pressure. In the analysis, the position vectors of celestial bodies relative to the Sun were taken from Ephemeris DE421; Apophis position vector is defined on the corresponding JPL site or by the numerical integration. The Apophis gravitational parameter is taken in the range μ_A = 1.8-2.86 m^3/s^2 (for the Apophis mass 2.7-4.3·10^{10} kg). The average Apophis radius was taken equal to R_A = 160 m. The initial orbit of the spacecraft was taken circular with a radius r_0 in the range 0.5-2 km (with orbital velocity of 6-3 cm/s, orbital period ~ 15-116 hours for μ_A = 1.8 m^3/s^2).

Two models of asteroid were used to analyze the effect of asteroid's non-sphericity. This is, firstly, an approximate model of a homogeneous prolate spheroid, that is two-axial prolate ellipsoid of rotation [2]. Observations of the asteroid Apophis [3] showed that the asteroid is geometrically and dynamically close to this variant. Thus, an estimate of the ratios of the principal axes of a dynamically equivalent homogeneous ellipsoid yielded $b_A/a_A \approx 1.06$ (±0.02), $c_A/a_A \approx 1.5$ (±0.2), here a_A, b_A, c_A are the small, medium, and major semiaxes of the ellipsoid for Apophis. In addition, a variant of a homogeneous triaxial ellipsoid with shown values of the semiaxes is considered [4].

Moreover, at this stage of the analysis, the case of uniaxial rotation of an asteroid around the small axis a_A was considered, and it was assumed that this axis of rotation has a constant orientation in space along the vector of kinetic moment $\mathbf{K}_A$ specified in the ecliptic coordinate system by the longitude $\lambda \approx 250°$ and the latitude $\beta \approx -75°$ [1-3].

When calculating the acceleration from SRP, $\mathbf{a}_3$, it was assumed for a mini-satellite that it has the shape of a ball with a diameter of D = 40 cm, mass m = 10 kg, and for it the reflection coefficient is C_{SC} = 1.4-1.5.

*Corresponding author. E-mail: ivashkin@keldysh.ru

For these models, a numerical analysis of the spacecraft motion in the close vicinity of the Apophis asteroid was performed. The starting date t_0 was selected on April 23, 2020 [1, 2], in accordance with the analysis of the trajectories of the Earth-asteroid-Earth mission.

First, an analysis was made for the SC motion under the influence of partial perturbations. This analysis showed the importance of the SRP. It was revealed that if the orbital plane is not very successful, when the direction from the Sun to the asteroid is close to the orbital plane, then the SRP will greatly affect the size of the EC orbit. In this case, the distance in the orbit apocenter increases at one half of the revolution, and the distance at the orbit pericenter decreases at the its other half, the eccentricity of the orbit increases, and the spacecraft can quickly collide with the asteroid surface or fly away from it. More acceptable is the initial choice of the satellite's orbital plane approximately perpendicular to the direction of the solar light. In this case, the SRP causes a precession of the SC orbit, a rotation of the SC orbit plane, so that the normal to the SC orbit plane remains close to the direction to the sun. In this case, it is possible to ensure the SC long-term motion near the asteroid.

Then, the main analysis was performed, where the combined influence of all disturbances was taken into account. The importance of the SRP as the main disturbance remains. Moreover, the influence of this pressure increases with increasing radius of the orbit. Therefore, for orbits close to the surface of the asteroid, the main perturbation will be the influence of non-sphericity, and for orbits with a large radius, the solar radiation pressure becomes the main one.

From the point of view of the qualitative features of the SC motion near the asteroid, the most important will be the effect of nonlinearity due to the correlation between the influence of the non-sphericity of the asteroid and the SRP. The total change in the SC orbit is not obtained by summing the partial variations. As a result, under the joint action of perturbations, the situation can be greatly worse than in the variants of partial perturbations.

Another interesting and important from a practical point of view qualitative result was the detection of an “optimal” initial radius r_0 of the SC orbit, for which, with the correct choice of the initial orbit orientation (approximately perpendicular to the sun's light), the total perturbations in the linear dimensions of the orbit will be small enough, and the spacecraft remains in the close vicinity of the asteroid for a rather long time.

For the considered mini-spacecraft, the initial radius r_0 ~ 1.5 km is optimal, and then the mini-spacecraft moves near Apophis for ~9 years, before approaching the Earth in 2029. With this approach, the Earth’s gravity becomes the main and very large perturbation, and the spacecraft flies away from the asteroid. The figure below shows a typical dependence of the spacecraft altitude H (km) above the asteroid surface for t-t_0 ~9 years, until 2029.

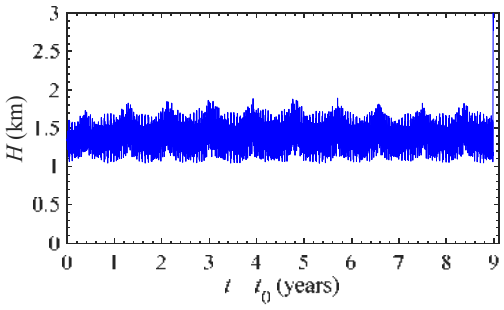

Figure 1. The evolution of the mini-spacecraft altitude above the surface of the asteroid Apophis

CONCLUSIONS

The analysis performed has shown the existence of the asteroid satellite’s stable orbits, which allow the motion of spacecraft near the asteroid for several years before the asteroid approaches the Earth in 2029. This provides an opportunity to realize radio measurements of satellite motion parameters by ground measurement stations and to define better the Apophis orbit.

MULTIBODY DYNAMICS AND CONTROL OF ELECTRIC SCOOTERS

Daniel García-Vallejo*[1], Werner Schiehlen[2], and Alfonso García-Agúndez[1]
[1]Universidad de Sevilla, 41004 Seville, Spain
[2]University of Stuttgart, 70550 Stuttgart, Germany

Summary Everyday more and more companies are joining the business of electric single-passenger vehicles for urban micro-mobility. These single-person vehicles are usually based on the use of small diameter wheels as a rolling element. The modeling and computational analysis of their dynamics, as well as the study of their stability and, therefore, of the physical parameters that decisively influence it, are the object of this project. The theoretical results for bicycle lateral stability analysis are used for escooters. The knowledge of how the main parameters of the model affect its stability and control will allow design modifications that may lead to safer vehicles and may result in the reduction of accidents in urban mobility through these vehicles.

LATERAL STABILITY AND CONTROL

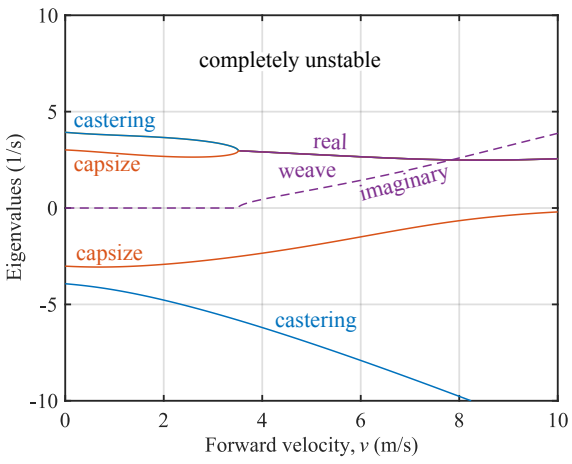
The lateral motion is related to the balancing required for two-wheelers. In particular, the bicycle research reported in [1, 2] resulted in a validated benchmark. The equations of lateral motion can be reduced to two degrees of freedom subject to 25 parameters. The equations of motion linearized to riding straight ahead read as

$$\boldsymbol{M}\ddot{\boldsymbol{q}} + v\boldsymbol{C}_1\dot{\boldsymbol{q}} + \left[g\boldsymbol{K}_0 + v^2\boldsymbol{K}_2\right] = \boldsymbol{f} \tag{1}$$

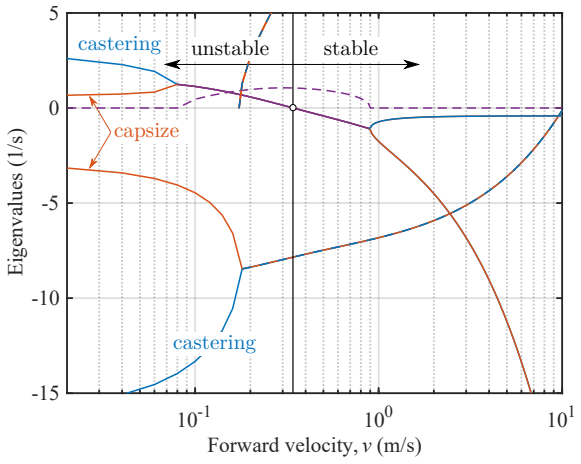
where the vector of generalized coordinates $\boldsymbol{q} = [\phi(t)\ \ \delta(t)]^T$ represents lean or roll motion, and the steering angle. The generalized torques $\boldsymbol{f} = [T_\phi(t)\ T_\delta(t)]^T$ describe lean disturbances and steering torques by the rider. The constant matrices $\boldsymbol{M}$, $\boldsymbol{C}_1$, $\boldsymbol{K}_0$ and $\boldsymbol{K}_2$ represent inertia, velocity dependent damping, gravitational stiffness as well as gyroscopic and centrifugal effects.

Computing the eigenvalues of the linearized equations to check the lateral stability, see Ref. [1, 2], it turns out that the benchmark bicycle is statically unstable at low speeds, asymptotic stable for medium speeds (4-6 m/s) and oscillatory unstable at high speeds. However, the self-stability is weak.

In this project, the SEAT eXS Kickscooter ES2 powered by Segway-Ninebot is used. Detailed information is available in the user manual [3]. The corresponding 25 parameters of the escooter were recently computationally evaluated and documented in Ref. [4, 5]. Now, it turns out that the benchmark escooter is completely unstable, it can't be ridden freehanded at all, Fig. 1a). However, for bicycles at low and high speeds as well as for escooters at all speeds stable riding is achieved by steering torques controlled by the experience of the rider.



a)



b)

Figure 1: a) Eigenvalues from the linearized speed analysis for the benchmark eXS KickScooter [4] without control;
Figure 1: b) Eigenvalues from the linearized speed analysis for the controled kickscooter in a semi logarithmic speed scale.

In 2014 Lipp [6], utilized different strategies to stabilize the lateral motion of the benchmark bicycle [1] based on instantaneous and delayed feedback. In principle, the idea of the controller is to generate a steering torque to compensate the lean of the bicycle. This leads to the following steering torque control law:

$$T_\delta = k_p\phi + k_d\dot{\phi}, \tag{2}$$

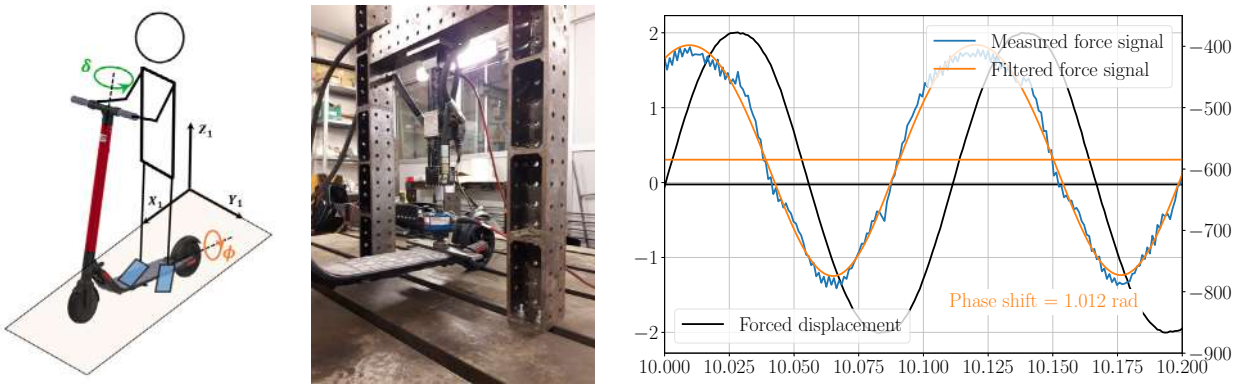
*Corresponding author. E-mail: dgvallejo@us.es.

where k_p and k_d are two gains that needs to be fixed. It makes sense to explore the use the same controller model (with instantaneous feedback) to stabilize the lateral motions of a kickscooter, too, in upward advance at constant velocity.

Figure 1b) shows the stability diagram of a controlled kickscooter in a logarithmic x-axis to better show the behaviour at low speed. The gain values were larger than those used for the bicycle benchmark controller in Lipp's Thesis (k_p = 0.2 Nm/rad and k_d = 20 Nm/rad/s) [6]. The stability diagram for the kickscooter in Fig. 1b) has been obtained with gains k_p = 85 Nm/rad and k_d = 205 Nm/rad/s. It is interesting that the stability is always lost for low enough speeds. According to the behaviour shown by the system, the controller behaves in such a way that the proportional gain, k_p, has larger influence for low speed while the derivative gain, k_d, has larger influence for high speeds.

MULTIBODY MODEL OF THE ESCOOTER AND THE DRIVER

A three dimensional multibody model of the escooter with the driver is developed, see Fig. 2a) where lean and steer angles are also represented. The model consists of five main bodies: the two wheels, the footboard, the handlebar and the driver, which is assumed to be connected by a spherical joint to the foot board. The wheels are modeled both as ring shaped and toroid shaped wheels, with the ground contact modeled as rolling without slipping. The escooter and the driver are constructed in an open kinematic chain with 6 coordinates for the footboard, 1 for the handle bar, 2 for the wheel rotations and 3 for the driver. A set of 4 (ring wheels) or 6 (toroidal wheels) holonomic plus 4 non-holonomic constraints arise from the contact with the flat ground. In a subsequent step, the stiffness and damping of the two suspensions are included in the model, by adding the required suspension dofs. In order to find the stiffness and damping constants, some test have been carried out in the laboratory of Mechanical Engineering of the University of Seville, see Fig. 2b) and Fig. 2c), where static and dynamic harmonic tests were conducted. Details of the results of the analysis can be found in Ref. [4].



a) b) c)

Figure 2: a) Model of the Kickscooter, considering the rider; b) picture of the kickscooter during the tests for stiffness and damping estimation; and c) results of the dynamic tests for damping parameter estimation: measured and filtered load signals together with displacement with the load applied close to rear axis at a frequency of 9 Hz.

SIMULATION RESULTS

Numerical simulations of the multibody model were carried out to validate the stability behaviour of the linearized model described in Fig. 1. In addition, simulations are used to study the accuracy and efficiency of the ring shaped and torus shaped wheel models. The driver action is approximated by adding a harmonic relative motion between the driver modeled as an inverted pendulum and the footboard.

HOW HUMAN SITTING ON THE SWING PUMPS IT

Alexander Formalskii*, Liubov Klimina
Institute of Mechanics, Lomonosov Moscow State University, Moscow, Russia

Summary The three-link hinged mechanism as a model of person sitting on the swing is considered. In the knee- and hip-joints of this model, the control torques limited in absolute value are applied. Problem of generation of oscillations/rotations about the suspension joint is studied. First, the double-link mechanism is analyzed as auxiliary (simplified) model of a person sitting on the swing. For this auxiliary model, the autonomous feedback control strategy is designed in order to maximize the amplitude of the swing at the end of each semi-oscillation. Then it is shown that the similar strategy allows solving the named above problem for the three-link hinged mechanism. Designed control torques depend on the angle and angular speed of the swing. Numerical simulation is performed.

INTRODUCTION

It is possible to find in the literature many papers devoted to the swing pumped by human standing or sitting on it (see, for example, [1-5]). Here we study a rigid swing with a sitting human. Most authors consider double-link models of a person on the swing while here three-link hinged model is investigated. The quasi-optimal feedback strategy of the swing pumping is found with respect to the rate of increasing of amplitude. It is shown by numerical simulation that this strategy can pump the swing to oscillations with constant amplitude (if a viscous friction at the suspension joint is taken into account) as well as to rotations. This strategy is close to anthropomorphic one.

SIMPLIFIED MODEL: STATEMENT AND SOLUTION OF THE PROBLEM

Let us consider the double-link mechanism as an auxiliary model of a person sitting on the swing (see figure 1). In this model, a human is substituted by a single rigid body. Angle θ is a limited control input: $\theta_{\min} \le \theta \le \theta_{\max}$. The angle of rotation of the swing is denoted as φ.

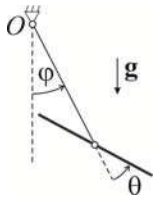

Figure 1: The scheme of the simplified double-link mechanism.

The quasi-optimal control strategy is designed in order to pump the swing with large as possible amplitude. In other words, we maximize the swing deviation from the vertical at the end of each semi-oscillation. The designed control strategy is presented by the picture in figure 2.

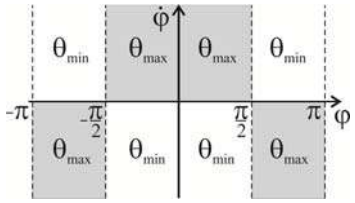

Figure 2. Dependence of control input θ on angle φ and angular speed $\dot{\varphi}$.

The following relay-type function $\theta(\varphi, \dot{\varphi})$ corresponds to the program law shown in figure 2:

$$\theta(\varphi, \dot{\varphi}) = \begin{cases} \theta_{\max}, & \text{if} \quad \dot{\varphi}\cos\varphi \ge 0, \\ \theta_{\min}, & \text{if} \quad \dot{\varphi}\cos\varphi < 0. \end{cases} \tag{1}$$

PLANAR THREE-LINK HINGED MECHANISM

The three-link mechanism is shown in figure 3. Link *HP* models a body, link *PK* – both thighs, and link *KF* – both shins. The inter-link hinge *K* models two knee-joints, the hinge *P* – two hip-joints. Link *PK* is rigidly joined to the swing (the rigid rod) pivotally attached to the suspension joint *O*. The viscous friction torque at axis *O* with coefficient *c* is taken into account.

*Corresponding author. E-mail: formal@imec.msu.ru.

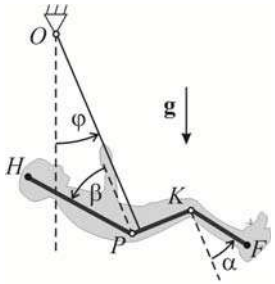

Figure 3. Three-link hinged mechanism as a model of human sitting on the swing.

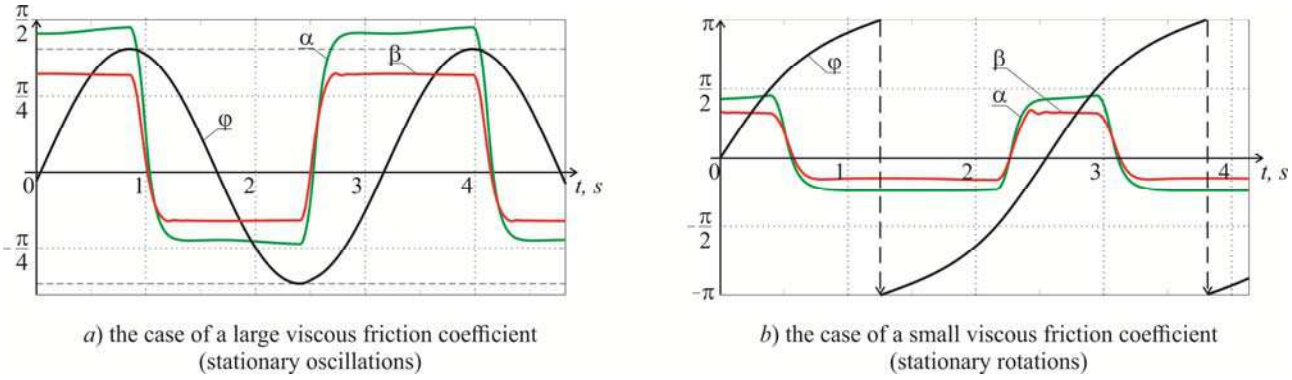
Two limited control torques are applied at inter-link joints K and P. Thus, the system has three degrees of freedom, but only two control torques are applied. So, this system is under-actuated one. Angles α in joint K and β in joint P are limited: $\alpha_{\min} \le \alpha \le \alpha_{\max}$, $\beta_{\min} \le \beta \le \beta_{\max}$. The limitation upon these angles is modeled via relatively strong single-side spiral springs in joints K and P which ensure that angles α and β do not leave the prescribed domains. These springs model ligaments and tendons. The goal of the control is to pump the swing to the largest amplitude taking into account the restrictions imposed on the control. In this paper, the solution that is "close to optimal" is proposed. Function (1) is used as the program function in the initial problem for the three-link mechanism (substituting α or β instead of θ). Control torques are designed as combinations of linear feedbacks with respect to the differences between the current and program angles and their derivatives. Efficiency of this control strategy is illustrated by numerical simulation with anthropomorphic parameters of the mathematical model. This simulation shows that if friction coefficient c is rather large, then oscillations of the swing tend (if time t grows) to a stationary oscillatory mode (see figure 4a) corresponding to a cycle in the configuration space. But if friction coefficient c is sufficiently small, then the swing is pumped to a stationary rotation (see figure 4b) corresponding to the cycle in the configuration space $(\varphi \bmod 2\pi, \alpha, \beta)$. These cycles are attracting ones.



a) the case of a large viscous friction coefficient (stationary oscillations)

b) the case of a small viscous friction coefficient (stationary rotations)

Figure 4: Stationary oscillations and rotations of the swing.

CONCLUSIONS

The designed control maintains oscillations in wide range of amplitudes as well as rotations with a constant period depending on the restrictions upon angles α, β and on the viscous friction coefficient c.

INTEGRATED SIMULATION OF DYNAMICAL-OPTICAL SYSTEMS USING MULTIBODY APPROACHES

Peter Eberhard* and Luzia Hahn
Institute of Engineering and Computational Mechanics, University of Stuttgart, Stuttgart, Germany

Summary In this work, methods and procedures are investigated for the simulation of the dynamical behavior of high-performance optics like lithography objectives or mirror telescopes. Flexible multibody systems in combination with model order reduction methods and optical system analyses are used for transient simulations of the dynamical behavior of optical systems at low computational cost. In addition, the influence of temperature changes in optical lenses on the dynamical-optical systems will be analyzed using the proposed method.

INTRODUCTION AND MODELING

High-performance optical instruments like lithographic objectives or astronomical telescopes, are high resolution optical systems consisting of precise mirrors or lenses. The optical elements are mounted with high accuracy and they are very sensitive with respect to mechanical vibrations and temperature changes. In order to produce wavers, scanning systems use lithography objectives to project structures for a certain time onto the wafers. During the operation time, even small mechanical disturbances of the mirrors or lenses can be sufficient to produce aberrated images. Sources of these small vibrations can be minimal excitations at the objective frame, e.g., from noise of coolers or influences of the wafer motion system. The power of the used lasers in the scanning systems rises due to ever-growing demand of throughput [1]. This heats up the lenses or mirrors and can result in thermal aberrations. The thermo mechanical behavior of the optical systems can be described by a combination of rigid body motion, small deformations, the related stresses, and the temperature distribution. In order to investigate the overall dynamical-thermal-optical behavior, multi-disciplinary methods and software tools with suitable interfaces have to be used and combined as also shown in [2] and [3]. Here, a method is proposed for simulating the performance of dynamical-optical systems and a method for the additional analysis of thermal effects in these systems. An exemplary dynamical-optical system with a controlled adaptive optics is presented.

In order to simulate the dynamical-optical system behavior, a generalized workflow for such simulations using cooperating software packages according to Fig. 1 can be used. The first step in the dynamical-optical simulation is, to model the sensitive optical components of the system separately as elastic bodies using a finite element software like ANSYS. The system matrices and the node coordinates leading to the equations of motion can then be extracted using a software like MatMorembs. Additionally, the mode shapes are extracted and can be used in a model order reduction (MOR) in order to reduce the number of degrees of freedom and to speed up the mechanical simulations. For the assembly of the system and the mechanical simulation, a multibody software like Neweul-M2 is effective. It is able to import and to join several rigid and elastic bodies into a flexible multibody system [4]. The movements and deformations of the dynamical-optical system are resulting from a numerical time integration.

For the calculation of the optical aberrations of deformed surfaces, the mode shapes of a reduced body have to be approximated accurately, e.g., using a minimal set of Zernike polynomials. Furthermore, an optical simulation yields the related wavefront aberration (WFA). For this task, the program OM-Sim is developed, where ray tracing and Fourier optical methods are implemented. Since the deformation of a dynamically excited surface results from the superposition

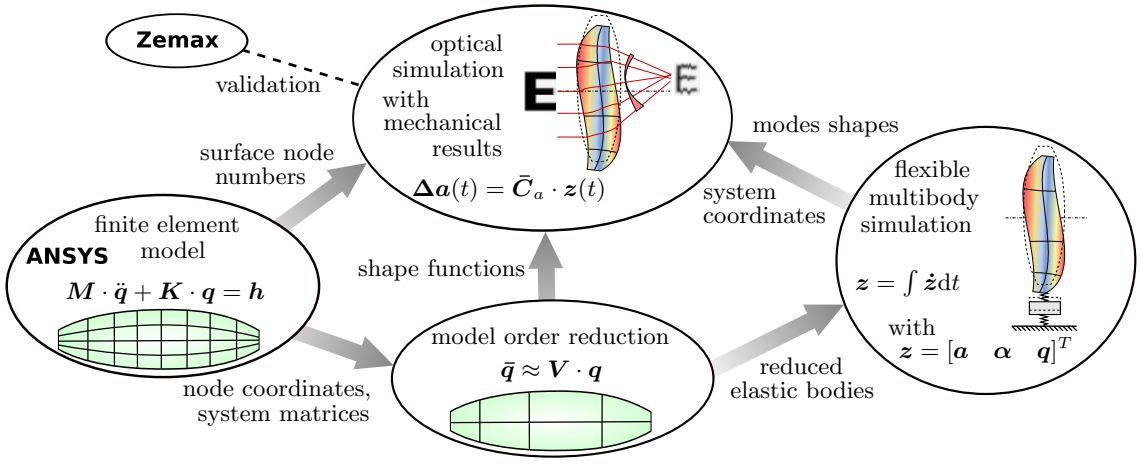

Figure 1: Workflow of the described dynamical-optical system simulation.

(a) ray tracing (b) deformation of M2 (c) image simulation with controlled deformation of M2 (d) image simulation with rigid M2

Figure 2: Snapshot of the dynamical-optical simulation of a segmented mirror with a controlled deformation of the second mirror (a), (b) and the resulting images after an exposure duration of 100 ms with the shape of the letter 'F' with a controlled deformation of M2 (c) and without the deformation of M2 (d).

of the mode shapes, the corresponding WFA can also be superposed if the mechanical disturbances are small enough to ensure diffraction limitation for the optical behavior. This case is mostly given in our applications and thereby, the overall integrated model considering the mechanical-optical behavior can even be regarded as a linear system [3].

Dynamical-Thermal-Optical System Analysis

Additional to mechanical disturbances, high resolution optical systems are sensitive to thermal influences. The refraction index changes with the temperature. Thus, the heating of the lens caused by the passing light or environmental influences can lead to thermal aberrations. For the additional analysis of transient thermal effects in dynamical-optical systems a thermal analysis of the optical elements has to be performed using FE-Methods. In order to consider the temperature dependency of the refraction index in the ray tracing, the discrete node temperatures must be described analytically, i.e. with polynomials. Cylindrical polynomials are well suited, especially for circular lenses. The combination of Zernike polynomials for the circular area with any one-dimensional polynomial like Chebyshev polynomials for the height portion is useful. In that way, the refraction index changes within an optical element due to temperature changes can be considered during the ray tracing and thermal WFA can be calculated. The superposition of the thermal WFA and the dynamical WFA makes the simulation and analysis of the transient behavior of dynamical-thermal-optical systems possible.

EXAMPLE AND CONCLUSIONS

As an example of the performance of an integrated dynamical-optical system simulation a segmented mirror with an adaptive optic (AO) is presented in Fig. 2. The mirror segments are mechanically disturbed in the z-direction using a predefined movement. The task of the AO unit is to control the deformation of the elastic mirror M2 such that the current aberration is compensated. This ensures an undisturbed space observation or perfect image exposure. The lightweight structures of a telescope mirror are sensitive with respect to deformations and dynamical disturbances. During the astronomical observation, e.g., dynamic wind loads, the AO unit, or other motion systems can unintentionally excite the whole system. In order to compensate for the resulting mechanical vibrations, they can be detected in real-time, e.g., using Laser Doppler vibrometers or they can be estimated by a model-based state observer. Based on this, the reconstruction of the mechanical mirror deformation can be performed [5]. Thus, the resulting optical aberrations can be compensated with a controlled deformation of the second mirror. The improvement of the image simulation with the controlled M2 in Fig. 2 (c) in comparison to the image simulation with the rigid mirror M2 in Fig. 2 (d) illustrates this compensation.

MULTI-ROBOT OBJECT TRANSPORTATION WITH OPTIMIZED MANIPULATION KINEMATICS

Henrik Ebel*, Wei Luo, and Peter Eberhard
Institute of Engineering and Computational Mechanics, University of Stuttgart, Germany

Summary Employing multiple, cooperating robots for object manipulation can increase flexibility, robustness, and efficiency of operation. However, it introduces challenges regarding the coordination of the motion of the involved robots. With the cooperative transportation of arbitrary polygonal objects by mobile robots, this contribution focuses on a challenging subtask in multi-robot object manipulation. The contribution shows how the kinematic requirements of a successful transportation can be cast into an optimization problem, considering a robustness measure to reduce the time spent on reorganization. Furthermore, it is shown how the resulting non-convex problem can be solved by means of distributed optimization. Applying a distributed control scheme, challenging simulation results and insights from hardware experiments show the capabilities and applicability of the transportation strategy.

In recent times, the application of autonomous robotic systems has lead to efficiency gains in manufacturing, logistics, and transportation. In many applications, improved capabilities with regard to the manipulation and transportation of objects have contributed to this development. Further potential for progress may be found in the application of multi-robot systems, since they may increase flexibility, robustness, and efficiency of operation by means of a closely coordinated cooperation between multiple robots. Additional robots may join if larger or heavier objects need to be handled, and the robots may be able to reconfigure and continue task solution in case of hardware failures of individual robots. On the flipside, however, a successful coordination of the motion of the involved robots may be challenging and strongly depends on the type of object handled, with the multi-robot system ideally adapting self-reliantly to different scenarios. In light of these considerations, this contribution looks at a class of cooperative transportation problems as a model task in the area of multi-robot object manipulation. This kind of task has been studied extensively in scientific research, with the proposed approaches varying greatly with respect to the methods used, types of objects transported, robot dynamics considered, and the type of physical connection to the object [1]. In some approaches, the robots attach rigidly to the object, e.g. by means of suitably designed grippers, while in others, the robots merely push the object yielding unilateral constraints. This contribution studies the latter case, because it allows for a swift reorganization around the transported object. Dynamics-wise, the robots are assumed to not be subject to any non-holonomic constraints. An illustration of the task can be seen on the left-hand side of Figure 1, whereas the right-hand side shows a group of real-world robots that meet the dynamic requirements and that have been purpose-built at the ITM for this contribution's task.

Existing approaches are usually limited to different subclasses of object shapes that can be handled, often enough restricting themselves to convex shapes [2], or even cuboid or ellipsoidal shapes [1, 3, 4]. In contrast, by means of a distributed optimization taking into account the kinematic requirements of a successful transportation, this contribution's scheme can deal with any kind of polygonal shape, including non-convex ones. The intricacies of the formulation of the underlying optimization problem are discussed in detail. On the one hand, the robots need to be able to compensate the current translational and rotational errors of the object. Therefore, for instance, the translational error must be representable as a conic combination of the inner normal vectors at the contact points. On the other hand, configurations shall be preferred that do not necessitate immediate reorganizations if the desired transportation direction changes. To that end, a robustness measure is proposed that allows the evaluation of the robustness of a given configuration towards changes of

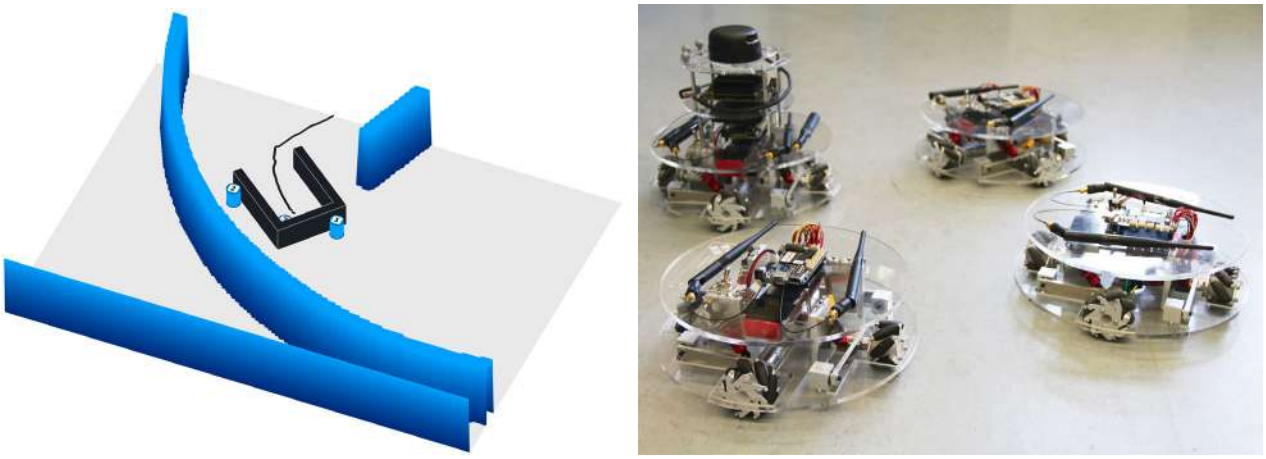

Figure 1: The left-hand side illustrates a transportation scenario in which three robots transport a U-shaped object through a narrow passageway, whereas the right-hand side shows robots tailor-made for such a transportation task, see www.itm.uni-stuttgart.de.

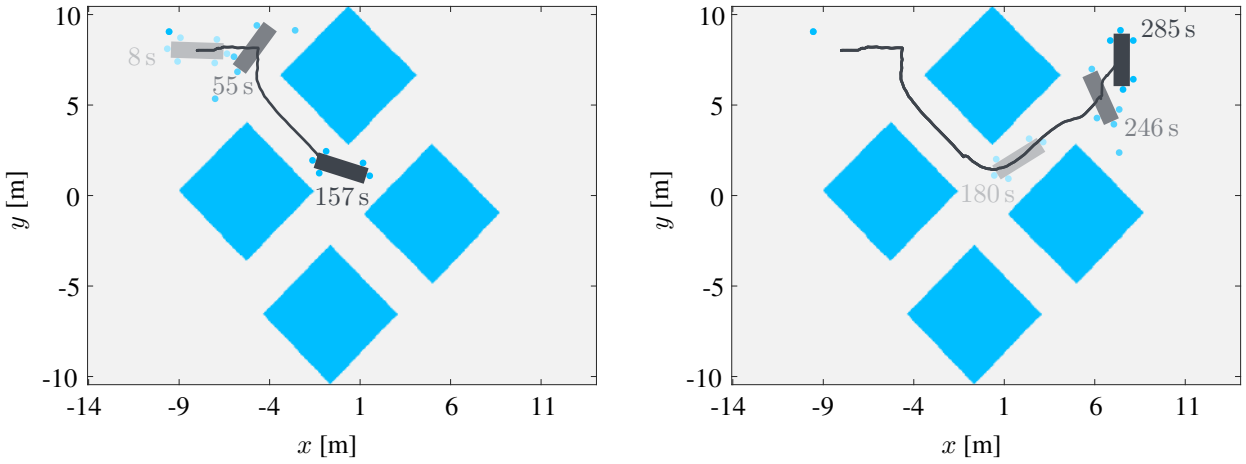

Figure 2: Simulation result with up to 6 robots transporting an object through an only partly known environment. The upper obstacle is discovered during system runtime, and robots are joining and leaving the transportation process in the course of the simulation.

the transportation direction. Incorporating this measure into the optimization problem enables a more efficient transportation process with less time spent on reorganization. It is shown that the resulting optimization problem is non-convex, with potentially multiple local minima. Due to its properties, the problem is solved with a custom, distributed version of an augmented Lagrangian particle swarm optimization algorithm [5].

While this aspect is in the focus of the contribution, the challenges posed by the task, and henceforth discussed in the contribution, are manifold. Ranging from the modeling of the robots and objects for simulation and for control synthesis purposes, to distributed control design, and to the navigation through obstacle-ridden environments, all major subaspects are discussed. Building upon our previous work [6, 7], having found a kinematically suitable configuration around the object, the task is treated as a formation control task. The resulting formation control problem is solved by means of distributed model predictive control. The latter is an optimization-based control approach, in which, in each time step, an optimal control problem is solved over a finite time horizon to obtain the control input, allowing to explicitly incorporate constraints in the optimization problem [8]. In this contribution's distributed setting, each robot solves its own optimization problem concurrently to the other robots, considering communicated information to allow for cooperative behavior [9].

Having introduced the transportation strategy and the underlying methods, the contribution intently analyzes the properties and performance of the multi-robot system in a variety of challenging and large-scale simulation scenarios, with different kinds of objects, requiring different transportation configurations. This includes scenarios that require reorganization, with robots dropping out of and rejoining the transportation process. Furthermore, scenarios are considered in which also unknown obstacles complicate the transportation process, requiring a careful planning and replanning of the object motion. Figure 2 provides an example of such a scenario, with one of the four obstacles in the environment being discovered during the transportation. The contribution concludes with insights from experiments in which the proposed transportation strategy is employed to real-world robotic hardware, suggesting that the strategy translates well from simulations to experiments.

MICRO-SLIP CONTROL OF WET DUAL CLUTCH TRANSMISSION BASED ON MODEL PREDICTIVE CONTROL METHOD

Xiwen Wang[1], Tongli Lu*[1], Leila Bridgeman [2]
[1]School of Mechanical Engineering, Shanghai Jiao Tong University, Shanghai, P.R. China
[2]Department of Mechanical Engineering and Materials Science, Duke University, Durham, USA

Summary In order to attenuate the vibration of the powertrain and improve the performance of wet dual clutch transmission, micro-slip control based on model predictive control is proposed. The vehicle powertrain with a hydraulic actuator model is modelled in MATLAB/Simulink. After verifying the feasibility and stability of the control algorithm with a simplified control-oriented model by applying appropriate terminal set and terminal cost, the model predictive controller is applied to enable a desired micro-slip on the clutches. The controller is validated by simulation works and the numerical results indicate that the proposed control strategy can reduce the gearshift time, improve the driveability and fuel economy of wet dual clutch transmission.

INTRODUCTION

Due to the high efficiency and quick gearshift response without power interruption, dual clutch transmissions (DCTs) are gradually favoured by vehicle manufactures. Nowadays, traditional control strategies keep the clutches locked after launch or gearshift, resulting in engine torque fluctuations to be transmitted through transmission, thus reducing drive comfort to some extent. An innovative control strategy based on model predictive control (MPC) is proposed to keep an appropriate micro-slip between the clutches to improve the performance of wet DCT. This article mainly includes the following aspects:

1. The dynamic system of the powertrain of wet DCT vehicle is established in MATLAB/Simulink including a hydraulic actuator model.

2. The main shifting processes of wet DCT is accurately analysed and divided to two phases: torque and inertia phase while the micro-slip control is also applied before and after gearshift. The simplified model of different stages based on the dynamic driveline model mentioned earlier is applied to reduce the complexity of the control algorithm. In order to verify the feasibility and stability of the model predictive controller, the terminal set and terminal cost are discussed and selected appropriately. Besides, the terminal set is the significant factor to ensure successful switching between all phases.

3. After sufficient and reasonable certification of the controller, it is applied to the entire driveline model with wet DCT. Simulation results of MPC strategy and lockup strategy are compared to demonstrate the necessity of micro-slip control in the wet DCT system. And the simulation results will indicate the effectiveness of the proposed model predictive controller.

DRIVELINE MODEL

A DCT-based driveline is shown in Figure 1. A DCT is consisted of two clutches, two input shafts, two output shafts and several gears. Specifically, the odd shift gears are controlled by clutch 1 and the even shift gears are controlled by clutch 2. Smooth shifting without power interruption can be achieved by disengaging one clutch while engaging the other one during the gear shift. The whole powertrain with a hydraulic actuator model is modelled in MATLAB/Simulink with Simscape block to properly express the clutch and other component in the driveline.

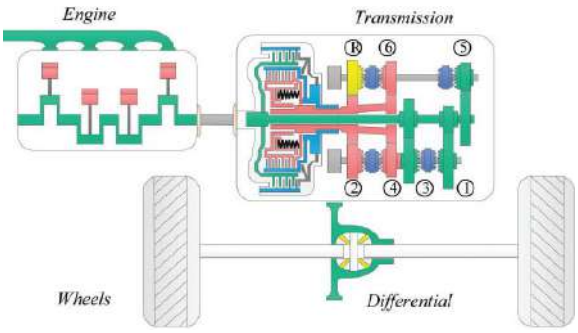

Figure 1. Configuration of a DCT-based drive

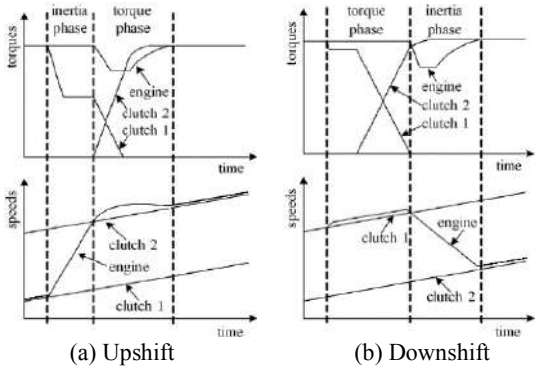


(a) Upshift (b) Downshift

Figure 2. Control strategy in gearshift

MICRO-SLIP CONTROL PRINCIPLE

There are two main phases during gearshift: torque phase and inertia phase. The power switching is achieved in the torque phase and in the inertia phase, the engine speed is changed to synchronize with the target clutch. During the upshift, the torque phase precedes the inertia phase, while the order is reversed in the downshift phase.

*Corresponding author. E-mail: **tllu@sjtu.edu.cn**
This work was supported by National Science Fund of China (Grant No. 51675326).

Micro-slip control can be applied in both torque phase and inertia phase of upshift and down shift. In torque phase, the micro-slip on the current clutch should be maintained so that the undesirable stick slip transition can be avoided. While in inertia phase, the micro-slip control can also be used to decrease the speed difference between the engine and the target clutch and keep the slip at a stable value. As a result, the simplified model of each stage in the gearshift process needs to be constructed, thereby reducing the complexity of the control algorithm.

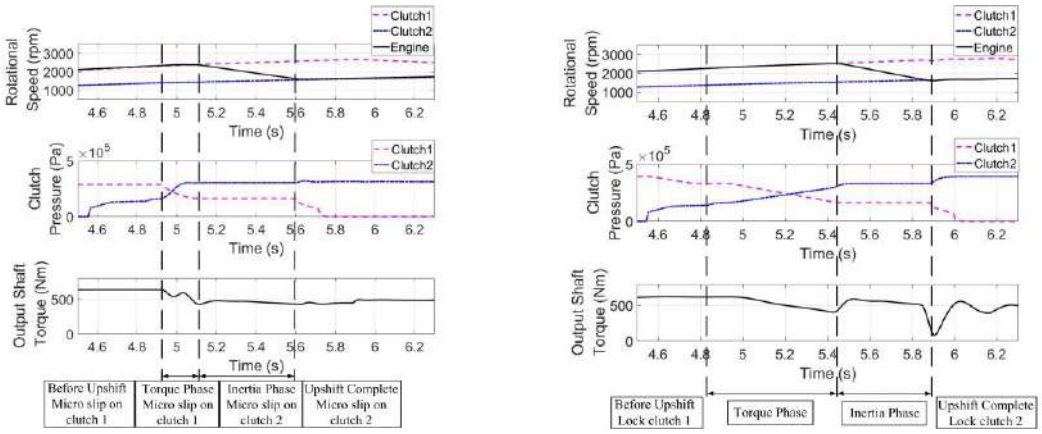
MODEL PREDICTIVE CONTROLLER

In micro-slip control of wet DCT, the speed difference between engine and clutch, and the torque of engine and clutch are selected as states, and the variations of torque are selected as inputs. The purpose of this state selection is to keep a desired micro-slip between the engine and the clutch, and meanwhile achieve the torque switching in the torque phase or maintain the torque value in the inertia phase.

At each sample time, a constrained finite time optimization problem formed in Formulae (1) is solved to obtain the optimal control vector U_0. In this optimization, the constraints of states and inputs (X and U) are expressed in the form of polyhedron. According to the related control theory, terminal set X_f and terminal cost P are the vital factors to ensure the feasibility and stability of the control problem. Specific theories, proofs and calculation results of terminal set and terminal cost will be explained in the full text.

$$\begin{aligned} J_0^*(x(t)) = \min_{U_0} \quad & J_0(x(t),U_0) = x_N^{\mathrm{T}} P x_N + \sum_{k=0}^{N-1} x_k^{\mathrm{T}} Q x_k + u_k^{\mathrm{T}} R u_k \\ \text{subj. to} \quad & x_{k+1} = Ax_k + Bu_k,\ k = 0, \quad ,N-1 \\ & x_k \in X,\ u_k \in U,\ k = 0, \quad ,N-1 \\ & x_N \in X_f \\ & x_0 = x(t) \end{aligned} \tag{1}$$

Due to the different motion equations and constraints in different phases, a corresponding model predictive controller is constructed for each stage. And then all phases are integrated together to achieve the micro-slip control of the gearshift process for the wet DCT. Take the upshift from gear 1 to gear 2 as an example. The simulation results of micro-slip control and lockup control are compared in Figure 3.



(a) Micro-slip control based on MPC (b) Lock up control

Figure 3. Numerical results of transient responses in upshift.

In the micro-slip control, the upshift process can be divided into two main stages. Before the upshift begins, the micro-slip on clutch 1 is stabilized at around 20 rpm by the model predictive controller and it is also maintained in the torque phase to avoid the undesirable stick slip transition. In the inertia phase, the micro-slip control is transferred to clutch 2. Engine speed is decreased by reducing the engine torque until it can be synchronized with clutch 2. After the upshift is complete, the micro-slip control is still on the clutch 2 to reduce the transmission of the engine torsional vibration. The whole upshift can be completed in about 0.7s and there is smaller torque fluctuation of the transmission of the transmission output shaft. While in the lockup control strategy, the torque fluctuation is larger especially in inertia phase which will reduce the shift smoothness. Besides, it takes longer time to complete the upshift in lockup controller. Therefore, the proposed micro-slip control based on MPC can achieve better shift performance. Other working conditions such as downshift are also discussed to provide a more comprehensive support.

CONCLUSIONS

The dynamic system of the vehicle powertrain is basically modelled, including a hydraulic actuator model. The micro-slip control based on model predictive control is then proposed to improve the shift quality of wet dual clutch transmission. The feasibility and stability of the control algorithm is verified and the model predictive controllers for each stage of gearshift is established to achieve micro-slip control during the entire gearshift. Simulation results are obtained by the present dynamic system and the proposed control strategy is validated to have better performance compared to the lockup control.

EVALUATING THE UDWADIA-KALABA APPROACH FOR MODELLING MULTIBODY ROTORCRAFT MECHANISMS

Aravind Kumar Kamaraj*[1], Djamel Rezgui [1], and Branislav Titurus [1]
[1]School of Civil, Aerospace and Mechanical Engineering, University of Bristol, Bristol, UK

Summary Udwadia-Kalaba (UK) approach allows for the construction of the equations of motion of a constrained multibody system as a set of ordinary differential equations (ODEs) even when redundant coordinates are employed. The approach utilizes the concept of Moore-Penrose generalized inverse of non-square matrices to calculate constraint forces that account for the holonomic and non-holonomic constraints present in the system. Thus, UK approach can improve the ease of implementation of the multibody simulation engine as a computer program and allows for the use of explicit time integration schemes. In this work, the accuracy of UK method is first explored considering the example of a double four bar mechanism for which the results have been compared against existing techniques such as minimal coordinates approach and augmented Lagrangian formulation.

INTRODUCTION

In most of the exisitng multibody dynamics software, redundant coordinates approach is adopted and the constraints are enforced with the help of Lagrange's multipliers. This results in the equations of motion of a system being formulated as a set of differential algebraic equations (DAEs). The solution of DAEs require specialized implicit numerical methods for time integration and are often tedious to implement in a computer program. Further, the accuracy of the numerical integration decreases with increase in the index of DAEs that are solved. As the engineering problems solved by these multibody dynamics software become increasingly complicated, various techniques such as index reduction techniques, constraint violation stabilization techniques and constraint violation elimination techniques have been developed to improve the accuracy of DAE solvers [1]. While most of the modern multibody dynamics software employ such improvised DAE solution algorithms, there is a huge potential for improvement in this area.

Udwadia and Kalaba, in 1992, proposed a new formulation of the equations of motion for a system of constrained rigid bodies wherein the equations of motion could be reduced to a set of ordinary differential equations (ODEs) even when redundant coordinates are used [2]. Furthermore, the formulation also treats both schleronomic and rheonomic constraints in the same way. These features make the Udwadia - Kalaba (UK) approach attractive for implementation in a computer program. We intend to develop a multibody dynamics code for the analysis of rotorcraft systems based on the UK approach. To this end, a simpler exploratory example of double four bar mechanism has been modelled using the UK approach and the accuracy of the obtained results is compared with that of those available in [3].

DOUBLE FOUR BAR MECHANISM

In [3], a collection of benchmark problems in multibody dynamics have been provided, amongst which a double four bar mechanism has been chosen for this study. This particular benchmark problem has been chosen as multiple published results based on different formulations such as augmented Lagrangian and minimal coordinates approach are available and could be used for comparison against the results obtained from this study. The initial configuration of the double four bar mechanism, with all the links having a length of 1 m and a uniform mass distribution of 1 kg/m, is indicated in Fig. 1. For each link, three coordinates have been assigned, two corresponding to the global x and y coordinates and the other corresponding to the angle subtended by the link with respect to the global x-axis. Consequently, a total of fifteen redundant coordinates and fouteen constraints have been used for the formulation.

Let the redundant coordinates be denoted as $\mathbf{q}$. If the equations of motion of the unconstrained system are represented as $\mathbf{M}\ddot{\mathbf{q}} = \mathbf{Q}(\mathbf{q}, \dot{\mathbf{q}}, t)$ and the holonmic constraints are differentiated twice and represented as $\mathbf{A}(\mathbf{q}, \dot{\mathbf{q}}, t)\ddot{\mathbf{q}} = \mathbf{b}(\mathbf{q}, \dot{\mathbf{q}}, t)$, then the equations of motion of the constrained system can be formulated based on the UK approach as follows [2]:

$$\mathbf{M}\ddot{\mathbf{q}} = \mathbf{Q} + \mathbf{M}^{1/2}\left(\mathbf{A}\mathbf{M}^{-1/2}\right)^{+}\left(\mathbf{b} - \mathbf{A}\mathbf{M}^{-1}\mathbf{Q}\right) \tag{1}$$

where the superscript $+$ denotes the Moore-Penrose generalized inverse. For the double four bar mechanism, using the UK approach leads to a set of fifteen second order ODEs as the final equations of motion. In comparison, the Lagrange multipliers method yields a set of DAEs consisting of 15 second order ODEs and 14 algebraic constraints.

RESULTS AND DISCUSSION

In [3], the time histories of the x-coordinate of displacement and velocity at joint 1 and the drift in the total energy with respect to that of the intial condition were reported by employing various formulations and ODE (or) DAE solvers. In this work, UK approach was adopted for formulating the problem and the in-built explicit ODE solver in MATLAB, *ode45*, was used for time integration. For the solver configuration, the relative tolreance was set as 10^{-5} and the other

parameters were left with default values. The simulated results corresponding to the x-displacement of joint 1 is shown in Fig. 2 (a) and that of velocity is shown in Fig. 2 (b).

In [3], the maximum drift in the total energy, $E_d(t) = E(t) - E(t_0)$, has been taken as a measure of accuracy. Hence, a lower drift in energy indicates a better accuracy. The accuracy, expressed as $\max(E_d(t))$, obtained using the UK approach is reported in Table 1 and compared aginst the results reported by other researchers in [3]. It could be seen that the UK approach provides an order of magnitude improvement in accuracy over the augmented Lagrangian method while the best accuracy is obtained with the minimal coordinates approach. This highlights the potential of UK approach as a promising candidate for the implementation of multibody dynamics formulation as a computer program.

CONCLUSIONS

The remarkable improvement in accuracy along with the ease of handling constraints in the UK approach has encouraged its implementation in the multibody dynamics suite that we intend to develop for rotorcraft applications. Further investigations regarding the applicability of UK approach to mechanisms that are of interest to the rotorcraft community will be performed and the results will be presented at the conference.

UNCERTAINTY ANALYSIS OF MECHANICAL DYNAMIC USING HHT AND LMD

Jiang Cui[1], Zhihua Zhao [*1], Jiawei Liu [1], Xuanbo Shu [1], and Gexue Ren [1]
[1]Department of Engineering Mechanics, Tsinghua University, Beijing, China

Summary For time-dependent uncertainty analysis, the response surface (RS) method suffers from a problem that the accuracy decays with time increasing. This study proposes two methods: RS method incorporated Hilbert-Huang transform (RS-HHT) and RS method incorporated local mean decomposition (RS-LMD) to solve the problem. The main steps are that firstly HHT or LMD is used to decompose the original signal into several monocomponent signals, and then the instantaneous amplitude and phase of each monocomponent are fitted with the uncertainty parameters. Two examples, the single pendulum and the slider crank mechanism, are used to show the effectiveness of the proposed methods. Both of RS-HHT and RS-LMD can get tighter bound than RS method. Furthermore, RS-LMD is a litter better than RS-HHT. When the response is monotonous, RS-HHT and RS-LMD are degenerated to RS method.

INTRODUCTION

The effect of uncertainty is significant in the engineering, because the important uncertainty factor should not be neglected [1]. One important purpose of solving the interval uncertainty dynamic problem where the uncertainty parameter is interval type rather than probabilistic type to get the upper bound (UB) and lower bound (LB), as is shown in Figure 1. The conventional response surface (RS) method is widely used to obtain the time bound and the main idea of RS method is to develop surrogate models at each time instant. The conventional RS method faces a serious problem that the accuracy deteriorates at long time instants. Many methods [2, 3] have been proposed to overcome the problem that conventional RS method possesses but did not solve the problem completely. There remains a strong need for an efficient method that can overcome the shortcoming of RS method. To this end, this paper proposes two methods: RS method incorporated Hilbert-Huang transform (RS-HHT) and RS method incorporated local mean decomposition (RS-LMD).

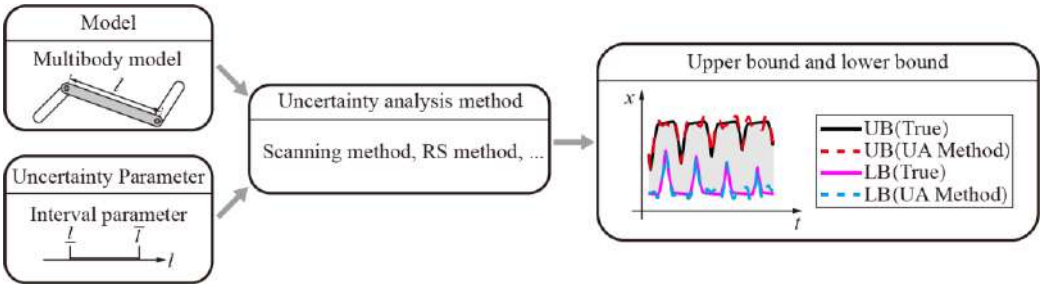

Figure 1. A schematic of the interval uncertainty analysis (UA) method for the dynamic problem.

PROBLEMS AND METHODS

The conventional response surface (RS) method shown in Figure 2(b) encounters the greatest challenge that the accuracy decreases with the increment of time. The linear single-degree-of-freedom (1DOF) model shown in Figure 2(a) is used as an example to illustrate the problem of the conventional RS method, in which the surrogate model of RS method is trained by three samples and corresponding responses. A quadratic polynomial surrogate model $P(\omega,t)$ is used to approximate the relationship between the response x and the uncertain frequency ω through three obtained points at each time instant, as is shown in Figure 2(b). When the time becomes large, RS method fails to approximate the real relationship, thus the upper and lower bound calculated from the maximum and minimum of each RS model are not accurate.

The above problem of 1DOF model can be overcome by the method shown in Figure 2(c), in which the amplitude a and phase φ are fitted with the uncertain parameter ω using the quadratic polynomial model. The relationship between the amplitude/phase and the parameter is simple and is nearly linear with time. The proposed surrogate model is

$$\text{given } t: x(\omega,t) \approx \hat{a}(\omega,t)\cos\left(\hat{\varphi}(\omega,t)\right) \tag{1}$$

where $\hat{a}$ is the amplitude surrogate model and $\hat{\varphi}$ the phase surrogate model. Therefore, the relationship is correctly approximated no matter t is small or large, and the upper and lower bound are accurate.

For the multicomponent response, the signal decomposition should be implemented before conducting surrogate models, thus RS-HHT and RS-LMD are proposed. A mechanic response is always a multicomponent signal which contains several monocomponent signals. Hilbert-Huang transform (HHT) and local mean decomposition (LMD) are two well-understood adaptive signal decomposition methods. With HHT or LMD technique, any multicomponent signal can be decomposed into a set of monocomponent signals, and every monocomponent signal can be written as $a(t)\cos\varphi(t)$ form no matter it is non-linear or linear, non-steady or steady. Combined with HHT or LMD, a new surrogate model is proposed as

*Corresponding author. E-mail: zhaozh@tsinghua.edu.cn.

$$\text{given } t: x(\mathbf{b},t) \approx \sum_{i}^{m} \hat{a}_i(\mathbf{b},t)\cos\left(\hat{\varphi}_i(\mathbf{b},t)\right) + \hat{r}(\mathbf{b},t) \tag{2}$$

where m is number of the monocomponent signals, $\mathbf{b}$ the uncertainty parameter vector, $\hat{a}_i$ the amplitude surrogate model of each monocomponent, $\hat{\varphi}_i$ the phase surrogate model of each monocomponent, and r is the residual. The surrogate model is a new surrogate type, and the non-linearity degree of the proposed surrogate model is improving with time increasing. RS method incorporated Hilbert-Huang transform is named RS-HHT, and RS method incorporated local mean decomposition is named RS-LMD.

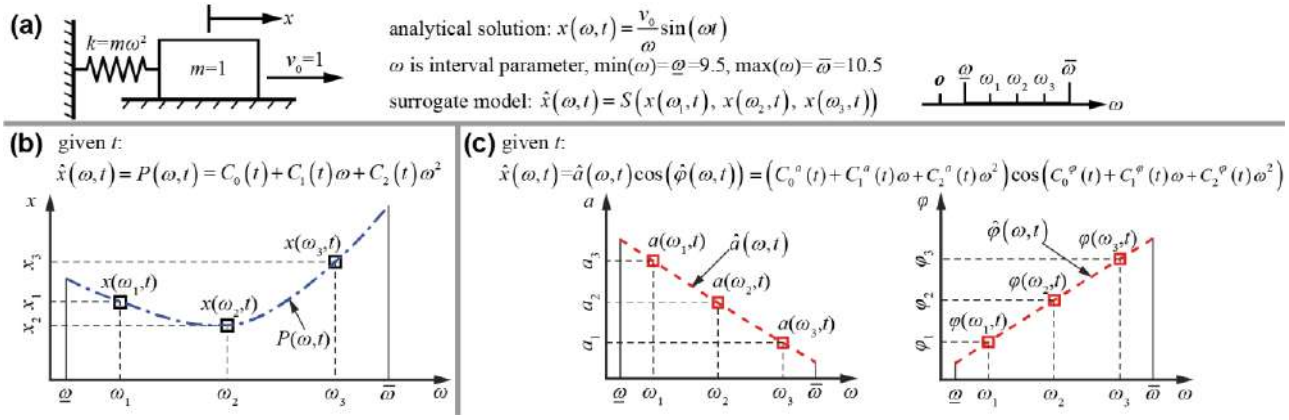

Figure 2. The problem of the conventional method and the main idea of the proposed method: (a) 1DOF model with an uncertainty parameter ω. (b) The surrogate model of the conventional method. (c) The surrogate model of the proposed method.

APPLICATIONS

A rigid slider crank mechanism is used to show the effectiveness of the proposed methods. Figure 3(a) is a rigid slider crank model with two uncertainty parameters, the crank length l_1 and the torque τ. The scanning method, conventional RS method, RS-HHT, RS-LMD are used to get the bounds of the slider displacement x_3. The scanning method is to scan the original equation to get precise bounds as a reference result using 50×50 samples. 12 samples and corresponding responses are used to train the surrogate model of RS, RS-HHT, RS-LMD method. From Figure 3(b), RS method cannot get a reasonable result, but RS-HHT and RS-LMD can approximate the real solution. From Figure 3(c), RS-HHT and RS-LMD can get high-accuracy bounds. Furthermore, RS-LMD has a little better performance than RS-HHT. RS-HHT and RS-LMD can also be effective in the flexible slider crank and flexible pendulum model.

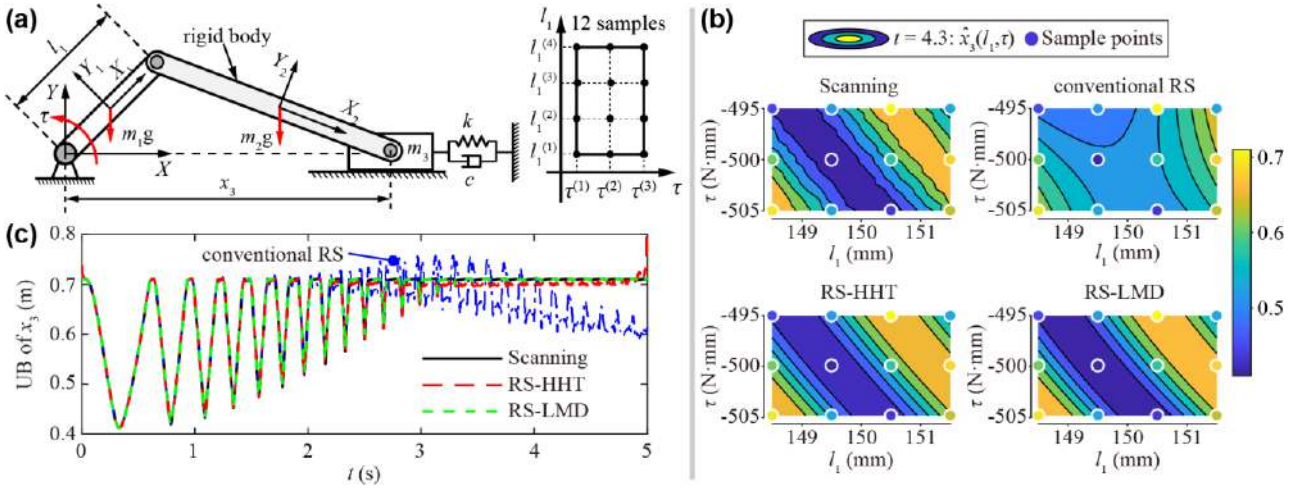

Figure 3. Uncertainty analysis of a rigid slider crank model: (a) The rigid slider crank model with 2 uncertainty parameters. (b) The surrogate models by scanning, RS, RS-HHT, RS-LMD method at t = 4.3s. (c) The upper bound (UB) of x_3 by different methods.

SIMULATION OF ROAD SURFACES PROFILES BY A STOCHASTIC PARAMETRICAL MODEL OF SECOND ORDER

Alfons Ams
Institute of Mechanic and Fluiddynamic, Technical University of Freiberg, Freiberg, Germany

Summary Road irregularities have an important influence on the dynamic behavior of vehicles. Knowledge of their characteristics and magnitude is essential for the design of the vehicle. The problem of interest is the simulation of road surfaces profiles because modern test facilities and computer simulations of vehicle dynamics needs driving excitations. An import issue is the power spectral densities and the approximation by analytical formulas. In the paper a stochastic parametrical nonlinear model of second order with bounded amplitudes will be discussed. Some analytical and numerical results will be shown.

Road Surface Profiles

The road surface profiles are defined by ISO8608 Mechanical vibration – Road surface profiles – Reporting of measured data [1]. Figure 1 shows an example of a measured road.

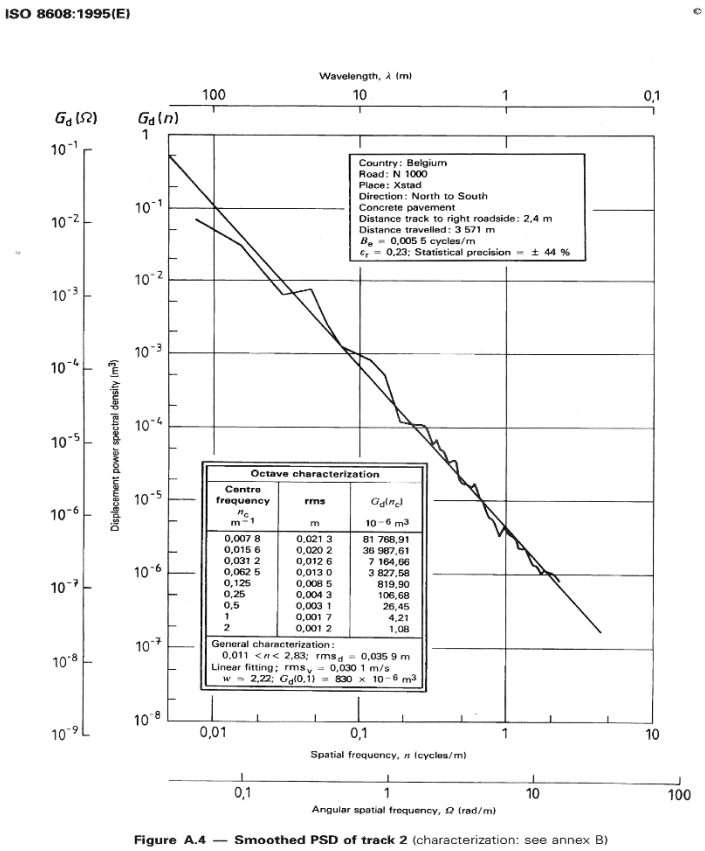

Figure A.4 — Smoothed PSD of track 2 (characterization: see annex B)

Figure 1: Measured road surface profile [1]

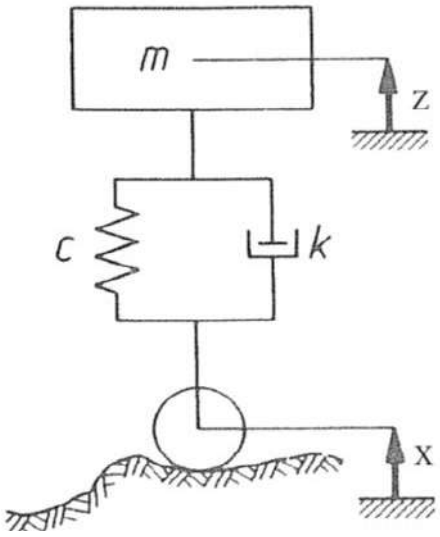

Figure 2: A quarter car (1 DOF) with road surface profile X_t

Stochastic Parametrical Model of Second Order

The stochastic parametrical nonlinear model of second order

$$\ddot{X}_t + 2\vartheta\omega_0\dot{X}_t + \omega_0^2 X_t - \frac{\sigma^2}{2}(X_0^2 - X_t^2)\dot{X}_t + \sigma\sqrt{(X_0^2 - X_t^2)(\dot{X}_0^2 - \dot{X}_t^2)}\,\dot{W}_t = 0$$

With the parameters σ intensity of white noise, ω_0 the corner frequency, ϑ the damping coefficient (Lehr), X_0 and $\dot{X}_0$ are the maximum values of the amplitudes $|X_t| \le X_0, |\dot{X}_t| \le \dot{X}_0$ and W_t the Wiener process with the mean value $\mathrm{E}\{dW_t\} = 0$ and the variance $E\{dW_t^2\} = dt$. With the coordinates of state space $X_{1t} = X_t$ and $X_{2t} = \dot{X}_t$ the stochastic differential equations (Ito) are

$$\mathrm{d}X_{1t} = X_{2t}dt$$

$$\mathrm{d}X_{2t} = (-2\vartheta\omega_0 X_{2t} - \omega_0^2 X_{1t})dt - \sigma\sqrt{(X_0^2 - X_{1t}^2)(\dot{X}_0^2 - X_{2t}^2)}\,dW_t \qquad \text{with} \quad |X_{1t}| \le X_0, |X_{2t}| \le \dot{X}_0$$

The Fokker Planck equation of the probability density function $p(x_1, x_2)$ is

$$\frac{\partial \mathrm{p}}{\partial \mathrm{t}} + x_2 \frac{\partial \mathrm{p}}{\partial x_1} - \frac{\partial}{\partial x_2}(2\vartheta\omega_0 x_2 + \omega_0^2 x_1)p - \frac{\sigma^2}{2}\frac{\partial^2}{\partial x_2^2}(X_0^2 - x_1^2)(\dot{X}_0^2 - x_2^2)p = 0$$

Examples: Probability density function $p(x_1, x_2)$

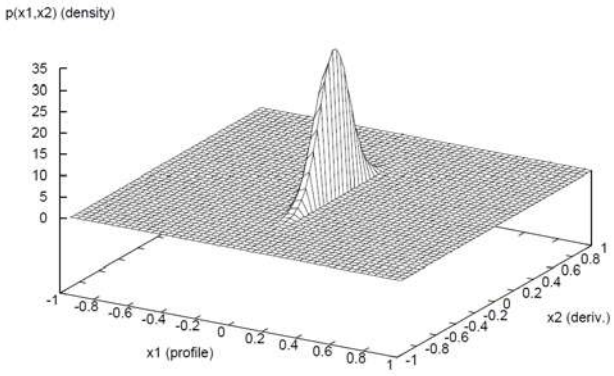

Figure 3: $\vartheta = 50, \omega_0 = 10, \sigma = 5, X_0 = 1, \dot{X}_0 = 1$

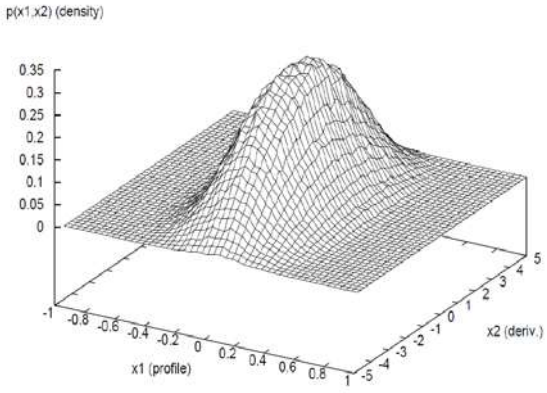

Figure 4: $\vartheta = 3, \omega_0 = 10, \sigma = 5, X_0 = 1, \dot{X}_0 = 5$

3-D STABLE MOTION AND STABILITY ANALYSIS OF UNDERWATER GLIDERS

Bo Wang[1], Caishan Liu *1
[1]State Key Laboratory for Turbulence and Complex Systems, College of Engineering, Peking University, Beijing, China

Summary This paper focuses on the study of the equilibrium solution and the stability for the 3-D motion of underwater gliders. Equilibrium solution is critical because it represents the working pattern of an underwater glider and has essential dynamic features embedded. This stable 3-D motion, spiral mode motion, given by the equilibrium solution is the gliding mode of the underwater glider during the designated sea area observation. In order to facilitate analysis, we establish a reduced-dynamics model of the underwater glider based on symmetry reduction, and we can utilize the physical quantities projected into the quotient space to characterize the motion of the glider. We further analyse the stability characteristics of the equilibrium solution and conclude that the equilibrium solution is asymptotically stable.

INTRODUCTION

Since Stommel [1] first proposed the concept of the underwater glider, as a movable underwater measurement platform, the underwater glider has great application potential in the observation and characterization of marine ecosystems, underwater detection and seabed exploration. It glides downwards and upwards in the ocean by controlling its buoyancy to make itself negatively and positively buoyant, and it adjusts attitude by moving the location of the battery pack. The research on the motion performance of the underwater glider starts from the establishment of dynamic equations. Many scholars have contributed to the dynamic model of underwater gliders and investigated the characteristics of the stable motion [2,3]. However, these models ignore the problem of motion arbitrariness in the process of solving the equilibrium solution and the stability of the underwater glider under 3-D motion is rarely studied, which is the main motion of the observation of the designated sea area.

DYNAMICS MODELING OF UNDERWATER GLIDER

Configuration space and dynamic equation

As shown in the Figure 1, we regard the shell, the counterweight, the antenna, and the buoyancy adjustment device (gasbag) as a rigid body, and its mass is represented by m_b. The attitude adjustment system (battery pack) is served by a movable battery pack, whose mass is represented by m_c. To facilitate the description of the dynamic model of the underwater glider, we define a inertial coordinate frame $E-xyz$ and a body-fixed coordinate frame $B-XYZ$. The configuration space of the underwater glider is a six-dimensional manifold,

$$Q=\underbrace{(-\pi/2,\pi/2)\times(-\pi/2,\pi/2)}_{R}\times\underbrace{\mathrm{SE}(2)\times\ ^{1}}_{G}, \tag{1}$$

with the coordinates $\boldsymbol{q}=(\varphi,\theta,(z,x,\psi),y)$, where (x,y,z) are the coordinates of the glider buoyancy centre in $E-xyz$, and (φ,θ,ψ) are three Euler angles. In the body-fixed coordinate frame, we use $\boldsymbol{r}_b$ to represent the position vector between the gasbag buoyancy centre and the glider buoyancy centre, and use $\boldsymbol{r}_t=(l_t,e_r\cos\phi,e_r\sin\phi)$ to represent the position vector between the centre of mass of the battery pack and the floating centre, where l_t is the position of the centre of the battery pack along the X-axis, e_r is the rotation radius about the X-axis, and ϕ is the rotation angle.

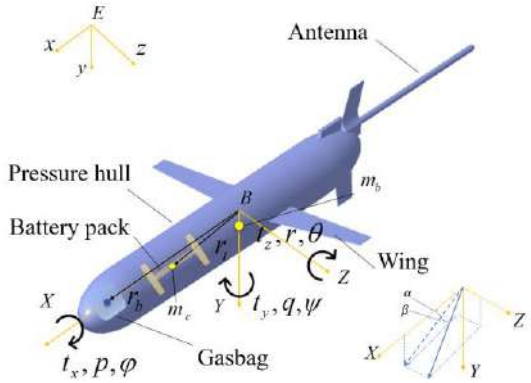

Figure 1. Schematic diagram of underwater glider structure and coordinate system.

Denote by $L:TQ\to\mathbb{R}$ the modified Lagrangian of the underwater glider system with the effect of the inertial hydrodynamics taken into account, and by $\boldsymbol{F}:TQ\to T^*Q$ the force field including gravity, buoyancy and viscous hydrodynamics. In coordinates, $\boldsymbol{F}$ takes the form $\boldsymbol{F}(\boldsymbol{q},\dot{\boldsymbol{q}})=F_i(\boldsymbol{q},\dot{\boldsymbol{q}})\mathrm{d}q^i$. The dynamic equations with six-degree-of-freedom can be established using the Euler-Lagrangian equation [3]:

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial T}{\partial \dot{q}^i}-\frac{\partial T}{\partial q^i}=F_i,(i=1,\quad,6), \tag{2}$$

*Corresponding author. E-mail: liucs@pku.edu.cn

Symmetry and reduced system

Noting the decomposition $Q = R \times G$ shown in (1), we define the action of the Lie group G on Q as follows: $\forall \boldsymbol{h} \in G, \forall \boldsymbol{q} = (\boldsymbol{r}, \boldsymbol{g}) \in Q$, where $\boldsymbol{r} \in R$, $\boldsymbol{g} \in G$, we have $\boldsymbol{\Phi_h}(\boldsymbol{q}) := \boldsymbol{hq} = (\boldsymbol{r}, \boldsymbol{hg})$. More specifically, for $\boldsymbol{h} = ((a, b, \alpha), c)$, $\boldsymbol{r} = (\varphi, \theta)$ and $\boldsymbol{g} = ((z, x, \psi), y)$, we have $\boldsymbol{hq} = (\varphi, \theta, (z\cos\alpha - x\sin\alpha + a, z\sin\alpha + x\cos\alpha + b, \psi + \alpha), y + c)$. We claim that the underwater glider system has the following two symmetries:

(1) The Lagrangian is invariant, i.e., $L(\boldsymbol{q}, \dot{\boldsymbol{q}}) = L(\boldsymbol{hq}, \boldsymbol{h}_*\dot{\boldsymbol{q}}), \forall (\boldsymbol{q}, \dot{\boldsymbol{q}}) \in TQ, \forall \boldsymbol{h} \in G$, where $\boldsymbol{h}_*: TQ \to TQ$ represents the tangent map induced by the action of $\boldsymbol{h}$ on Q.

(2) The force field is invariant, i.e., $\boldsymbol{h}^*\boldsymbol{F}(\boldsymbol{hq}, \boldsymbol{h}_*\dot{\boldsymbol{q}}) = \boldsymbol{F}(\boldsymbol{q}, \dot{\boldsymbol{q}}), \forall (\boldsymbol{q}, \dot{\boldsymbol{q}}) \in TQ, \forall \boldsymbol{h} \in G$, where $\boldsymbol{h}^*: T^*Q \to T^*Q$ represents the cotangent map induced by the action of $\boldsymbol{h}$ on Q.

Therefore, we can define a reduced Lagrangian l on the quotient manifold $TQ/G \cong TR \times \mathfrak{g}$, where $\mathfrak{g}$ is the Lie algebra of G. A set of coordinates of TQ/G is given by $\boldsymbol{u} = (\boldsymbol{r}, \dot{\boldsymbol{r}}, \boldsymbol{\xi})$, where $\boldsymbol{\xi} \in \mathfrak{g}$. We have the following theorem:

Theorem 1 For a curve $\boldsymbol{q}(t) = (\boldsymbol{r}(t), \boldsymbol{g}(t)) \in Q$, $t \in [a, b]$, let $\boldsymbol{\xi}(t) = ((\boldsymbol{g}(t))^{-1})_*\dot{\boldsymbol{g}}(t)$. If $\boldsymbol{q}(t)$ satisfies the Euler-Lagrange equations (2), then $\boldsymbol{u}(t) = (\boldsymbol{r}(t), \dot{\boldsymbol{r}}(t), \boldsymbol{\xi}(t)), t \in [a, b]$ satisfies the following reduced equations:

$$\begin{cases} \dfrac{\mathrm{d}}{\mathrm{d}t}\dfrac{\partial l}{\partial \dot{r}^\alpha} - \dfrac{\partial l}{\partial r^\alpha} = f_\alpha^R, \alpha = 1, 2, \\ \dfrac{\mathrm{d}}{\mathrm{d}t}\dfrac{\partial l}{\partial \xi^a} - C_{ba}^c \xi^b \dfrac{\partial l}{\partial \xi^c} = f_a^G, a = 1, \quad, 4, \end{cases} \tag{3}$$

where $\xi^1, \cdots, \xi^4$ are the components of $\boldsymbol{\xi}$ decomposed in a basis $\{\boldsymbol{e}_a \mid a = 1, \cdots, 4\}$ of $\mathfrak{g}$, $f_\alpha^R, \alpha = 1,2$ and $f_a^G, a = 1, \cdots, 4$ are the components of $\boldsymbol{F}$ pulled back to T^*Q/G, and $C_{ab}^c, a, b, c = 1, \cdots, 4$ are the structure constants of $\mathfrak{g}$ defined by $[\boldsymbol{e}_a, \boldsymbol{e}_b] = C_{ab}^c \boldsymbol{e}_c$.

Equation (3) determines a reduced dynamic system on TQ/G:

$$\dot{\boldsymbol{u}} = \boldsymbol{Y}(\boldsymbol{u}), \tag{4}$$

where $\boldsymbol{Y}$ is a tangent vector field on TQ/G that can be obtained by transforming (3) into first-order forms.

EQUILIBRIUM SOLUTION AND STABILITY ANALYSIS

In the reduced dynamics system, we analyse the descending process in 3-D motion. We use the axis translation and circumferential rotation of the battery pack as the input conditions. Then we can get $\boldsymbol{u}_0 = [\varphi_0, \theta_0, \dot{\varphi}_0, \dot{\theta}_0, \xi_0^1, \xi_0^2, \xi_0^3, \xi_0^4]$ at each equilibrium point. In the reduced dynamic system, we can obviously transform the time-related physical quantities into time-independent physical quantities in the equilibrium solution. Under this transformation, in the equilibrium solution, $\dot{\varphi} = 0$, $\dot{\theta} = 0$. We can get equilibrium solution by changing the input pitch control and roll control of the battery pack, which do not show here due to space limitation.

For dynamic systems, we usually use the Lyapunov stability theory for analysing the stability characteristics near the equilibrium solution of the system. For the equilibrium solution $\boldsymbol{u}_0$ of the reduced dynamic system, its Lyapunov stability characteristic is determined by the eigenvalue of the Jacobi matrix of the system at this point. And the Jacobi matrix is defined as, $\boldsymbol{J}(\boldsymbol{u}_0) = \partial \boldsymbol{Y}/\partial \boldsymbol{u}$.

We choose six different positions of the battery pack as inputs, while the net buoyancy is 3N. According to the meaning of Lyapunov stability judgment conditions, we calculate the eigenvalues of the $\boldsymbol{J}$ matrix in these cases, the real parts of which are shown in Table.1. Obviously, these equilibrium solutions are all asymptotically stable.

CONCLUSIONS

The paper introduces the reduced dynamics model of the underwater glider, which based on the symmetry of the configuration space. And the reduced dynamics model in quotient space eliminates the arbitrariness of motion, allowing us to more clearly focus on the essential physical quantities in the 3-D spiral motion of the underwater glider. Besed on the reduced dynamics model, we have processed the equations to obtain the equilibrium solutions of its motion. Moreover, we have investigated the asymptotic stability of the equilibrium solution by linearizing the reduced equation.

Summary A motion planning method for automated vehicles in structured road scenarios is considered. Utilizing a Hermite interpolation method with three consecutive clothoids, it is shown that real time generation of feasible trajectories for automated vehicles is possible. Separate path generation and consecutive optimal velocity planning is considered. The path is generated by solving nonlinear equations of the spline using Newton's method. Optimal velocity planning includes forward, backward and joint iteration processes and additional smoothing steps. Multiple plans that are all feasible are generated and one can be chosen based on criteria of choice of the passenger. A left turn in an intersection scenario is used as an illustrative example.

INTRODUCTION

Interpolating curve planning methods for automated vehicles can generate smooth solutions for a given set of waypoints, and clothoid curves have the advantage of making smooth transitions between straight lines and curved arcs [1]. A G^2 Hermite interpolation proposed in [2] to generate curves that consists of three consecutive clothoids, are second order smooth and satisfy boundary conditions of arbitrary initial and final position, angle, and curvature. To apply such a path generation method to automated vehicles, feasibility of the path should be validated using a kinematic vehicle model. In this paper, we formulate the problem of motion planning in two consecutive parts: fFirst, path generation and second, velocity planning. Since the proposed method is computationally cheap, a set of multiple plans can be computed in real time. The motion planner can be applied to automated vehicles in urban road situations to perform a large set if different maneuvers. A left turn at an intersection will be used below as an illustrative example.

MOTION PLANNING STRATEGY

Problem description and flow chart

Figure 1 shows the configuration of the motion planning problem. The initial is at the origin, and final position and tangent are given from the global waypoint. For simplicity, it is assumed that both initial and final curvatures are zero. The motion planner should generate a path (a curve of drawn between the initial and final point) and desired velocity which is given as a function of traveled distance along the path. The generated path should be second order continuous, that means the curvature should be continuous. The desired velocity should meet the input constraints of the vehicle.

Figure 2 describes the flow chart of the motion planner. The planning problem is divided into two parts: lateral planning and longitudinal planning. First, in the lateral planning, the geometric feasibility of the given global waypoint is verified. Then, for multiple spline generated, the parameter space of the curve is truncated to the region where any parameters generate feasible paths. In the longitudinal planning level, the desired path is given from the lateral planning. Based on the idea of linear time optimal velocity planner proposed in [3], a desired speed profile that considers constraints is generated for each path.

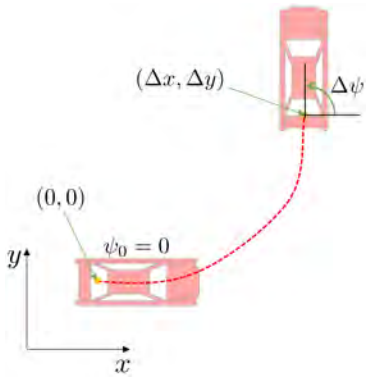

Figure 1: Motion planning configuration for a 90 degree left turn.

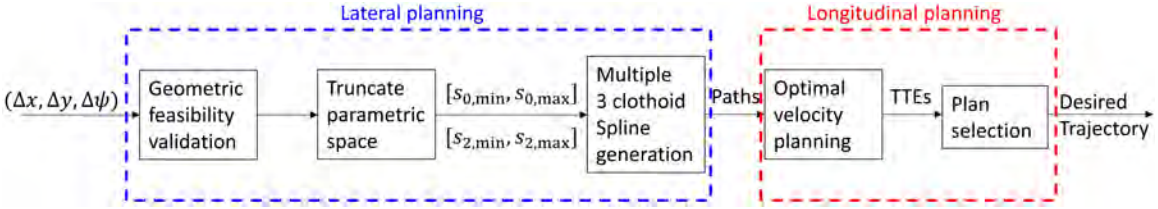

Figure 2: Flow chart of motion planner: Lateral planning and longitudinal planning is done sequentially. The input of the motion planner is the relative position and tangent of the waypoints. The output is the path and desired velocity along the path.

*Corresponding author. E-mail: orosz@umich.edu.

Lateral planning

The first step of lateral planning is validation of the geometric feasibility of the final position and tangent given by the waypoint. In this step, using 3-D lookup table that is computed offline is used to verify if the given waypoint id feasible. Next, the existence of G^2 Hermite interpolating curve with 3 clothoids is proven using the method presented in [2]. The interpolation problem has 10 unknowns and 8 equations, therefore two free variables can be used as parameters. We choose the length of the first arc s_0 and the length of the third arc s_2 as these two parameters. They can be initially assigned to certain values. Geometric feasibility validation is the process of finding the existence of the interpolating spline that satisfies the curvature constraint which comes from the maximum steering angle of the vehicle. In the truncation step, we numerically identify the region in the (s_0, s_2) parameter space where they admit feasible solutions. All the remaining constraints that are related to time derivatives of vehicle's state is handled in the consecutive longitudinal planning.

Longitudinal planning

The longitudinal planning problem is presented in equation (1). For ride comfort, lateral acceleration should be limited to some given level. Moreover, the the speed at which the steering angle can be turned is also limited. The velocity constraint $v_{\text{const}}(s)$ is chosen as the minimum value between the ride comfort or steering angle rate constraints. From generated path, limiting the lateral acceleration can be translated to limiting the velocity: $a_{\text{lat}} = \kappa(s)v(s)^2 < a_{\text{lat,max}}$. Since the steering angle rate constraint contains time information, it can also be translated to velocity constraint. We solve equation (1) as proposed in [3]. Thus, the longitudinal planning consists of 3 steps: 1) Forward iteration, 2) Backward iteration, 3) Joint iteration. Forward iteration is forward propagation using a_{max}, backward iteration is backward propagation using a_{min}, and joint iteration is choosing minimum value between the two on each point. Such iteration method can generate optimal velocity profile under given constraint with minimal computational burden since the computation time is linear to the number of steps [3]. Finally, combining multiple lateral desired paths from the lateral planning and desired velocity profile corresponding to each path, a set of different desired trajectories that are all feasible is generated. One may select one of these trajectories based on his/her own preferences.

$$\begin{aligned} &\min_{v(s)} t_f \\ &\text{such that} \\ &\dot{s} = v, \\ &\dot{v} = a, \\ &s(t_f) = s_{\text{fin}}, \\ &a_{\text{min}} \le a \le a_{\text{max}}, \\ &0 \le v(s) \le v_{\text{const}}(s) \end{aligned} \tag{1}$$

RESULTS

Example result of motion planning is shown in Figure 3. The waypoint is that of a left turn in an intersection with $(\Delta x, \Delta y, \Delta\theta) = (10\text{m}, 10\text{m}, \pi/2)$. Multiple different feasible paths are generated, and for the selected one the velocity profile and steering angle profile are depicted.

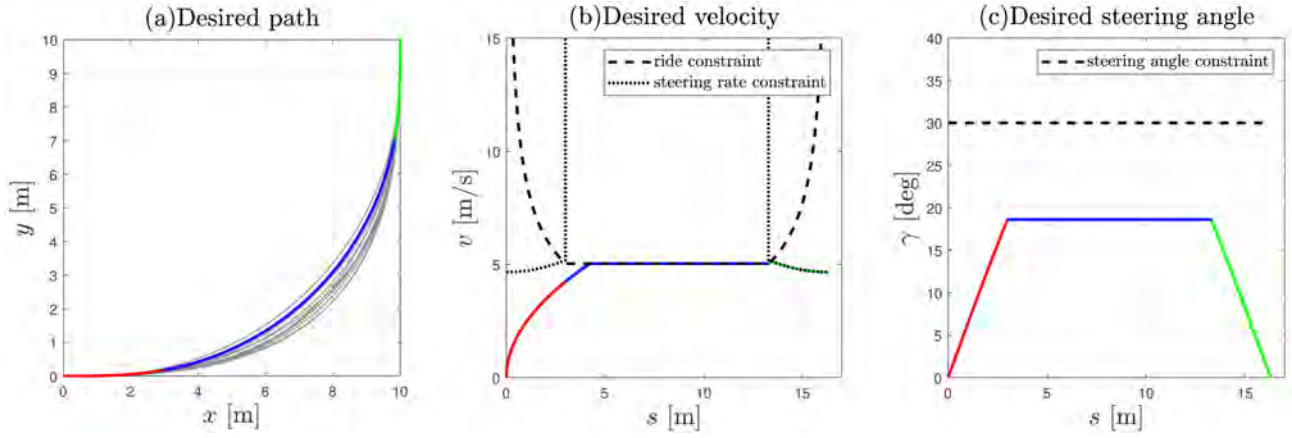

Figure 3: Motion planning results for a left turn. (a) Multiple feasible paths are colored gray and three segments of the selected one are colored red, blue, and green. (b) Velocity satisfying the constraints along the chosen path. (c) Steering angle satisfying the constraint along the chosen path.

UNLOCKING DYNAMICS OF LOW-SHOCK SEGMENTED NUT DEVICE

Juncheng Lin[1], Caishan Liu[1]
[1]State Key Laboratory for Turbulence and Complex Systems, College of Engineering, Peking University, Beijing 100871, People's Republic of China

Summary Low-shock segmented nut (LSN), a typical explosive separation device, consisting of three parts: connecter, actuator and separator. In this paper, a complete mechanical model including connection and unlocking stages is established for LSN device. Actuating is realized by pyrotechnics and separation is achieved by relative movement of internal parts. Dynamic equation of LSN is established in first order impulse form where LZB theory is introduced to deal with the coupling of multi-point contacts. The velocity of internal parts has sudden changes originated from outer impulses and subsequent internal collisions. Separation time are also obtained by numerical calculation. Parametric analysis is held to find out the influence of friction coefficient, restitution coefficient and other geometrical design.

INTRODUCTION

In aerospace engineering, separation devices are usually used between two adjacent sections of rocket [1]. Separation devices have three characteristics in common: 1) effective connection, 2) enough actuation power, and 3) reliable separation design. Thread fastener is a typical structure to enhance the link between neighbour sections. Bolt and connected parts are assembled precedingly to ensure enough connecting force. The screw connection, however, is a non-linear problem stems from its complex geometry, and is sensitive to preloading process and preload level. Pyrotechnics, such as zirconium potassium perchlorate (ZPP), have the capability to generate explosive pulse in milliseconds [2]. And huge shock aroused by explosion may up to 10000G, which will cause malfunction to electro-devices assembled on the connected part. Nowadays, new actuators are designed and applied to reduce the structure shock, such as SMA or Cool-air actuator. And advanced connection types are also showed up such as low shock separation nuts device (LSN).

In this paper, complete mechanical model of LSN system is established. Static contact model will provide initial contact conditions for subsequent dynamic process. During the unlocking procedure, kinetic equation should be integrated to impulse equations to avoid multi-scale problem. LZB method is introduced to solve the impulse equations, so that the configuration state of the system can be determined.

LSN MODEL AND UNLOCKING PROCEDURE

The whole process of separation consists of four typical stages: 1) bolt pre-tightening on earth, 2) actuator operates to generate high pressure gas at scheduled location, 3) ring constraint moves until full unlocked to free nuts, and 4) nuts expand along radial direction to free bolt. When bolt started to release, the whole unlocking procedure ends, which lasts within several milliseconds. The design is so subtle that making it unnecessary for bolt to unscrew. After the separation among bolt and nuts, the bolt begins to freefall with initial velocity which we do not focused on.

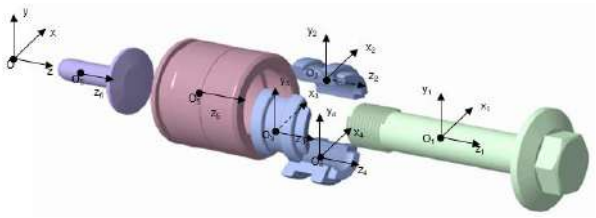

Figure 1. The geometry of LSN.

CONTACT MODEL OF THREAD FASTENER

Contact forces between threads originate in preload of thread fastener, consequently spread to other interfaces. To determine the initial stress state, the level of preload in bolt should be ascertained. Torque method is adopted to get preload in most cases which is originated from classical torque-preload equations mentioned by Motosh at 1976[3]. In this paper, simplified equation $M = k_M \cdot F$ is adopted, and preload F is set as static axial force on top side of bolt [4,5]. The component can be expressed in global system as

$$F = \begin{bmatrix} f^{\tau 1} \\ f^{\tau 2} \\ f^{n} \end{bmatrix} = \begin{bmatrix} (\cos\theta\cos\beta - \sin\theta\sin\alpha\sin\beta) f^{\tau 1} - \sin\theta\cos\alpha f^{\tau 2} + (\cos\theta\sin\beta + \sin\theta\sin\alpha\cos\beta) f^{n} \\ (\sin\theta\cos\beta + \cos\theta\sin\alpha\sin\beta) f^{\tau 1} + \cos\theta\cos\alpha f^{\tau 2} + (\sin\theta\sin\beta - \cos\theta\sin\alpha\cos\beta) f^{n} \\ -\cos\alpha\sin\beta f^{\tau 1} + \sin\alpha f^{\tau 2} + \cos\alpha\cos\beta f^{n} \end{bmatrix}$$

Supposing that contact forces are focused on the middle of threads, the equivalent axial contact stiffness and the contact force is equal to the stress of bolt in the axial direction. Setting a force on the top plane of the bolt and free on the bottom, the deformation u in equilibrium equation will be solved, and contact force can be expressed as

$$f^n = \frac{-F\omega}{\cot\alpha\cos\beta(e^{\omega l} - e^{-\omega l})}(e^{\omega z} + e^{-\omega z})$$

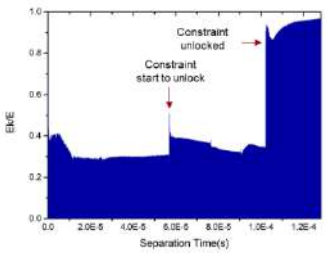
Contact forces on other contact region can be calculated as well, which will provide initial stress status to unlocking process together.

DYNAMIC MODEL FOR LSN IN UNLOCKING PROCESS

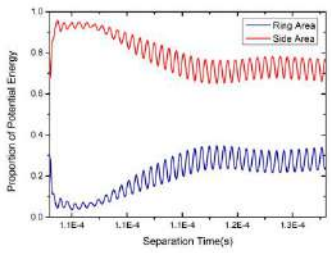
There exist collisions during unlocking process, provoking intensive interactions among contact couples within several milliseconds [6,7]. The second order differential equation should be integrated into

$$Mdq = dP + N_1 dP^{\tau 1} + N_2 dP^{\tau 2} + WdP^n + dP^i$$

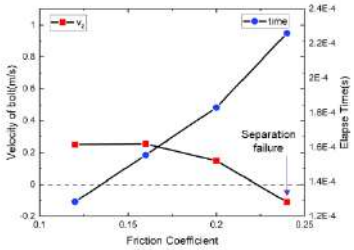
Results calculated by numerical method mentioned in this paper are shown as follows. The kinetic energy experienced three major stages as seen in Fig. 2(a). Stage 1 has a relatively high peak at the beginning, which indicates the influence of initial impulse. Stage 2 includes the whole unlocking process of ring constraint, and there exists a continuous decline after a sharp peak. While in the final stage, potential energy is almost transferred to kinetic energy, and support base undertakes the main potential energy of the whole system after unlocking process seen in Fig. 2(b).



(a)kinetic energy during unlocking process



(b)potential energy of support base



(c)parametric analysis

Figure 2. Numerical results.

Parametric analysis is held for separation prediction. As shown in Fig. 2(c), separation time is sensitive to coefficient of friction, which is doubled at the case of μ=0.24 compared with that of μ=0.12. The final axial velocity of bolt is stable when μ varies around 0.15, which is the most commonly status. However, there occurs a potential separation failure in the case of μ=0.24. In this special case, the axial velocity of bolt after unlocking process is below zero, which means the motion direction of bolt is reversed to the preconfigured one.

CONCLUSIONS

The whole mechanical model of LSN device is set up in this paper, and high effective and accurate algorithm and program are also established. Separation prediction can be easily held to find out crucial parameters of the system, which makes great contribution to parametric design.

MEMS CORIOLIS VIBRATORY GYROSCOPES: A PERFECT PLAYGROUND FOR NONLINEARITY ENTHUSIASTS

Carlo Valzasina[1*], Gabriele Gattere [1], Luca Guerinoni[1], Patrick Fedeli[1] and Luca Falorni [1]
[1]Analog, MEMS and Sensors (AMS) Group R&D, STMicroelectronics, Cornaredo, Italy

Summary Coriolis Vibratory Gyroscopes (CVG) realized in MEMS technology represent a unique playground for nonlinearity enthusiasts. During development of high-volume MEMS CVG sensors, a strong effort is put on avoiding or minimizing all possible nonlinear effects, nevertheless the small physical dimensions and the complexity of structures increase the probability to introduce nonlinearities in the system, posing strong challenges to the system designer.
In this paper we report several case studies of MEMS CVG sensors realized by STMicroelectronics, in which nonlinear behaviour was observed and studied. We describe sensors showing hardening and softening mechanical nonlinearity [1], internal resonance, parametric resonance. We also report for each case study the best-known method to us for assessing, preventing or dealing with the effect.

NONLINEAR EFFECTS IN MEMS CAPACITIVE GYROSCOPES

MEMS sensors, and in particular Capacitive CVG, are widely studied as systems exhibiting nonlinear behaviour [2], because they are more prone than macroscopic systems to operate far from linear conditions. The main causes for this peculiarity are the small dimension of CVG MEMS structures and the complexity of the system.

Small dimensions of CVG conflicts with the need of high displacement in the drive motion to achieve decent Signal-To-Noise Ratio (SNR) [3] and to minimize effects of external vibrations [4]. Mechanical deformation could achieve a relevant amount of the characteristics dimensions, potentially introducing in the system hardening, softening effects and parametric resonance, as described below.

MEMS CVG are usually described in textbooks as two Degree-of-Freedom mechanical elements [3], but the technology and design constrains such as space limitation, minimum width of flexible elements, and multiple-axis operation usually force the MEMS designer to increase the complexity of the mechanical system. This can be easily understood by comparing the design of first capacitive MEMS CVG by DRAPER [5] to current 3-axis consumer CVG [6]. The complexity of the mechanical structure introduces a high number of low-frequency undesired vibration modes, usually referred as spurious vibration modes, prone to excitation by superharmonics generated in the drive motion through internal resonance.

The small dimensions of flexible elements make the effort of dealing with spurious modes even worse, by increasing the variability of eigenfrequencies due to dimensional process control and increasing the probability of mode-crossing in some process corner or operative conditions.

MEMS system design is targeted to provide reliable, repeatable and robust structures capable of performing within specified limits in all process corners and applicative conditions. This goal may be jeopardized by the presence of nonlinear effects, with small deviations in the operative or process conditions resulting in strong change in system output. In the following section, it is presented a selection of case-studies among STMicroelectronics MEMS CVG sensors development experience, in which nonlinear behaviour appeared.

CASE-STUDIES OF MEMS CVG WITH NONLINEAR EFFECTS

Mechanical Hardening or Softening

Hardening effects for large deformation of CVG flexures are well reported in literature: the spring constant deviates from linear term due to participation of axial strength to the main flexural deformation of the spring. This is modelled by adding a quadratic and positive cubic term to the conventional Hook law [3]. In less common cases, mechanical deformation of the spring may induce a softening effect, i.e. the reduction of stiffness with increasing displacement. This has been reported in Zega et. Al. [1] due to reduction of cross-section moment of inertia of the spring during deformation.

Assessment method is based on static FEM simulation where input displacement is given to the mechanical structure in order to reproduce the spring deformation during normal operation and the force-displacement relation is extracted and fit with polynomial law. Other methods to simulate these effects are reported in Putnik et. al. [7].

The presence of hardening or softening effects in drive dynamics of CVG has the main effects of increasing the temperature dependence of closed-loop drive oscillator frequency and of generating superharmonics potentially interacting with high-order spurious modes. Therefore, nonlinearity of CVG drive mode should be minimized during design phase.

Internal Resonance

Internal resonance is the process of excitation of secondary vibration modes due to energy coupling with a primary, forced vibration mode [8]. In CVG this effect can occur, as reported in Fig. 2, when drive mode couples with a spurious mode in presence of: 1. Spurious mode being at an exact multiple frequency of drive mode, 2. Drive mode exhibiting

*Corresponding author. E-mail: carlo.valzasina@st.com

nonlinear terms capable of generating superharmonics, 3. Drive motion induced force has a nonzero Lagrangian component on secondary mode.

In order to assess potential internal resonance, the three conditions above should be checked by: selection of critical modes potentially crossing drive harmonics through modal analysis in corner conditions, simulation of drive nonlinearity (as per paragraph above), harmonic FEM at multiples of drive frequency. Other methods to simulate these effects are reported in Frangi et. al. [2].

Avoiding any crossing of spurious modes with drive harmonics may be very challenging, due to the presence of several spurious modes located near to the first few drive harmonics. In addition to this, spurious mode eigenfrequency variation in process corner and across operative conditions (temperature, packaging, external stress) should be taken into account too. Main effect on system, observed and reported in Fig. 1, is the CVG sensor output change when mode-crossing occurs, due to a change in drive-sense phase relation.

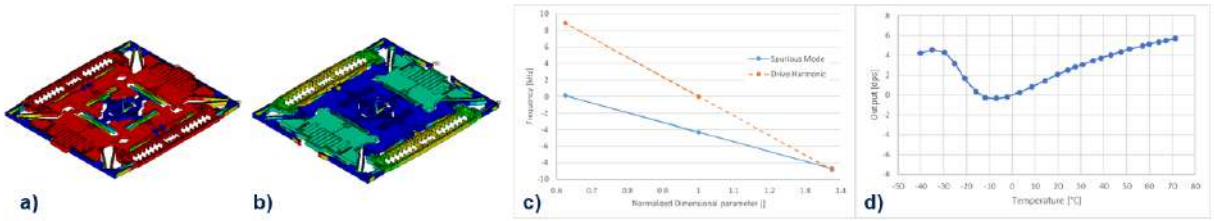

Figure 1. Example of internal resonance effect. a) Drive mode FEM simulation, b) Spurious mode FEM simulation, c) Frequency relation of Drive and Spurious mode vs. process variations, d) Effect of mode-crossing on gyroscope output.

Parametric Resonance

As per hardening or softening, a variation of spring stiffness modulated by drive motion can occur in CVG in case of large deformations. This is modelled by adding an additional, time-varying stiffness term in the system equation of motion of the secondary mode.

This is reported in Fig 3. where a modulation appears in the secondary mode transfer function, represented by the generation of two sidebands around sense resonance peak at ω_s.

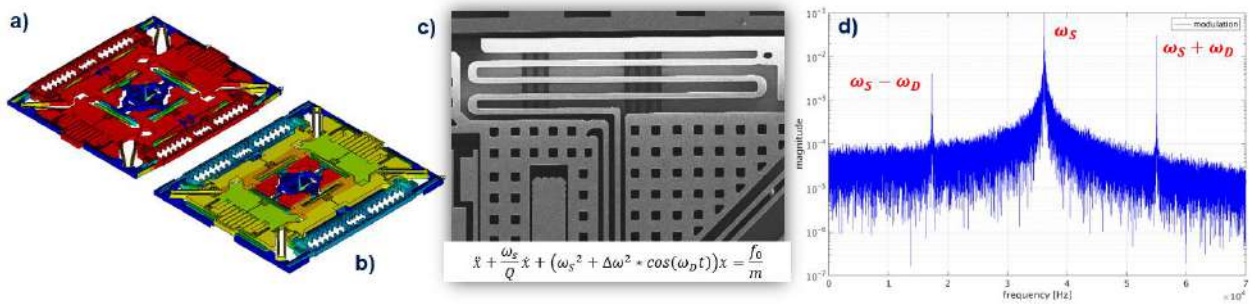

Figure 2. Example of parametric resonance. a) Drive mode simulation, b) Secondary mode simulation, c) SEM image of the spring and oscillator equation for including parametric resonance term. d) Effect of dive motion on secondary mode transfer function.

CONCLUSIONS

The reported case-studies on mechanical hardening, softening, internal and parametric resonance show how MEMS CVG represent a perfect playground for nonlinearity enthusiast, since pure linear models are not enough to describe the mechanical system on all process and operative conditions.

NONLINEAR MODAL INTERACTIONS IN MICRO/NANOELECTROMECHANICAL SYSTEMS

Ashwin A. Seshia[1]
[1]Department of Engineering, University of Cambridge, Cambridge, UK

Summary Modal interactions in micro/nanoelectromechanical structures are commonplace. Nonlinear modal interactions evidenced also by autoparametric / internal resonances have been studied for many decades at macroscopic length scales but the engineering of these effects has only recently been explored as a route to enhanced device performance at the microscale. An increasing body of literature has emerged around the theme of tuning and control of nonlinear modal interactions in micro/nanoelectromechanical systems to address specific device features and performance attributes. This paper summarizes work in this area and discusses applications to inertial sensors, vibration energy harvesting, and frequency synthesis.

INTRODUCTION

Nonlinear effects are widely observed in micro/nanoelectromechanical systems (M/NEMS) [1]. Device nonlinearities can be detrimental to system performance but they can also be harnessed to provide features or performance benefits not conventionally possible through linear approaches alone. Common examples of engineered nonlinearity for practical device benefit include nonlinear suspensions as highly compliant, yet robust spring elements for inertial sensors [2], and nonlinear resonators providing features including increased parametric sensitivity [3], noise suppression [4] and temperature immunity [5]. The sources of nonlinearity may be geometric, inertial, material, or damping related or a combination thereof, and the associated nonlinear parameters can be tailored through design. Further, the integration of such devices with nonlinear transducers (e.g. parallel-plate electrostatic transducers [6]) and the precise control of driving conditions using external circuits provide further knobs, enabling electronic tunability of nonlinear effects.

This paper summarises relevant recent studies with a focus on practical device applications that could exploit engineered nonlinearity, specifically nonlinear modal coupling [7, 8]. Recent relevant device case studies include autoparametric excitation in the context of MEMS energy harvesters, micromachined devices describing phononic frequency combs, and the manipulation of the nonlinear modal coupling in micro/nanoelectromechanical gyroscopic resonators using electrostatic fields.

DEVICE APPLICATIONS

MEMS technology has been widely applied to the development of miniaturized sensors, vibration energy harvesters, frequency references and radio frequency signal processing (filters). Nonlinear effects have not been extensively exploited in first generation devices, and are often studied in this context only to set design boundaries and limits to achievable performance. However, in recent years, operation in the nonlinear regime with a view towards enhancing performance is being revisited and a number of studies (particularly over the past decade) have demonstrated advances arising from a thorough understanding of these effects applied to practical device engineering. This paper summarises research addressing three applications exploiting nonlinear modal coupling in MEMS/NEMS with application to inertial sensors, vibration energy harvesters and radio frequency comb synthesis.

Vibration Energy Harvesters: Vibration energy harvesters offer a means of converting ambient vibrations to electrical energy [9]. There has been much interest in the design of MEMS vibration energy harvesters due to their potential for enabling compact, chip-scale, self-powered sensors [10]. However, the vast majority of initial approaches have been based on employing a single-degree-of-freedom linear or Duffing resonators for this purpose. Power scalability for MEMS is poor unless the resonances are precisely tuned to the frequency of a stable periodic source (e.g. steady vibrations on a continuously operated motor or pump). Vibration energy harvesters employing two coupled modes (e.g. with frequencies in a 2:1 ratio) have been recently proposed where a second mode is autoparametrically excited through coupling to a directly excited primary mode. Mechanical amplification resulting from the autoparametric excitation of the second mode can lead to amplitude build-up even at low vibration levels. A prototype piezoelectric MEMS vibration energy harvester based on a coupled cantilever topology demonstrated an output power of 180 μW and a power density per acceleration squared metric, nearly an order of magnitude higher than the equivalent state-of-the-art [11].

Phononic frequency combs: The excitation of multiple modes in a standalone piezoelectric MEMS resonator using a single drive tone, as well as different combinations of modes by varying the drive parameters has been previously demonstrated [12] in a series of studies on autoparametric excitation / internal resonances in MEMS. Under specific driving conditions in such devices, nonlinear mixing of the resulting multimode responses can lead to the formation of phononic frequency combs [13] – a response defined by a set of equispaced discrete frequencies in the radio frequency domain. These phononic frequency combs (the mechanical analogue of optical frequency combs) are a direct result of nonlinear modal coupling within a composite resonator device. The response of such a device can be tracked continuously

without recourse to a feedback oscillator for e.g. by replacing the drive by a stable frequency source with well-defined characteristics [14]. The comb features of such devices can be tuned, demonstrating either high temperature sensitivity or relative insensitivity to temperature effects [15]. Applications include device elements for sensors and RF signal processing.

Resonant inertial sensors: Vibratory MEMS rate gyroscopes operate on the principle of coupling two orthogonal modes via the Coriolis effect and, therefore, modelling modal coupling accurately is integral to the design of these sensors [16]. Micromachined disk resonator gyroscopes have demonstrated near-navigation performance [17] and are based on Coriolis coupling of two elliptical modes within a single disk resonator structure. The modes of interest can be excited using electrostatic fields generated by parallel-plate transducers situated around the disk periphery. Recently, excitation of multiple internal resonances has been demonstrated in such devices. This can enable self-induced parametric amplification due to nonlinear elastic coupling between degenerate orthogonal vibratory modes resulting in an increase in rate sensitivity [19]. Additionally, by tailoring the electrostatic fields it is also possible to dynamically tune the modes of interest towards mode matching, and utilise nonlinear electrostatic fields to couple otherwise uncoupled modes to a driven primary mode [18]. Furthermore, a related parametric pumping scheme can enable dynamic tuning of the sensitivity of mode-localized sensors [20].

SUMMARY

The engineering of nonlinear modal coupling has been studied in M/NEMS demonstrating the potential for significant practical benefit. Three case studies are specifically highlighted including (1) the generation of elevated power output levels for MEMS inertial energy harvesters, (2) resonator devices demonstrating frequency comb response with application to the tracking of slow variations in parameters, and (3) the ability of dynamically tune modal interactions using nonlinear electrostatic fields for mode tuning in gyroscope devices or for tuning the coupling strength in coupled resonator micro/nanostructures including mode-localized accelerometers resulting in over an order of magnitude increase in parametric sensitivity and a consequent experimentally demonstrated reduction in noise floor.

SUCTION CUPS IN LIQUID AT MICRO SCALE

Yue Yang[1], M Taher A Saif[*1], [2]and Eduard Arzt [*1,3]

Summary Dry suction cups are extensively used for attachment to substrates without any chemical glue. Van der Waals forces and air suction provide the adhesion. However, suction cups inundated in liquids are not commonly used, even though octopus and other aquatic animals use them gracefully at multiple size scales for locomotion (Fig 1). The precise mechanism of operation of suction cups in liquid remains elusive to date. Here we hypothesize a physical mechanism for suction cups in liquids, develop a mathematical model implementing the mechanism, and test the hypothesis by carrying out experiments with suction cups at micro scale.

INTRODUCTION

Suction cups in liquids are counter intuitive, particularly when the surfaces are hydrophilic. Here, the liquid wets the surfaces and the hydro dynamic lubrication layer between the cup and the substrate prevents them from coming in contact. Hence, the cups must employ suction pressure alone to adhere. In order to gain insight on the mechanism of operation, we explored (1) the process by which suction pressure evolves with time and (2) modes of failure, i.e., the detachment of the cup from the substrate. We start with the following working hypothesis.

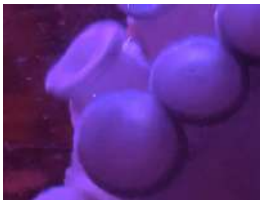

Figure 1. Suction cups of an octopus.

PROPOSED HYPOTHESIS

On suction pressure

A typical cup has a stalk and a compliant rim. The cup deforms elastically when pressed against a surface, while liquid is pushed out reducing the volume of the cup. Upon release, the cup tends to return to its original configuration immediately. This fast demand for increasing volume cannot be met by the slow flow of liquid from outside through the narrow gap between the rim and the substrate. This lag between demand and supply results in a suction pressure inside the cup and further reduces the gap in a positive feed forward way. If the stalk is retracted by applying a force, then suction increases even more, increasing the holding force. Faster the rate of retraction, higher is the suction pressure.

On modes of detachment (failure)

If the stalk is held fixed, or no external force is applied to retract, suction pressure decreases over time due to liquid seepage from outside, and the cup detaches. Under a prescribed rate of retraction, there can be two modes of failure. Mode 1: the applied force on the rim exceeds the suction force it experiences. Here, the rim opens as a crack from its inner boundary. Mode 2: During stalk retraction, the rim slides radially inward by hydro-plating. It undergoes a transition from circumferential tension to compression (Fig 2) which may lead to out-of-plane buckling of the rim along the outermost perimeter. The buckling waves create channels for flow from outside, relaxing the pressure leading to the detachment of the cup.

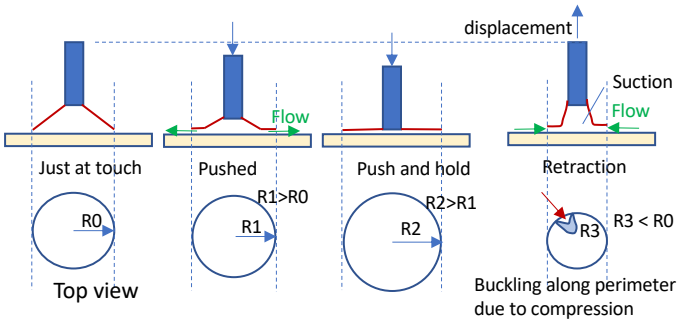

Figure 2. Proposed working principle of a suction cup in liquids and a possible failure mechanism by peripheral buckling of the rim.

MATHEMATICAL MODEL

A simple mechanical analogue of a suction cup consists of a cylindrical chamber with a rim (Fig 3). The spring K1 represents the compliance of the cup without any fluid. In the presence of an incompressible fluid, the deformation of the cup is constrained and its compliance decreases. This is accounted by a second chamber connected to the rigid substrate. Its spring constant is K2. If the rim is sealed and no liquid is allowed to flow inwards, the effective stiffness of the cup is K1 + K2. The gap, d, between the rim and the substrate decreases with increasing suction pressure. However, due to asperity contacts, the decrease in gap with suction is non-linear which we model with an exponential function: d = d0 Exp[-p/p0], where d0 is the initial gap, and p0 is a reference pressure. *Initial condition:* At time t=0, the stalk is pushed towards the substrate when the chamber volume decreases by pushing fluid out. Now, the suction pressure is zero, p(0)=0, i.e., pressures inside and outside are balanced.

Mass conservation

Upon release of the cup, with or without a prescribed retraction velocity, the volume of the chamber increases. The increased volume is balanced by inflow of liquid under pressure gradient through the gap d. This mass balance gives the governing equation for the suction pressure, p(t), with the initial condition, p(0)=0.

Failure criteria

During a constant rate of retraction, the spring force increases linearly with time (Fig 3) while the rim slides inward. Failure initiates due to earlier of the two events: spring force from K1 exceeding the suction force on the rim, or the sliding rim buckling along the periphery.

Experimental verification: hypothesis testing

Micro scale suction cups are fabricated with polyurethane elastomer and 3D printing (Fig. 4). The cups are inundated in water and pressed against a glass surface. The stalk is then retracted with a constant prescribed velocity until failure, while the mode of failure is observed. Force evolution with time shows a trend similar to that predicted by the model (Fig 3, right). Failure is preceded by the rim sliding radially inward followed by spontaneous buckling along the periphery. One of the buckling waves increases in amplitude resulting in a radial channel. This allows water to flow inwards causing failure of the cup, positively testing the hypothesis on failure mode 2.

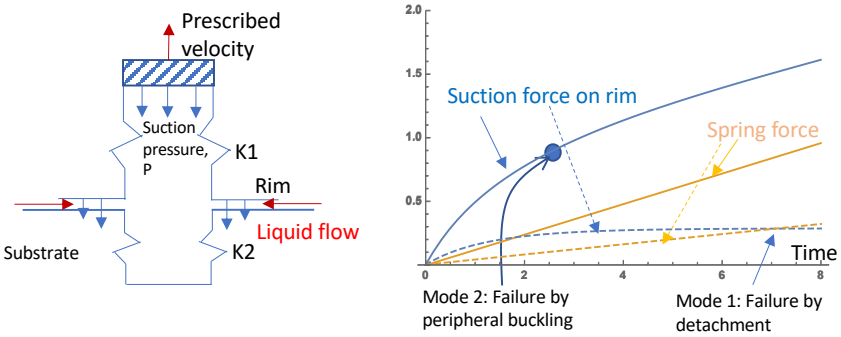

Figure 3. (left) Mechanical model of a suction cup in liquid. The cup is retracted to detach. (Right) The evolution of force on the rim due to suction between the rim and the substrate compared to the spring force. Two modes of failure are shown.

CONCLUSIONS

Here we proposed and tested a hypothesis on the mechanism of attachment of suction cups in liquids, and their failure modes. The mechanism was implemented in a mathematical model. Experiments with micro scale suction cups were used to test the hypothesis. The model predictions match experimental observations qualitatively. The work lays the foundation for designing and developing suction cups for a wide range of underwater applications.

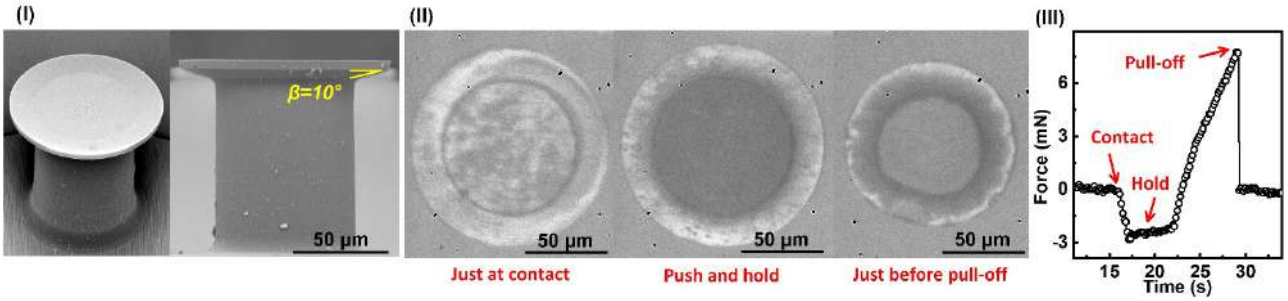

Figure 4. (i) Image of a suction cup in water contacting a glass surface. (ii) The three images show the rim in contact with substrate as the stalk is retracted. The last image is prior to detachment showing buckling from the periphery. Also, the rim diameter is much smaller indicating circumferential compressive stress initiating buckling. (iii) Force of retraction as a function of time. Retraction velocity: 10 um/s.

COARSE–GRAINED MODEL FOR SINGLE LAYER MOS_2. RIGID GRAINS APPROACH.

Summary Single–layer molybdenum disulfide ($SLMoS_2$) is a promising two–dimensional material with a wide range of possible applications in NEMS. We develop a coarse–grained model combining the atoms of crystal lattice into rigid 'grains'. The interaction between the grains is based on Stillinger–Weber potential with parameters recalculated to fulfill the elastic properties of the original lattice. The model is applied to calculate the phonon spectrum and for the nanoindentation problem. It is shown that in the case of small strains the model is as accurate as regular MD simulations, but uses much less interatomic interactions; hence, it is much more time–efficient.

INTRODUCTION

Traditional molecular dynamics (MD) simulations of $SLMoS_2$ are very time–consuming and cannot be applied to the real microscopic–level systems. We propose another way to simulate the atomistic structure using the coarse-grained (CG) modeling: combining atoms of the lattice into 'grains'. The grain combines three unit cells of the $SLMoS_2$ hexagonal close-packed (HCP) structure, which is infinite in the plane of transverse isotropy and has only three layers in the orthogonal direction. As a result, they form a two-dimensional triangular lattice. We consider them as the rigid bodies, taking their rotational degrees of freedom into account. In this case, a specific potential has to be developed to add torques arising between the grains to the forces of interaction. Such type of potential was used before for the original $SLMoS_2$ crystal lattice [1], but not for the CG structure.

SIMULATION TECHNIQUE

Dynamics of the grains

The main idea of the simulations method is close to the discrete [2] and distinct [3] element methods and other generalizations of classical molecular dynamics. The position and rotation of a specific grain is determined by the solution of the following equations of motion:

$$m_i\ddot{\mathbf{u}} = \sum_\alpha \mathbf{F}_\alpha, \qquad \boldsymbol{\Theta}\cdot(\boldsymbol{\omega})^{\cdot} = \sum_\alpha \mathbf{M}_\alpha, \tag{1}$$

where $\mathbf{u}$ is displacement, $\boldsymbol{\omega}$ is an angular velocity $\mathbf{F}_\alpha$, $\mathbf{M}_\alpha$, sum of forces and torques caused by interaction between atoms of neighboring grains. We apply the quaternions formalism [4] to calculate a new orientation of the grain.

Elasticity of the CG–lattice

As the grains are rigid, the overall stiffness of the lattice increased and we cannot use the original SW potential. Instead we need to redefine its parameters. In order to determine the components of stiffness tensor we need to solve a set of problems in which the material is subject to homogeneous strain field $\varepsilon_{ij} = \pm 10^{-5}$ with one non-zero component. We write the Hooke's law in the form:

$$\frac{\Delta\sigma_{kl}}{\Delta\varepsilon_{ij}} = \frac{1}{2}\left(C_{klij} + C_{ijkl}\right), \qquad i,j,k,l = x,y, \qquad \boldsymbol{\sigma} = \frac{1}{2V_0}\sum_\alpha \mathbf{a}_\alpha\mathbf{F}_\alpha, \tag{2}$$

where ε_{ij} and σ_{kl} are the components of strain and Cauchy stress ($\boldsymbol{\sigma}$) tensors respectively, and C_{ijkl} are the components of stiffness tensor, V_0 is the unit cell volume, $\mathbf{F}_\alpha$ are the respective intergrain forces, and $\mathbf{a}_\alpha$ are the vectors connecting the given grain with its neighbors. The boundary effects in the plane of isotropy are eliminated by introduction of periodic boundary conditions, whereas the upper and lower boundaries are free.

A Simulated Annealing (SA) algorithm [5] was used to determine the parameters of the SW potential using the known values of the stiffness tensor. The highest relative error was obtained for C_{xxyy} and is 11%.

The corrected SW potential parameters for coarse–grained model are given in Table 1.

PHONON SPECTRUM

A phonon spectrum determination can be used to validate the system dynamics. Phonon spectrum of the coarse–grained lattice is measured using an approach based on molecular dynamics simulations [6].

Even though we consider the phonon spectrum of grains instead of atoms, we obtain a good agreement with the experimental results. The lower and upper curves give a good approximation of experimental data from [7]. The middle curve varies significantly from the experimental data in case of long waves, but the difference decreases at higher values of the wave vector.

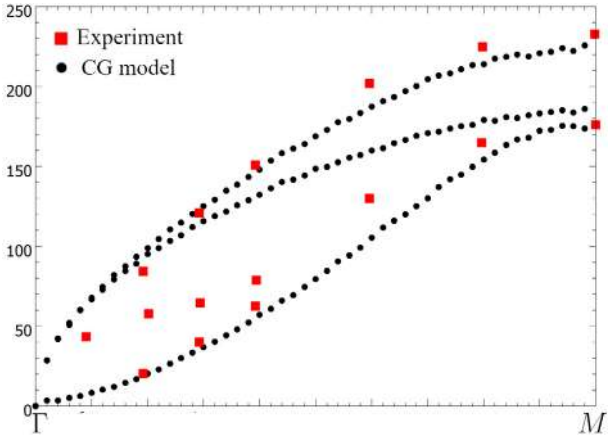

Figure 1: Phonon spectrum for grain–structured $SLMoS_2$ with the new parameters

CONCLUSIONS

We developed a coarse–grained model of $SLMoS_2$ with the grains considered as rigid bodies. For this specific study, the interactions between the grains were based on Stillinger–Weber potential with the parameters re-calibrated to fulfill the elastic properties of the original lattice. Note, that the same approach can be used with any other potential of interaction. The phonon spectrum was calculated, and it shows a good correspondence to the acoustic waves of the original lattice.

In this work, we considered the minimal possible grains. In this case, the number of interaction reduces almost twice. The larger grains with the same geometry can be used for the higher increase of the calculation speed.

The major advantage of the model is an opportunity to combine the coarse–grained and the original lattices in one model. For example, the original lattice can be considered near the stress concentration points in the tasks of nanoindentation or crack initiation, and the CG–lattice can be merged with the original on the relatively far distance from such points.

The drawback of the model yields from its main feature: the rigid grains 'freeze' part of the interactions. As a result, the bonds between the grains are highly elongated in comparison with the ones in the original lattice at the same strain, which lead to higher stresses in the CG–lattice. This effect limits the application of the model for problems with large deformations. However, in the small strain cases such as elastic wave propagation, thermal problems, and others the model can be used successfully. A possible solution to the aforementioned disadvantage may be considered by using elastic grains instead of rigid ones, which is a topic of further investigation.

NONLINEAR PIEZOELECTRIC BEHAVIOR OF PZT THIN FILMS: MODELING AND EXPERIMENTAL VALIDATION

Andrea Opreni*[1], Nicolò Boni[2], Patrick Fedeli[2], Roberto Carminati[2], Massimiliano Merli[2], Gianluca Mendicino[2], and Attilio Frangi[1]

[2] Analog and MEMS Group, STMicroelectronics, Milan, Italy

Summary Piezoelectric materials in Micro-Electro-Mechanical Systems provide an enhanced linear response and lower actuation voltages compared to their capacitive counterparts. In this work, we propose a material model for thin films of piezoelectric materials derived from the Landau-Devonshire theory of ferroelectrics. The proposed model is validated with tests conducted on a cantilever made of monocrystalline silicon actuated with a PZT patch in quasi-static conditions in both unipolar and bipolar cycles.

INTRODUCTION

Piezoelectric Micro-Electro-Mechanical Systems (MEMS) represent an important class of devices both for actuation and sensing and they are often preferred to capacitive MEMS for their improved linearity and more reliable operation.

Most modeling procedures for the design of piezoelectric MEMS proposed in literature exploit a linear material model. Nevertheless, in application as micromirrors, the piezoelectric materials used for actuation are subjected to voltage biases of the order of tens of Volts, generating electric fields with maximum values that exceed the linear range of the piezoelectric material. As a consequence material nonlinearities are observed.

Extensive research has been performed to model the nonlinear electromechanical behavior of piezoelectric MEMS. First nonlinear models date to the work by Guyomar [1] during the analysis of Langevin transducers. Subsequent works developed constitutive models starting from a nonlinear electric enthalpy density function from which the constitutive model is derived. Most recent works included also terms to mimic the hysteretic behavior of the piezoelectric material [2].

Only in recent years intensive effort has been put to develop models for ferroelectric materials in MEMS considering the meso- and microscopic structure of the material itself. The Phase field approach [3] has emerged as the most effective tool to account for the irreversible part of the material polarization by simulating the process of domain reorientation in the piezoelectric material. The aim of this investigation is to formulate a macroscopic material model based on the theory of ferroelectrics developed by Landau-Devonshire [4]. The model does not introduce any semi-empirical constant and only the polarization history of the piezoelectric material during device operation is required. Our proposal is here validated on silicon cantilevers fabricated by STMicroelectronics actuated with a Lead-Zirconate-Titanate (PZT) patch.

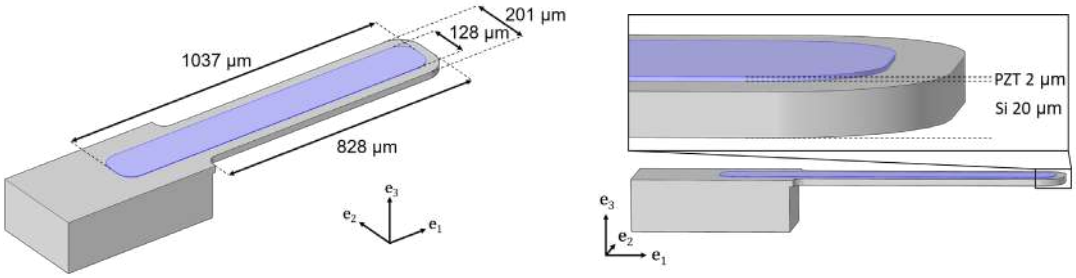

Figure 1: Cantilever geometry. Silicon appears in grey color. PZT is highlighted in light purple.

MODEL

Landau-Devonshire theory states that the polarization vector $\boldsymbol{P}$ induces inelastic strains ε^P associated to the deformation of the elementary cells of the piezoelectric crystal due to spontaneous polarization below the Curie temperature. Inelastic strains contribute to the Cauchy stresses $\boldsymbol{\sigma}$ according to the linearized theory of elasticity:

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}^{\varepsilon}[\boldsymbol{u}] - \boldsymbol{\sigma}^{P}[\boldsymbol{P}] \qquad (1)$$
$$\boldsymbol{\sigma}^{\varepsilon}[\boldsymbol{u}] := \mathcal{C} : \varepsilon[\boldsymbol{u}], \quad \boldsymbol{\sigma}^{P}[\boldsymbol{P}] := \mathcal{C} : \varepsilon^{P}[\boldsymbol{P}]$$

*Corresponding author. E-mail: andrea.opreni@polimi.it.

where $\boldsymbol{\varepsilon}$ is the infinitesimal strain tensor, $\mathcal{C}$ is the fourth-order elasticity tensor, and the superscripts $(\cdot)^{\varepsilon}$ and $(\cdot)^{P}$ define elastic and inelastic quantities. We now impose linear momentum conservation of the system in its weak form neglecting active forces, and assuming that inertia forces are negligible:

$$\int_{\Omega} (\boldsymbol{\sigma}^{\varepsilon} - \boldsymbol{\sigma}^{P}) : \boldsymbol{\varepsilon}[\boldsymbol{w}] \, \mathrm{d}\Omega = 0 \tag{2}$$

where $\boldsymbol{\varepsilon}[\boldsymbol{w}]$ is the strain associated to the virtual displacement. If the film is deposited along the $\boldsymbol{e}_1\boldsymbol{e}_2$ plane, then the electric field is reasonably approximated as $\boldsymbol{E} = E\boldsymbol{e}_3$. If the dielectric behavior is isotropic, then the polarization has the form $\boldsymbol{P} = P\boldsymbol{e}_3$. Therefore, from Equation (1) we derive that inelastic shear stress components are zero and Equation (2) becomes:

$$\int_{\Omega} \boldsymbol{\sigma}^{\varepsilon} : \boldsymbol{\varepsilon}[\boldsymbol{w}] \, \mathrm{d}\Omega = P^2 \int_{\Omega_P} \Big[c_{13} \left(\varepsilon_{11}[\boldsymbol{w}] + \varepsilon_{22}[\boldsymbol{w}] \right) + c_{33} \varepsilon_{33}[\boldsymbol{w}] \Big] \, \mathrm{d}\Omega \tag{3}$$

where c_{ij} are constants that embed ferroelectric and mechanical properties of the piezoelectric material, and Ω_P is the volume occupied by the piezoelectric film.

NUMERICAL RESULTS AND EXPERIMENTAL VALIDATION

The model was validated on monocrystalline silicon cantilevers with (100) orientation actuated in quasi-static condition with a PZT patch. The geometry of the cantilever is reported in Figure 1. The cantilever was actuated by applying either unipolar or bipolar sinusoidal potential histories. In the former, the potential oscillated within 0 and $+V_0$, while in the latter it ranged between $-V_0$ and $+V_0$. The comparison between the tip displacement predicted from the proposed model and the values measured from experiments for $V_0 = 35$ V are reported in Figure 2. The charts report a remarkable agreement in both unipolar and bipolar measures.

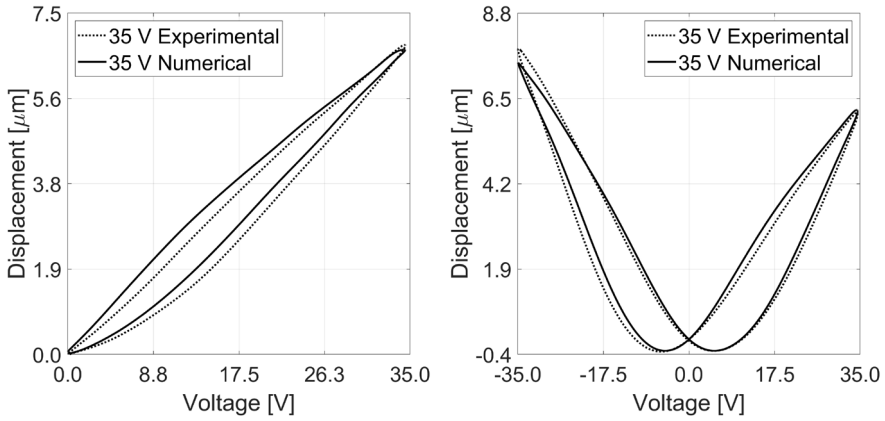

Figure 2: Comparison between proposed model and experimental data in unipolar (a) and bipolar (b) measures.

CONCLUSIONS

We have proposed a model to predict the nonlinear ferroelectric behavior of PZT thin films in MEMS. The model is based on first principles of ferroelectric materials theory, and it does not introduce parameters that require calibration. Furthermore, the presented model can be implemented in finite element codes for the design of realistic piezo MEMS.

REDUCED ORDER MODEL FOR IN-WATER LARGE ARRAY OF PMUTS ANALYSIS

Gianluca Massimino*[1], Attilio Frangi[1], Raffaele Ardito[1], Fabio Quaglia[2], and Alberto Corigliano[1]
[1]Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy
[2]Analog, MEMS & Sensors Group, ST Microelectronics, Cornaredo, Italy

Summary In this work a multiphysics ROM for the electro-mechanical-acoustic problem is presented. The solution strategy consists of two main stages. The former is devoted to the determination of the electro-mechanical eigenmodes of a representative PMUT. Then, the acoustic-structure interface of each transducer is mapped onto the fluid domain boundary. In the latter stage, the electro-mechanical-acoustic problem is solved by means of a staggered algorithm, considering the PMUTs vibration as a combination of few selected modes. The numerical comparison with the COMSOL 5.2 full order FE model is reported in terms of pressure maps and histories at the PMUT center.

INTRODUCTION

Piezoelectric materials in smart microsystems [1] are widespread, in view of some recent techniques that allow for the fabrication of layered structures with thin films of piezoelectric material, namely lead zirconate titanate (PZT) or aluminium nitride (AlN). Piezoelectric micromachined ultrasonic transducers (PMUTs) are layered plates with a piezoelectric active layer for emitting and receiving ultrasonic waves [2]. Several applications involve the use of such piezo vibrating diaphragms; medical acoustic imaging [3] and hydrophones exploit the in-water wave propagation of ultrasonic pulses. The primary focus of the present work is to show the novel reduced order model (ROM) for electro-mechanical-acoustic analyses and the corresponding simulation performance related to the study of beamforming and interaction problems, involving several transducers. The presented model has been implemented into a Fortran code and represents a suitable tool to carry out pressure propagation analyses in which the transducers are independently driven. Furthermore, the acoustic interaction among multiple vibrating transducers, in the near field, is taken into account by means of the full order FEM approach for the acoustic problem [4], in spite of the order reduction of the PMUTs dynamic behaviour. Hence, the interference phenomena during the wave propagation is properly simulate.

METHODOLOGY

The generic piezoelectric transducer has a circular geometry with a radius of 115 μm and an overall thickness of 8 μm, so the diameter over thickness aspect ratio is 28.75. It consists of several layers with different elastic properties and thicknesses. The structural layer is made of silicon, while the active layer is made of PZT. It has thickness equal to 2 μm and is in a circular hat configuration with radius of 80.5 μm, coaxial with the plate. The transducers interaction surfaces belong to the flat fluid domain boundary while a hemisphere of water has been considered (see a detail in Figure 1).

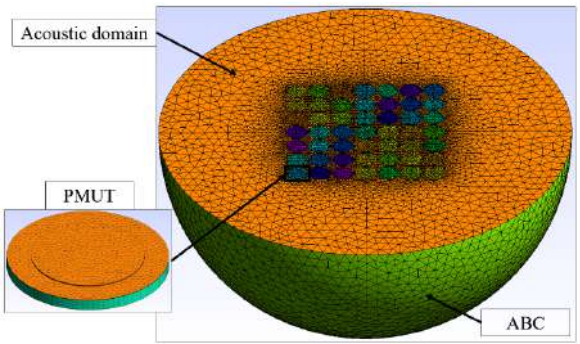

Figure 1: FE model: PMUT mesh detail (left), fluid domain mesh detail with 7x7 mapped PMUT interaction surfaces (right).

The solution strategy consists of two main stages. In the former one, the eigenvalue piezoelectric problem is solved, for the complete stack of a representative PMUT, by means of the Arnoldi method and few selected modes are extracted. Then, the acoustic-structure interaction surface of each transducer is mapped onto the fluid boundary. In the latter stage, the in-time domain piezo-acoustic problem is solved through a staggered procedure in which the electro-mechanical dynamic behaviour is obtained by a combination of the selected modes, reducing each transducer to few DOFs, while for the full order acoustic problem the solution is computed by means of the finite element method. The described procedure allows one to simulate in an exact manner the acoustic-structure interaction as the transducers are vibrating according to the selected modes. Moreover, the involved computational burden is basically related only to the pressure DOFs and depends on the size of the fluid domain in which the propagation wave pattern is simulated without any order reduction.

RESULTS

The benchmark case study is reported in which the comparison between the reduced order model implemented in the custom code and the COMSOL 5.2 full order model is shown. The analyzed system consists of a single central vibrating transducer interacting with a hemispherical water domain with radius equal to $3\lambda = 1092.2$ μm where $\lambda = \nu_s/f_0 = 364.06$ μm is the wavelength, $\nu_s = 1481$ μm/μs is the speed of sound in water and $f_0 = 4.068$ MHz is the fundamental electro-mechanical frequency of the PMUT. The adopted excitation voltage is equal to 15 sinusoidal cycles at the fundamental frequency with 1 V amplitude. The considered common discretization, is characterized by the 15 elements in the PMUT radius, 4 elements through the thickness for the PZT and the silicon layers, while the other layers are discretized with 1 element through the thickness. Indeed, a maximum elements size of $\lambda/10$ is adopted for the fluid mesh. The numerical comparison, considering a ROM generated by the fundamental mode, in terms of pressure maps, at the final computation time $t = 3.69$ μs, on a cut plane passing through the transducer diameter is shown in Figure 2, while the corresponding pressure time histories, at the PMUT center, are reported in Figure 3.

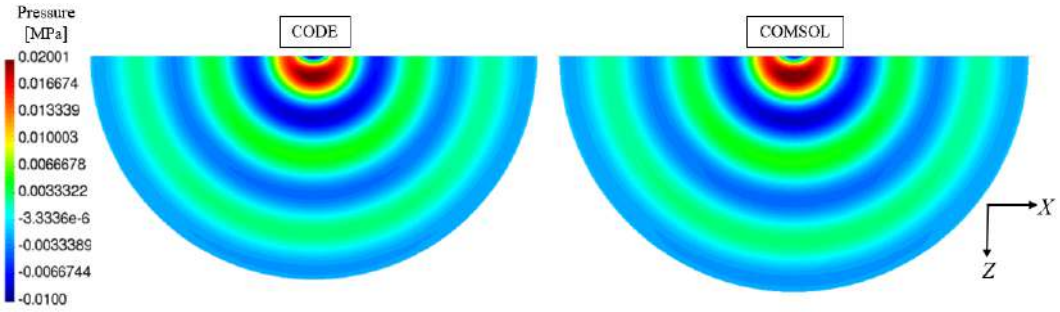

Figure 2: Pressure maps at $t = 3.69$ μs.

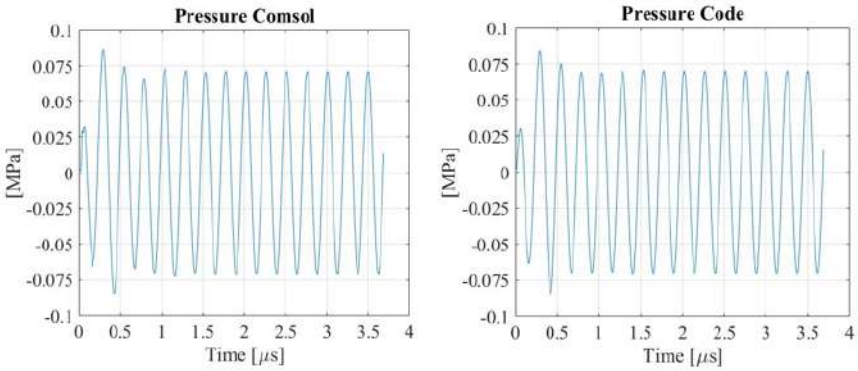

Figure 3: Pressure time histories at the PMUT center.

It is worth noting that the reduced order model predicts the same pressure history and propagation map of the COMSOL 5.2 model. Furthermore, the ROM computational time is about 8 mins while the corresponding one involved in the full-order finite elements model, built with the commercial code, is about 1 h 20 mins, running on the same machine with 6 Xeon CPU cores @3.6 GHz and 64 GB RAM.

CONCLUSION

The proposed ROM shows faster computational time than the standard procedure and the results are in good agreements with the full order finite element ones. Indeed, the novel approach represents a suitable tool to study the transmission and reception problems involving several PMUTs.

MODELLING MICRO-PLATES IN VISCOUS FLUIDS WITH THE FUNDAMENTAL SOLUTIONS METHOD

Andre Loch Gesing*[1], Daniel Platz[1], and Ulrich Schmid[1]
[1]Institute of Sensor and Actuator Systems, TU Wien, Gußhausstraße 27, 1040 Vienna, Austria

Summary Micro-plates exhibit low losses in viscous fluids when vibrating in roof tile-shaped modes. Roof tile modes are often not considered for micro-sensors due to the lack of methods to predict the viscous losses of micro-plates vibrating in fluids. We develop a numerical method to predict the displacement of micro-plates in viscous fluids based on the Kirchhoff-Love plate equation - which we solve with the interior penalty method - with the method of fundamental solutions for the linearized Navier-Stokes equations for incompressible fluids. We show-case our method with the analysis of a silicon micro-plate in water. With our method it is straight forward to categorize peaks correspondent to flexural bending, torsional and roof tile modes and calculate the fluid flow associated to each mode. Our method provides a crucial understanding of the dynamics of micro-plates in viscous fluids.

INTRODUCTION

Micro electro-mechanical systems (MEMS) devices exploit as key building block the Euler-Bernoulli (EB) bending modes of narrow beams. These modes are chosen because methods to predict dynamic response and thermal calibration of narrow beams in viscous fluids are well established and straightforwardly implemented [1]. Higher order bending modes of beams in viscous fluids are subject to high viscous losses, while high order roof tile-shaped modes of micro-plates exhibit extraordinarily low losses in viscous fluids [2]. However numerical methods for the prediction of viscous losses of micro-plates oscillating in roof tile shaped modes are missing. A method for the prediction of the dynamic response of micro-plates in fluids is of utmost importance.

NUMERICAL METHOD

We solve the Kirchhoff-Love (KL) plate equation combined with the method of fundamental solutions for the linearized Navier-Stokes (LNS) equations. KL plate theory is based on a fourth order partial differential equation (PDE), which can't be solved with out-of-the-box Finite Element Method (FEM). We solve the KL PDE with a continuous / discontinuous method called interior penalty (IP). IP method enables us to use Lagrange-type continuous elements (C0 continuous) while minimizing discontinuities in first order derivatives (obtaining thus C1 continuity) and weakly enforcing clamped and free-end boundary conditions. For comparison purposes we also implemented the IP method for the EB beam equation. To model the fluid-structure interaction, we assume the non-slip condition at the plate's surface, and assume that the fluid velocity in the longitudinal direction of the plate is small in comparison to the other components. With this latter assumption, there is a fundamental solution for the LNS that relates pressure at the plate surface and the plate's transverse displacement at each cross-section [3]. Evaluation of the fundamental solution at top and bottom surfaces of the plate results in a pressure jump over the plate which is linearly and non-locally dependent on the plate's transverse displacement.

RESULTS

As an application example we consider a $300 \times 300 \times 5\ \mu\mathrm{m}^3$ silicon micro-plate immersed in water. The micro-plate is clamped on one side and free on the three others, and is excited by an external force at one of the free corners. Fig. 1 shows the displacement spectrum per unit excitation force ϕ/F of the free corner of the plate where the force is applied. Note that some of the peaks in the displacement spectrum are predicted by both KL and EB models. These peaks correspond, evidently, to flexural bending modes predicted both by EB and KL equations. The second peak in KL displacement spectrum corresponds to the first torsional mode. First beam bending mode and first torsional mode are shown in Figs. 2a and 2b, respectively. Roof tile modes for this micro-plate in water occur at frequencies equal to 237.4 kHz and 651.8 kHz and are shown in Figs. 2c and 2d. Evidently, these modes are predicted only with the KL method. Once the plate spectral displacement is calculated, we can reconstruct the velocity field at any point of the fluid domain by applying once again the fundamental solutions for the LNS. Velocity field associated with the first bending mode in Fig. 3a exhibits two vortices at the edges of the plate's cross section with opposite directions, and the fluid velocity near the center of the cross section is dominated by a normal component. For the first torsional mode we see in Fig. 3b that the vortices at the edges exhibit opposite directions, and the fluid moves across the plate's surface dominated by a tangential component. For roof tile modes in Figs. 3c and 3d the fluid moves back and forth across the plate's surface with a pattern that varies with the number of nodal lines of the vibrating mode. Note also that for roof tile modes the velocity field can reach higher velocities near the middle of the plate than at its edges. Vortices at the edge therefore are less dominant with increasing roof tile mode number, which could help explain the reduction in viscous losses with increasing mode number.

CONCLUSIONS

We showed that with the KL method we can model micro-plates vibrating in roof tile modes in viscous fluids. What is more, we are able to calculate the fluid flow associated to each vibrational mode, and better understand the viscous losses mechanism of micro-plates in fluids. Our numerical method can specially enable the use of roof tile modes in viscous fluids as novel strategies to further decrease energy losses of micro-sensors to the fluid. Future developments include implement 3D fundamental solutions for the LNS, comparison to experimental data and calculation of the thermal calibration.

ANALYSIS OF MECHANICAL AND GEOMETRIC PROPERTIES OF HIERARCHICAL LATTICE DEFECTS IN LOW-DIMENSIONAL CARBON NANO-MATERIALS

Xiao-Wen Lei*[1], Ako Kihara[1], and Yoshitada Tomioka[1]
[1]Department of Mechanical Engineering, University of Fukui, Fukui, Japan

Summary Low-dimensional carbon nano-materials have attracted significant attentions for its unique functional material properties, and graphene sheet (GS) is well-known as a fundamental 2D carbon nano-material. In this study, we focus on the mechanical and geometrical properties of GS with introduced hierarchical lattice defects for designing and controlling curved GS with out-of-plane deformation. According to the origami approach, we build atomic models of GS with different hierarchical lattice defects and perform their shape deformations with the molecular dynamic method. For GS, the out-of-plane deformation caused by the spontaneous curvature from lattice defects are often observed, so we consider such effects as well as the in-plane interaction, and discuss the relationship between the site potential energy, the mean curvature, and the Gauss curvature in details. In addition, we propose a general methodology for designing curved GS.

ANALYSIS MODEL OF GS WITH LATTICE DEFECTS

The lattice defects often cause remarkable out-of-plane deformation, which is a unique characteristic observed in low-dimensional carbon nano-materials [1]. For graphene sheet (GS) generally composed by hexagonal arrays of carbon atoms, according to the local variation of mechanical properties, pentagon defect can be considered as a positive disclination, whereas heptagon defect can be considered as a negative disclination. In this study, we define the hierarchical lattice defects as a combination of the positive disclination and the negative disclination that includes isolated disclination, isolated dislocation, dislocation dipole, dislocation array, and so on. Moreover, we use the technology of traditional Japanese paper craft art called "origami" to obtain the atomic position with complex out-of-plane deformation caused by the isolated disclination, dislocation, and dislocation array in GS. The initial atomic models are relaxed to the equilibrium states using the conjugate gradient method in molecular dynamics simulation to obtain the stable curved structures of GS.

MEAN CURVATURE AND GAUSS CURVATURE

To investigate the out-of-plane deformation of GS from plane to curved surfaces, we proposed a mathematical method to calculate the curvature tensor using the atomistic configuration. During the compression process, each GS initially modeled as 2D plane deforms to different 3D curved surfaces owing to the out-of-plane deformation [2], and this 2D–3D transition may generate folds and kink deformation. We introduce the mean curvature defined by the atomic configuration, such that we can characterize the out-of-plane deformation with quantification. Perfect GS has a hexagonal lattice structure, in which each atom is connected to three adjacent atoms via C–C covalent bond. As shown in Fig. 1, three neighboring atoms I, J, and K are connected to the carbon atom O. We consider these four carbon atoms O, I, J, and K span a curved surface $\boldsymbol{S}$. It would be a good approximation when the normal vector $\vec{\boldsymbol{n}}$ is defined as the normal vector of the plane I–J–K. Then, we establish a local Cartesian coordinates O–uvw, where the direction of w is parallel to the normal vector $\vec{\boldsymbol{n}}$. Thus, the curved surface S can be expressed as:

$$\kappa_{11}u^2 + 2\kappa_{12}uv + \kappa_{22}v^2 + w = 0, \tag{1}$$

where κ_{11}, κ_{12}, and κ_{22} are the components of curvature tensor $\boldsymbol{\kappa}$.

The mean curvature H is the average value of the principal curvature components κ_{11}^{P} and κ_{22}^{P}, and the Gauss curvature K is the product of the two principal curvature components that are given as:

$$H = \frac{\kappa_{11}^{\mathrm{P}} + \kappa_{22}^{\mathrm{P}}}{2}, \quad K = \frac{\kappa_{11}^{\mathrm{P}}\kappa_{22}^{\mathrm{P}}}{2} \tag{2}$$

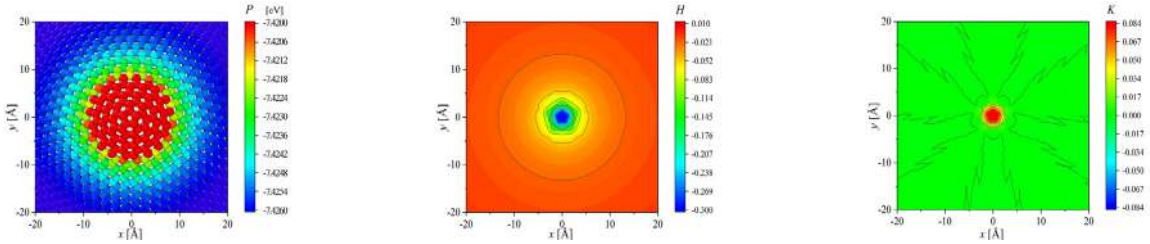
RESULTS AND DISCUSSION

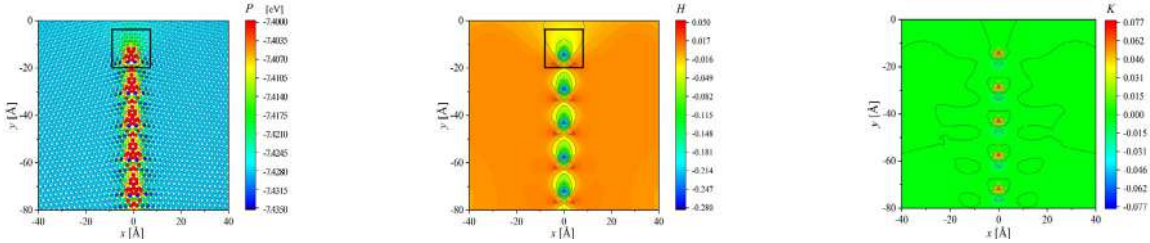
Figure 2 shows the distribution of potential energy, the mean curvature, and Gauss curvatre of the structure of GS with the isolated positive disclination. It can be seen that noticeable changes occur concentrically around the disclination core, and each distribution shows a concentric circle, respectively. It means the distribution values only depend on the distance from disclination corn, and do not depend on the angle. Furthermore, the Gauss curvature almost vanishes to 0 except for the part of the disclination. This phenomenon implies that the curved GS with isolated positive disclination has sufficient possibility to be regarded as a developable surface in mathematics.



(a) Distribution of potential energy (b) Distribution of mean curvature (c) Distribution of Gauss curvature

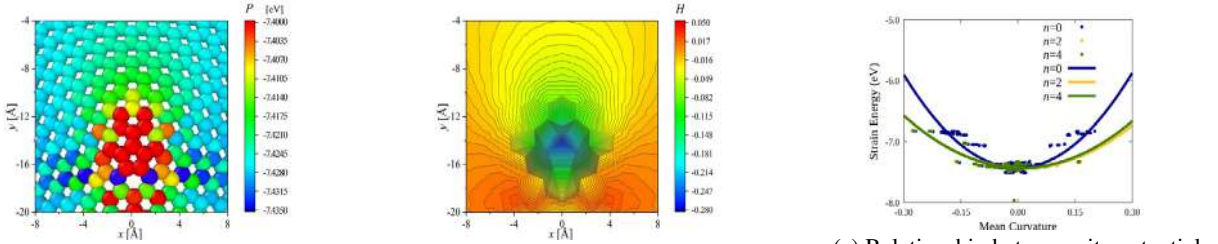
Figure 2: Mechanical and geometrical properties of positive disclination.

Figures 3 and 4 show the analytical results of GS with positive dislocation array. We consider different densities of dislocation array, which is represented by the numbers of unit hexagon cell n between the adjacent dislocations. GS with dislocation array shows a periodic curved surface of mountain-valley-mountain-valley. From the distribution of potential energy, the periodical distribution has the largest value in pentagon defect and the smallest value in the heptagon defect. The distribution of the mean curvature shows that the entire model has nonzero curvature owing to out-of-plane deformation caused by the lattice defects, where the parts around the dislocation array own the largest absolute curvature and the absolute mean curvature decreases as the distance from dislocation array increases. In addition, as the dislocation density increases, the interval between contour lines increases. The same as Fig. 2(c), the Gasuss curvature is almost 0 except for the parts of dislocation array, which shows that a semi-developable curved surface can be obtained.



(a) Distribution of potential energy (b) Distribution of mean curvature (c) Distribution of Gauss curvature

Figure 3: Mechanical and geometrical properties of positive dislocation array with $n = 2$.



(a) Enlarged view of distribution of potential energy (b) Enlarged view of distribution of mean curvature (c) Relationship between site potential energy and mean curvature with different densities of dislocation

Figure 4: Relationship of mechanical and geometrical properties of positive dislocation array.

The relationship between the mean curvature and the site potential energy of the positive dislocation array is shown in Fig. 4(c). Because the mechanical properties near the dislocation and the free edge of GS are strongly affected by lattice defects, the potential energy distribution does not always correspond to the distribution of the mean curvature and the dispersion value is relatively large. However, the site potential energy can be universally expressed as a function of mean curvature regardless of the density of dislocation array. It indicates that the bending strain energy function can be defined using the mean curvature, so we can obtain the bending stiffness. In this way, the curved surface of GS with the intrinsic curvature caused by different arrangement of lattice defect will be predictable and controllable.

SHANNON ENTROPY IN STOCHASTIC ANALYSIS OF MEMS

Marcin Kamiński[1] and Alberto Corigliano [2]
[1]Department Structural Mechanics, Łódź University of Technology, Łódź, Poland
[2]Department of Civil and Environmental Engineering, Politecnico di Milano, Italy

Summary This work is focused on the numerical determination of Shannon probabilistic entropy for MEMS devices exhibiting some uncertainty in their structural response. This entropy is a universal measure of statistical or stochastic disorder in static deformation or dynamic vibrations of engineering systems and is available for both continuous and discrete distributions functions of structural parameters. Interval algorithm using Monte-Carlo simulation and polynomial structural response recovery have been implemented to demonstrate uncertainty propagation of forced vibrations in MEMS devices. Computational example includes stochastic nonlinear vibrations described by the Duffing equation calibrated for some micro-resonator, whose damping is adopted as the Gaussian input uncertainty source.

INTRODUCTION

Probabilistic entropy is a mathematical extension of its thermodynamic origin invented by Boltzmann and serves now as a universal measure of disorder (uncertainty) in the given engineering system. Various theories and formulas existing in this area have been initiated by Shannon in 1948, continued by Renyi, Tsallis [1] or Kolmogorov [2], Sinai and Kullback [3], and are available for both discrete and continuous probability distributions of the stochastic response of a given system. The main numerical difficulty in probabilistic entropy calculation is the necessity of final probability density function availability. This makes many of the stochastic computer techniques like Karhunen-Loeve, polynomial chaos or stochastic perturbation technique simply inapplicable and this is why the traditional Monte-Carlo simulation scheme may be preferred in this context.

The main aim of this study is the determination of probabilistic entropy fluctuations in some micro-resonator forced vibration problems with uncertainty described by the Duffing equations [4]; its understanding seems to be necessary for further more general numerical analyses of the disorder propagation in nonlinear vibrations of various MEMS devices [5]. The damping coefficient of this micro-devices is chosen as the input uncertainty source, because this parameter decisively affects its dynamic response, and its probability distribution is modelled using alternatively uniform, triangular, Gaussian as well as lognormal functions; all these distributions are based on the same upper and lower bounds for the uncertainty interval. The deterministic vibrations spectrum is obtained numerically using the Runge-Kutta-Fehlenberg algorithm implemented in the computer algebra system MAPLE and this is the basis for polynomial Least Squares Method approximation of the micro-resonator displacements with respect to this damping coefficient. Further part programmed in the same system includes Monte-Carlo sampling (MCS) of the damping parameter and the same sampling of the dynamic response and final Shannon entropy calculation using a formula adjacent to the interval representation of the statistical data. The approach proposed in this work may be used for more advanced MEMS analyses using commercial Finite Element Method codes like COMSOL or ABAQUS, for computer simulation of inelastic deformation in solids, for disorder propagation analysis in various computational fluid mechanics problems.

PRELIMINARY RESULTS

Let us consider further a continuous random variable b with its probability density function $g_b(x)$ discretized by a set of subintervals of the same length δ having the following representation within each ith subinterval:

$$g_b(x_i) = \frac{1}{\delta} \int_{i\delta}^{(i+1)\delta} g_b(x)\, dx \,. \tag{1}$$

Next, the quantized random variable $\hat{x}$ is defined as $\hat{x} = x_i \;\; for \; i\delta \le \hat{x} \le (i+1)\delta$, whose probability equals to

$$p_i = \int_{i\delta}^{(i+1)\delta} g_b(x)\, dx = \delta\, g_b(x_i) \,. \tag{2}$$

Shannon entropy corresponding to a partition of $g_b(x)$ into n equal subintervals can be rewritten as

$$H(\hat{x}) = -\sum_{i=1}^{n} p_i \log(p_i) = -\sum_{i=1}^{n} \delta g_b(x_i) \log(g_b(x_i)) - \log(\delta). \tag{3}$$

Determination of this entropy for the given MEMS device proceeds directly thanks to determination and partition of the probability distribution function of its structural response and is obtained in this work as the iterative solution to the following Duffing equation:

$$m\ddot{x}_{(j)}(t)+c_{(j)}\dot{x}_{(j)}(t)+k_1x_{(j)}(t)+k_2x^2_{(j)}(t)+k_3x^3_{(j)}(t)=F\sin(\omega t), \tag{4}$$

where m denotes the mass of the vibrating structure, $c_{(j)}$ stands for the damping coefficients discrete values, k_1, k_2 and k_3 are first, second, and third order stiffness coefficients related to various physical fields and sources, F and ω are the amplitude and frequency of the forcing signal. Since the damping coefficient is taken as the Gaussian input variable with the expectation and standard deviation equal to $E[c]$ and $\sigma(c)$, respectively, its discrete realizations are obtained via equidistant partition of the interval $[E[c]\text{-}3\sigma(c), E[c]+3\sigma(c)]$. These discrete solutions substituted to the Least Squares Method fitting procedure enable to determine structural response as a polynomial of its damping, and order of this polynomial is optimized using minimization of the fitting variance and RMS error as well as maximization of the correlation factor of the approximating polynomial to the fitting dataset. Having determined response polynomial, one may apply classical MCS strategy make a histogram of this response, whose further processing results in Shannon entropy value; such an algorithm enables for application of non-Gaussian parameters or even a couple of various uncertainties at the same time. Numerical simulation provided here has been completed with the input data adopted after [4] and it has been preceded with initial verification of Shannon entropy sensitivity to a partition of the input histogram. Left diagram of Fig. 1 shows convergence of this entropy together with an increasing partitioning of this histogram for the Gaussian random variable having expectation equal to 10 and the few standard deviations. Determination of satisfactory partition of both input and output uncertainty guarantees efficient estimation of probabilistic entropy, which can be evaluated when coefficient of variation reaches its extreme value. Shannon entropy is expected to be more efficient in uncertainty evaluation while periodic or quasi-periodic vibrations are analyzed, because of enormously large increase of coefficient of variation, when the expected value tends to 0 (cf. Fig. 1). Application of this technique to large scale MEMS system is possible with replacing of Eqn. (4) with its matrix counterpart and determination of the optimal polynomial responses in local manner – for each degree of freedom separately.

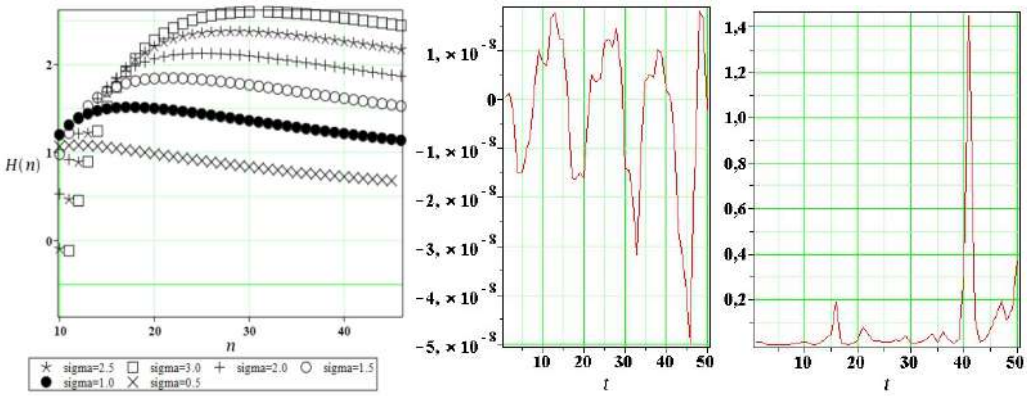

Figure 1. Convergence rate for the interval entropy computations (left) and expected values of MEMS device vibration (middle) and its coefficient of variation (right).

CONCLUDING REMARKS

Interval representation of the given probability density function applied together with Monte-Carlo simulation scheme of the structural response enables for reliable and relatively fast computation of probabilistic entropy propagation in many engineering systems including MEMS devices. As it was demonstrated, it does not demand large effort in discretization of the resulting probability distribution. In particular, one can model non-Gaussian distribution of any physical, material or geometrical parameters. It can be done both using some analytical solutions provided with the computer algebra systems like MAPLE as well as thanks to its common application with some Finite Element Method system.

HOMOGENIZATION OF HETEROGENEOUS PIEZOELECTRIC MATERIALS FOR VIBRATIONAL ENERGY HARVESTING

Denis Aubry and Ann-Lenaig Hamon*
Université Paris-Saclay,Centrale Supélec,CNRS,
Laboratoire de Mécanique des Sols,Structures et Matériaux,91190,Gif-sur-Yvette,France

Summary We study here energy harvesting systems derived from solid vibrations. They require an efficient tranduce which can be made of piezoelectric, ferroelectric or triboelectric materials, or a combination of these. Heterogeneous structures designed with materials with various electromechanical properties are thus good candidates but require a homogenization process of their properties.

We propose to describe the multiphysic homogenization procedure of the electromechanical properties of piezoelectric nano-architectures, used to feed the complete harvester model, and then to describe the electromechanical behaviour of a harvester using MEMS.

Keywords: MEMS, Vibrational energy harvesting, Autonomous microsensors

INTRODUCTION

With the increasing use of IoT, the need for smart, integrated, miniaturized and low-energy wireless devices is boosted. In parallel, a wide range of needs for autonomous microsensors emerges, among which the health monitoring of civil engineering structures (bridges, dams), railway tracks, or transport vehicles (terrestrial, maritime, aeronautics), but also biomedical applications (autonomous pacemaker, smart garments).

We propose here to consider energy harvesting derived from solid vibrations. Indeed, they are an ubiquitous and constant source of energy which requires an efficient tranducer in order to harvest electric charges which are then stored in a capacitor before use. These transducers can be made of piezoelectric, ferroelectric or triboelectric materials, or a combination of these.

Heterogeneous structures designed with materials with various electromechanical properties are thus good candidates but require a homogenization process of their properties.

We propose to describe the multiphysic homogenization procedure of the electromechanical properties of piezoelectric nano-architectures, used to feed the complete harvester model and then to describe the electromechanical behaviour of a harvester using MEMS.

HOMOGENIZATION OF THE HETEROGENEOUS TRANSDUCER

The homogenization procedure involves an asymptotic strategy with respect to a scaling factor ξ proposed originally by Sanchez-Palancia [1] and recently by De Bellis [2] for an electromechanical coupling. The displacement $\boldsymbol{u}$ and voltage v^e fields are sought as:

$$\boldsymbol{u}\left(\boldsymbol{x},\boldsymbol{y}\right) = \sum_{k\geq 0} \xi_k \boldsymbol{u_k}\left(\boldsymbol{x},\boldsymbol{y}\right) \qquad \text{and} \qquad v^e\left(\boldsymbol{x},\boldsymbol{y}\right) = \sum_{k\geq 0} \xi_k v_k^e\left(\boldsymbol{x},\boldsymbol{y}\right)$$

where $\boldsymbol{x}$ is the macroscopic and $\boldsymbol{y}$ the microscopic space variables, considered as independent.

The coupled equations to solve are

$$\begin{cases} \textbf{Div}\left\{\boldsymbol{C}\left[\boldsymbol{\epsilon}\left(\boldsymbol{u}\right)+\boldsymbol{D^e}\boldsymbol{\nabla} v^e\right]\right\} = \boldsymbol{0} \\ \text{div}\left[-\boldsymbol{D^e}^T\boldsymbol{\epsilon}\left(\boldsymbol{u}\right)+\boldsymbol{d^e}\boldsymbol{\nabla} v^e\right] = 0 \end{cases}$$

where $\boldsymbol{C}$ is the 4^{th}-order elastic tensor, $\boldsymbol{\epsilon}$ the small strain tensor, $\boldsymbol{D^e}$ the 3^{rd}-order piezoelectric tensor, and $\boldsymbol{d^e} = \epsilon_0\boldsymbol{\epsilon_r}$ the 2^{nd}-order absolute local permittivity tensor.

We can prove that $\boldsymbol{u_0}$ and v_0^e only depend on $\boldsymbol{x}$, and that there exist three tensors $\boldsymbol{A}$, $\boldsymbol{B^e}$ and $\boldsymbol{b^e}$ functions of the $\boldsymbol{y}$ variable, and such that the 1^{st}-order microscopic strain and electric fields are given by:

$$\begin{cases} \boldsymbol{\epsilon_y}\left(\boldsymbol{u_1}\right) = \boldsymbol{A}\boldsymbol{\epsilon_x}\left(\boldsymbol{u_0}\right)+\boldsymbol{B^e}\boldsymbol{\nabla_x} v_0^e \\ \boldsymbol{\nabla_y} v_1^2 = -\boldsymbol{B^e}^T\boldsymbol{\epsilon_x}\left(\boldsymbol{u_0}\right)+\boldsymbol{b^e}\boldsymbol{\nabla_x} v_0^e \end{cases}$$

$\boldsymbol{A}$, $\boldsymbol{B^e}$ and $\boldsymbol{b^e}$ are determined with nine carefully chosen problems solved on the representative periodic cell and from which are infered the homogenized tensors $\tilde{\boldsymbol{C}}$, $\tilde{\boldsymbol{D}}^{\boldsymbol{e}}$ and $\tilde{\boldsymbol{d}}^{\boldsymbol{e}}$. The computational solution is sought using finite elements and requires to take into account the specific symmetry of the representative cell with specific boundary conditions. The chosen test materials are GaN [3] or ZnO [4] nanowires embedded in PVDF [5], ferroelectric nanoparticles [6] or triboelectric composites [7]. Their individual anisotropy is taken into account.

HARVESTER ARCHITECTURE

The complete structure of the harvesting device can be decomposed into three stages, which has already proven effective for an autonomous pacemaker using interdigitated electrostatic combs as the transducer device ([8],[9]) as shown in Fig. 1.

First, the vibrational input sets into motion a seismic mass. The input signal frequency is not necessarily in the range of the transducing material and the storage circuit efficiency. Thus, bistable prebuckled beams are used in order to apply vibrations in the proper frequency range to the transducer. Secondly, the transducer can be modelled using the homogenized properties calculated as shown above. Thirdly, an electrical circuit with non linear diodes allows the storage into a capacitor of an electric charge which must be optimized.

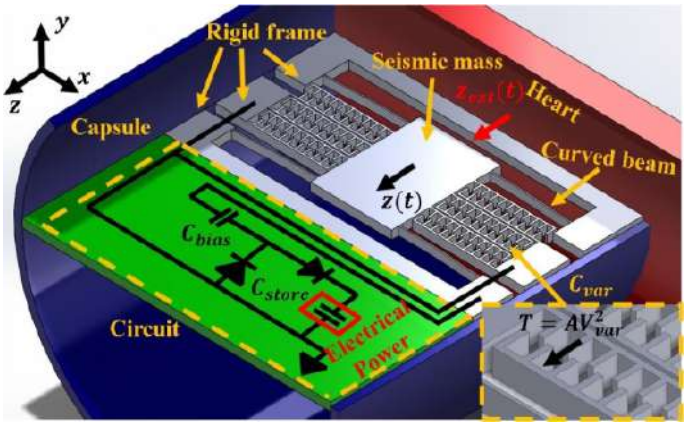

Figure 1: Typical architecture for a pacemaker: the transducing device consists in interdigitated electrostatic combs [10].

CONCLUSIONS

The homogenization process allows to exhibit the novel properties of the transducer and to select the most effective types of materials. Moreover, it allows to model the complete behaviour of a harvester and to size all of its components.

At last, let us note that specific attention must be paid to the different characteristic times involved, typically the vibration period versus the relaxation time of the electrical circuit.

ACKNOWLEDGEMENTS

This work is carried out within the NanoVIBES project supported by the NanoSaclay Labex and involving six academic partners of University Paris-Saclay.

NON-LINEARITIES MAPPING FOR MODEL ORDER REDUCTION IN MEMS

Giorgio Gobat*[1], Valentina Zega[1], and Attilio Frangi[1]
[1]Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy

Summary A numerical procedure able to simulate Micro-Electro-Mechanical-Systems (MEMS) resonant devices in presence of electrostatic and geometric non-linearities is proposed. The main idea is to represent MEMS devices as a collection of stiff components (e.g. moving mass or shuttle), compliant elements (e.g folded springs) and electrodes, thus reducing the original device to a model with the degrees of freedom (dof) of the stiff components. The non-linear elastic and electrostatic forces are evaluated through a mapping procedure starting from numerically precomputed tables. The method is applied to the analysis of a MEMS quad-mass structure and validated with experimental data.

INTRODUCTION

Micro-Electro-Mechanical-Systems are experiencing an explosive growth and pose new challenges also from the numerical simulation point of view. The increasing request of more sophisticated and smaller devices, in fact, often implies to consider many non-linear effects that can be strictly related to the mechanical response or to coupled electro-mechanical phenomena. Moreover, the high resonant frequencies (in the order of kHz-GHz) and the in-vacuum encapsulation (quality factors in the order of thousands) of such devices can result in difficulties in terms of computational effort.

The Finite Element Method (FEM) represents the most popular simulation tool employed so far to simulate the dynamic response of MEMS devices both in the linear and nonlinear regimes. It generates a second order differential system of equations that for complex mechanical structures (e.g. gyroscopes) can reach big dimensions and consequently require long computational times. There is then the need to find alternative methods able to simulate more efficiently the complex behaviours of MEMS devices. One possibility is represented by the Reduced Order Models (ROM).

In this work we propose a ROM procedure inspired by the lumped parameter ([1, 2]) and pseudo-rigid ([3, 4]) models. It consists in the reduction of the complex mechanical structure of the MEMS device in a simplified system made by rigid bodies connected one to the others and to the substrate through compliant elements. In this way it is possible to reduce the number of degrees of freedom to the ones of the identified rigid bodies and to evaluate the elastic and electrostatic forces from pre-computed tables, thus significantly reducing the computational time.

METHODOLOGY

The quad-mass MEMS structure proposed in [5] is considered in the following. It consists of four masses connected one to the others and to the substrate through folded beams and able to translate in-plane according to the beating-heart mode shown in Figure 1a. Comb fingers are also present in the four masses to allow for electrostatic actuation and readout.

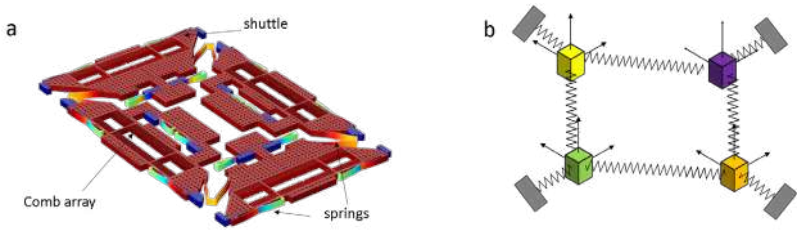

Figure 1: (a) Beating-heart mode of the quad-mass structure proposed in [5]. The contour of the displacement magnitude is shown in color. (b) Schematic view of the quad-mass structure employed in the proposed Reduced Order Model.

According to the proposed MOR procedure, we identify the stiff components with each moving mass (or shuttle) and the compliant elements with the folded springs (see Figure 1b). In order to apply the proposed ROM procedure, the stiff components are modelled as rigid bodies endowed with 6 dof each (colored cubes in Figure 1b), while compliant elements (zig-zag lines in Figure 1b) are simulated through nonlinear static FEM analyses to build the necessary pre-computed tables for the elastic nonlinear forces. To compute such tables, an admissible range for displacement and rotation amplitudes is evaluated a-priori according to the real quad-mass structure (i.e. maximum displacement to avoid contact between mechanical components or unstable phenomena such as pull-in). An increasing displacement and rotation amplitudes (in the admissible range before identified) are then applied to each compliant element and the corresponding reaction forces are computed and tabulated. The overall nonlinear elastic forces $\mathbf{F}_s$ acting on the rigid bodies can be then reconstructed through a numerical fitting of the tabulated discrete values.

*Corresponding author. E-mail: giorgio.gobat@polimi.it

A similar approach is adopted for the estimation of the nonlinear electrostatic forces acting on the rigid bodies. Each comb finger is subjected to a given increasing displacement (in the admissible range above identified) and the electrostatic forces are computed through a code based on integral equations and tabulated. The overall nonlinear electrostatic force $\mathbf{F}_e$ acting on the rigid bodies can be then reconstructed through a numerical fitting of the tabulated discrete values.

The equations of motion then read:

$$\mathbf{M}\,\ddot{\mathbf{q}} + \mathbf{F}_s(\mathbf{q}) = \mathbf{F}_e(t, \mathbf{q}) \tag{1}$$

where $\mathbf{M}$ is the mass matrix of the rigid bodies, $\mathbf{q}$ is motion parameters vector, $\mathbf{F}_s$ is the function describing the nonlinear elastic forces and $\mathbf{F}_e$ is the function describing the nonlinear electrostatic forces. In eq. (1) the number of differential equation to solve is dictated by the number of rigid bodies present in the ROM (e.g. 6 rigid motions x 4 bodies = 24 dof for the quad-mass structure under study) thus showing a great advantage with respect to a standard FEM approach that would discretize the full 3D geometry obtaining thousands of differential equations to solve.

EXPERIMENTS

To validate the proposed ROM procedure, we compare the numerical results with experimental data obtained on a quad-mass structure fabricated through the Thelma© surface micromachining process of STMicroelectronics [5].

A constant Direct Current (DC) voltage $V_{DC} = 10V$ is applied to the structure, while a Alternated Current (AC) voltage is applied on the driving electrodes located on the masses. The frequency of the AC voltage is swept from low to high frequencies (upward) and viceversa (downward) and the capacitance variation is measured on the readout electrodes located on the four masses. In Figure 2, the experimental frequency response of the quad-mass structure is reported in red dots for two amplitudes of the AC voltage. Note that the displacement amplitude is obtained from the capacitance measurements through standard relations [2] and the frequencies on the x-axis are normalized with respect to the natural frequency of the beating-heart mode ω_0 computed through a modal analysis.

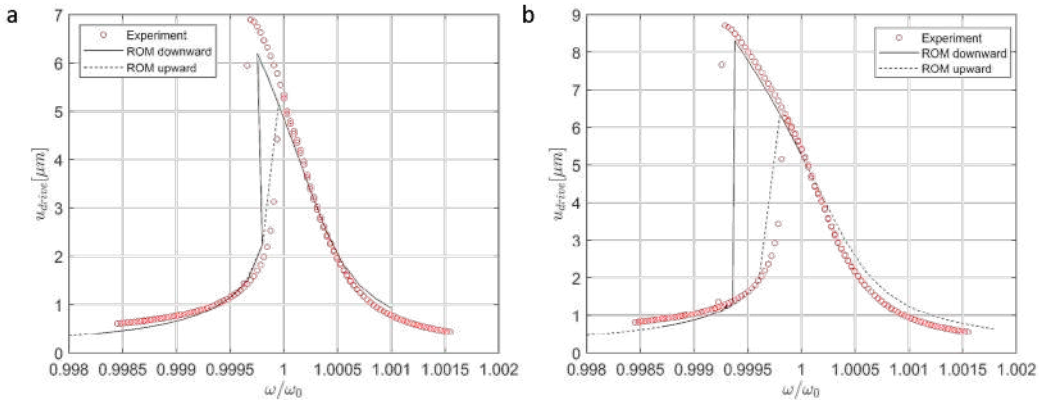

Figure 2: Frequency response of the quad-mass structure (beating-heart mode): experimental data vs ROM numerical prediction for (a) $V_{AC} = 1.5$ V and (b)$V_{AC} = 2$ V.

In Figure 2, the frequency response computed through the proposed ROM procedure is superimposed to the experimental data (black lines) and a good agreement is found. The nonlinear (softening) behaviour of the quad-mass structure is in fact well catched by the proposed model.

CONCLUSIONS

A ROM procedure able to simulate the linear and nonlinear dynamic response of a complex MEMS structure is here proposed. The proposed procedure is validated on a test structure and a good agreement between experiments and numerical predictions is found also in the nonlinear regime.

ON THE FAILURE OF SILICON THIN MEMBRANES DURING FREE FALL TESTS FOR MEMS MICROPHONES

Summary *The effect of the impact against hard surfaces on MEMS thin membranes attached to dummy devices, as observed through guided free fall (GFF) tests, is investigated through three-dimensional, finite element numerical simulations. Accounting for the different scales involved, a multiscale top-down approach is followed, and first both purely fluid-dynamics and purely solid-mechanics macro-scale simulations are carried out, to provide fluid pressure histories and anchor displacements as input for the silicon thin membranes. Then, a micro-scale mechanical analysis is carried out to judge whether possible failures arise in a given GFF test for each membrane. It is shown that in some cases possible failures actually depend from the combination of the fluid-induced and of the solid-induced input transferred to the MEMS membrane, and not from a single domain-induced loading condition.*

INTRODUCTION

Accidental drops of mobile phones or other consumer electronics devices containing MEMS structures can induce severe loadings to micro-sensors [1]. In particular, MEMS microphones [2] feature silicon thin membranes that are connected with the outside environment through narrow ducts, where the fluid (air) can flow freely. Unfortunately, through the same passages sudden fluid pressure rises, such as the ones generated during the last instants before the impact against a target surface (i.e. a rigid floor), are also transferred to the thin membranes, making them prone to fail to this extreme (and not easily-to-estimate) loading condition.

In the industry, the effect of impact against hard surfaces on these thin silicon MEMS membranes can be inspected experimentally through guided free fall tests. In the latter, MEMS microphones are set on an exemplary device, such as a dummy smartphone also known as "jig", that is driven downwards and then left to fall and collide against a rigid floor. Impact waves travelling inside the solid domain combine with the aforementioned pressure rise in the fluid (air) surrounding the membrane; henceforth, strongly varying loading conditions during the contact and the following bounce are present and it becomes difficult to predict eventual failures of the thin structures, justifying an accurate study.

MULTI-SCALE PROBLEM FORMULATION

Macro-scale analysis

To judge the goodness of the design choices on the impact resistance for the thin membrane, here we impose the displacement histories of the falling jig, captured by a high-speed camera, as input for a macro-scale fluid-dynamic numerical simulation. In the latter, only the air surrounding the jig is modelled and the jig surfaces are treated as movable walls, displacing in accordance to the aforementioned experimental measurements. While the jig surfaces are moving, a remeshing has to occur in the fluid domain surrounding it. Consequently, we can calculate the (transient) pressure histories at the inlet of the narrow ducts (on the jig surface, see Figure 1a) leading into the chamber where the MEMS membranes are placed on the jig (see Figure 1b).

Because of the difference in the scales involved, ranging from about ten centimetres for the jig to the one-micrometre membrane thickness, a multiscale top-down approach is needed: the macro-scale fluid pressure history during the impact transitory is transferred as input at the micro-scale, where only the silicon membrane is modelled (see Figure 1c). A second macro-scale analysis is also carried out, accounting for a purely mechanical domain for the jig (i.e. neglecting air): in this second macro-scale analysis, the displacement time-histories of the membrane anchor points are registered and, similarly to the fluid-dynamic case, they are then transferred as input to the micro-scale membrane model.

Micro-scale analysis

At this scale, with the aforementioned fluid pressure and displacement transient histories at the anchor points as input, the silicon membrane is analysed through an implicit dynamics, mechanical analysis, allowing for large displacements and contact, and the status of the membrane is checked for possible failures. Particular attention has been devoted to the synchronization of the input signals with respect to the first impact. Since each jig can accommodate four microphones, i.e. four silicon membranes, and each membrane feature four vertices, a total of sixteen displacement signals are at hand for each free fall test. A fluid-structure interaction analysis of the air duct and membrane showed that the pressure at the inlet, obtained at the macro-scale, is transferred almost unchanged to the chamber where the membrane is placed: therefore, only one time-varying pressure signal is imposed at the membrane. The membrane itself can enter into contact with an upper and lower surface delimiting the internal chamber: these boundary conditions are taken into account during the micro-scale analysis.

*Corresponding author. E-mail: aldo.ghisi@polimi.it

RESULTS AND DISCUSSION

Experimental repetition of the tests (for a total of 25 guided free fall tests) showed that eventual failures are hardly predictable from nominally equal initial conditions; local observations of the impact history are hence necessary to clarify the failure behaviour, provided the accurate numerical analyses described above are carried out. The stress levels inside the membrane are inspected in terms of the envelopes of maximum and minimum principal stresses (see Figure 2) and checked versus a Rankine-like criterion in the tensile regime and versus a resistance domain defined as in [3] in the other regimes. Crack patterns due to the impact with the lower and upper surfaces are eventually observed.
It is also obtained that, in some cases, the failure is not simply pressure-induced (i.e. caused by pressure rise/decrease) or simply solid-induced (i.e. caused by the waves propagating in the solid jig and reaching the membranes), but it is the combination of the two phenomena to count.

Summary The correct functioning of many micro-electromechanical devices requires the isolation from accidental vibration. Metamaterials, presenting band-gaps in the dispersion spectrum, i.e. interval of frequency in which propagating waves are attenuated, can provide an effective solution for isolation at the microscale. In the research work here presented we design, analyse and fabricate a prototype of an isolator made with a metamaterial fabricated through the two-photon polymerization process. The experimental validation is currently under development.

INTRODUCTION

Phononic crystals are periodic structures with properly conceived designs in terms of geometry and elastic properties of the constituent materials, that exhibit exceptional dynamic behaviours, such as frequency bandgaps formation. The presence of bandgaps in these structures, also called metamaterials, makes them very appealing for applications such as vibration shielding at different scales and this demonstrates the increasing interest of the scientific community on the topic. Several examples of macroscale vibration isolators made by phononic crystals are available in the literature [1], no much work has been done so far at the microscale where the complexity of the optimal geometry of the unit cell often makes difficult or impossible the fabrication process.

In the present work, we design through numerical simulations a 3D phononic crystal with a micrometric unit cell able to work as vibration isolator for a micro system. We then exploit the recently developed technique of the two-photon polymerization (2PP) [2, 3] to realize a prototype of the isolated system. Experiments are currently under development.

PHONONIC CRYSTAL: MECHANICAL DESIGN AND SIMULATIONS

The phononic crystal designed in this work is similar to the one proposed in [4]; it is constituted by a periodic repetition of cubic cells with nearly spherical masses suspended by slender beams mutually orthogonal (Figure 1a). This particular arrangement, thanks to an internal resonant mechanism [5], allows obtaining very peculiar dynamic properties (i.e. wide complete bandgap). Two 3D numerical simulations are performed in COMSOL-Multiphysics to demonstrate the dynamic behaviour of the proposed metamaterial and to identify the bandgap frequency interval. In particular, the Bloch-Floquet analysis conducted on the unit cell represented in Figure 1a, shows that the dispersion diagram exhibits very large complete band-gaps: waves of frequencies inside this interval cannot propagate without attenuation. For the case of a cell of 27 μm side, a bandgap from 4.5 MHz and 28 MHz is obtained as shown in Figure 1b.

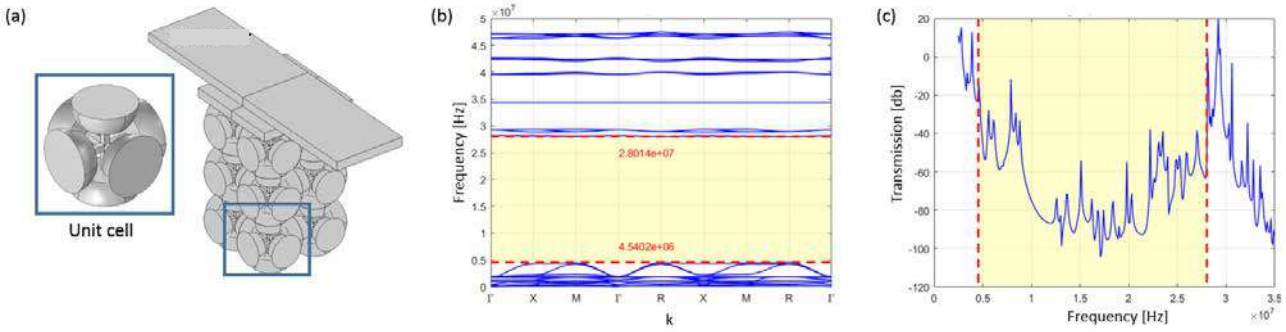

Figure 1. (a) Geometry of the proposed phononic crystal: a close-up view of the unit cell is also shown. (b) Dispersion and (c) transmission diagrams computed in COMSOL-Multiphysics.

In Figure 1c we report the transmission through the system made of the substrate and the 2 x 2 x 3 cells phononic crystal as a function of the frequency of the input waves. A prescribed sinusoidal displacement along the vertical direction is applied on the bottom substrate of the metamaterial and the resultant displacement on the top of the metamaterial is computed to show the attenuation properties of the proposed phononic crystal. From Figure 1c one can observe that, within the bandgap, shaded in the plot, a significant attenuation is obtained with 3 cells only. Note that the transmission diagram is reported only for the vertical direction because of the chosen configuration of the periodic cells (2 x 2 x 3) dictated by the application we want to prove as vibration isolator for the micro-beam.

With the aim of demonstrating the potentiality of this micro-structured material in vibration shielding of micro systems, we consider a beam that can oscillate in bending, and we isolate it from the support through the proposed metamaterial, see Figure 1a. The beam is designed to have the second bending resonant frequency inside the bandgap of the metamaterial.

FABRICATION BY TWO PHOTON POLYMERIZATION

Two-photon polymerization is a direct laser writing technology that allows the fabrication of fully 3D structures with sub-micron resolution. It is a technique based on two processes: two-photon absorption (2PA) and polymerization. The peculiar feature of 2PP with respect to conventional 3D laser printing is the sub-diffraction limit resolution. This feature is obtained thanks to the presence of two competing processes in the focal volume of the laser beam, polymerization and quenching, that tends to stop the polymerization. In fact, only the small region, called voxel, where the density of radicals is higher than a certain threshold value determined by the different quenching channels, is polymerized. The structures fabricated with 2PP strongly depend on the voxel characteristics that in turn depend on many factors, such as wavelength, pulse duration, repetition rate, numerical aperture, laser source polarization, laser power, writing speed and distance between lines.

The photoresist used in this work is called SZ2080 and it is a hybrid organic-inorganic negative sol-gel photoresist specifically developed for 2PP. It is made of two components: methacryloxypropil trimethoxysylane (MAPTMS) and zirconium propoxide (ZPO). A particular photoinitiator, called Irgacure 369 (IRG), is also added to enhance the 2PP effect. Compared to other photoresists, SZ2080 presents excellent mechanical properties [6], it is non-toxic and it shows negligible shrinkage after solvent washing.

To fabricate the structure one has first to prepare a bulky sample by drop-deposition, drop-casting and baking at 105°C, then the complex geometry of the micro-structure is realized within the sample through laser irradiation and finally the development process removes the non-irradiated zones of the drop and makes structures emerge.

In this work, we used a frequency-doubled erbium-doped fiber laser with wavelength of 780 nm, pulse duration of about 100 fs, and repetition rate of 80 MHz. The direct laser fabrication setup used is composed by a laser source, optical and optomechanical components to deliver, control, block, and focus the laser beam, a translation device to move the sample with respect to the laser beam focus, and a machine vision system for real-time monitoring of the fabrication process, as shown in Figure 2a.

Figure 2b shows the SEM image of the fabricated simple microstructure constituted by a beam clamped in the central part to the substrate without the presence of the metamaterial, while Figure 2c shows the prototype for vibration isolation of the micro beam, with a block of 2 x 2 x 3 cells of the metamaterial. The 2PP fabrication technique proved to be suitable to realize the very complex geometry of the metamaterial at the microscale.

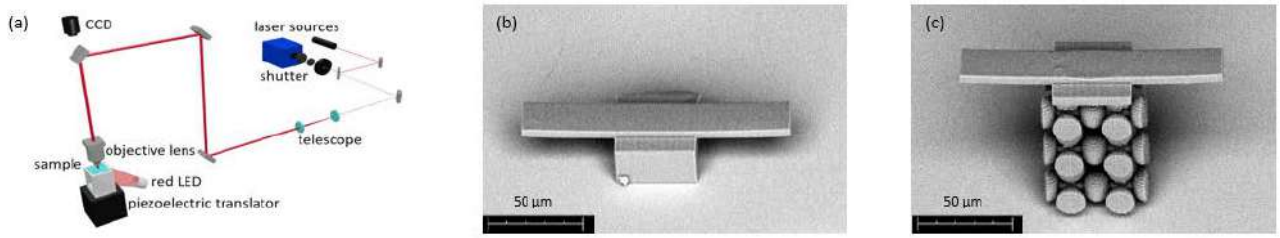

Figure 2. (a) Fabrication set-up. SEM images of the fabricated structures without (b) and with (c) an isolating phononic crystal.

The effectiveness of the proposed isolating system will be experimentally checked. Both structures will be excited at the resonant frequency of the beams by a piezoelectric actuator placed below the substrate. An optical system will allow to detect the oscillation of the beams which is expected to be attenuated by the presence of the metamaterial. This latter experimental apparatus is currently under development.

CONCLUSIONS

A vibration isolator for micro-systems has been designed through numerical simulations and a first prototype has been fabricated through the 2PP process. This represents an important step towards a new class of vibration isolators at the microscale that can be employed for example in microelectromechanical systems.

Summary New stable atomic arrangements in 2D nanostructures based on carbon (C) and as well as on molybdenum (Mo) using a memetic algorithm and the density functional theory (DFT) are presented. The semiconducting carbon allotrope as graphene-like material and the Single-Layered Molybdenum Disulfide ($SLMoS_2$) heterostructures with desired mechanical properties are created.

INTRODUCTION

2D materials play important role in modern materials science. Apart from materials based on carbon, e.g. graphene, there is possible to create new 2D materials based on molybdenum. New graphen-like materials X and Y created by hybrid intelligent approach [1, 2] represent the first class of materials. One of the most prominent 2D material based on molybdenum is the molybdenum disulfide (MoS_2), which reveals polymorphism at the nanolevel.

Optimal design technique enabling to obtain new 2D semiconducting carbon allotrope as graphene-like material and $SLMoS_2$ heterostructures with desired mechanical properties is presented. The proposed method is based on the memetic global optimization of the potential energy of the nanostructure. The behaviour and energy of the atoms is determined by the AEROBO potential in the case of graphene and the REAX-FF potential in the case of molybdenum. Examples of such semiconducting carbon allotrope and periodic $SLMoS_2$ 2H/1T heterostructure are presented with corresponding mechanical properties.

INTELLIGENT DESIGN BASED ON MEMETIC COMPUTING

The memetic algorithm, proposed and presented in this work, combines the parallel **E**volutionary **A**lgorithm (EA) prepared by the authors, and the classical **C**onjugated-**G**radient (CG) minimization of the total potential energy of the optimized atomic system. Since the processed structure is considered as a discrete atomic model, the behavior and the potential energy of carbon atoms are determined using the **A**daptive **I**ntermolecular **R**eactive **E**mpirical **B**ond **O**rder (AIREBO) in the case nanostructures based on carbon and REAAX-FF in the case of nanostructures based on molybdenum.

A chromosome represents design variables in the form of real-valued Cartesian coordinates of each atom in the considered unit cell of the newly created atomic lattice. Each chromosome represents a certain spatial arrangement of atoms. In the initial population, atoms have randomly generated coordinates and are placed in the area of the unit cell with periodic boundaries. Dimensions, the rectangular or triclinic type of the unit cell, as well as the number of atoms, are part of a set of parameters of the simulation. Such an approach enables controlling the value of atomic density of the newly-created structure. The periodicity of the atomic structure significantly reduces the number of design variables.

The fitness function is formulated as the total potential energy of the considered atomic system, i.e., the total sum of all potential energies of particular atomic interactions.

The periodicity of the newly-created structure is also achieved in this step by proper boundary conditions, imposed on the unit cell. After the CG minimization of the potential energy, the objective function is computed for each individual in the population. The CG optimization is the most time-consuming part of the algorithm. To overcome this problem, the authors decided to parallelize the proposed algorithm and make it suitable for running on multiprocessor computers. Thus, the population is scattered into certain number of parts using the MPI library. In the next step, each part is further processed in the parallel way.

DESIGNING OF NEW 2D SEMICONDUCTING CARBON ALLOTROPE

A new, single-atom thick semiconducting 2D-graphene-like material, called Anisotropic-Cyclicgraphene, is generated by the two stage searching strategy linking molecular and *ab initio* approaches. The candidate is derived from the memetic based algorithm and molecular simulations and next is profoundly analysed using the first-principles density functional theory from the structural, mechanical, phonon, and electronic properties point of view.

The structure of the 2D-graphene-like material is considered as a discrete atomic model, with imposed periodic boundaries. The behavior of such a system is investigated using one of the molecular methods. The potential energy of carbon atoms, the forces acting between them and the overall behavior is determined by the AIREBO potential, especially developed for hydrocarbons.

The goal is to discover an atomic structure with stable configuration, predefined number of atoms and elastic material properties. The elastic properties are computed based on the molecular analysis of a structure with applied small strains. The atomic structures with orthotropic elastic material properties are taken into account. The objective function depends on the norm of differences between of prescribed and computed elastic properties [3].

First-principles calculations with the use of the density functional theory (DFT) within the pseudopotential, plane-wave

approximation (PP-PW) are made using the Cambridge Serial Total Energy Package (CASTEP). For structural, mechanical and phonon calculations the modified Perdew-Burke-Ernzerhof generalized gradient approximation for solids is applied as an exchange-correlation functional whereas for band structure computations the hybrid exchange-correlation functional HSE06.
The material derived from the first stage is then profoundly analyzed using the first-principles density functional theory from the structural, mechanical, phonon and electronic properties point of view. The proposed Anisotropic-Cyclicgraphene is mechanically, dynamically and thermally stable and can be semiconducting-like with a direct band gap of 0.829 eV [4].

DESIGNING OF NEW 2D MATERIALS BASED ON MOLYBDENUM

One of the most prominent 2D material based on molybdenum is the Single-Layered Molybdenum Disulfide ($SLMoS_2$), which reveals polymorphism at the nanolevel.
The 2H phase has semiconducting properties and approx. Young's modulus equals to 130 N/m, while the 1T polymorph reveals metallic or ferroelectric properties and two times lower stiffness [2]. Both phases of MoS_2 can exist simultaneously [3].
Intelligent designing $SLMoS_2$ heterostructures (a 2H lattice with Δ-shape 1T inclusion) with desired mechanical properties is presented. The memetic optimization approach enabling to obtain MoS_2 heterostructures with desired mechanical properties is applied. The behaviour and energy of the atoms is determined by the REAX-FF potential [5]. Examples of such periodic $SLMoS_2$ 2H/1T heterostructures are presented in the paper with corresponding mechanical properties.

CONCLUSIONS

The presented approach is applied to design of 2D nano-materials based on carbon as well as molybdenum.
The process of designing nano-material based carbon consists of two stages. In the first molecular stage the optimization problem is solved using the memetic algorithm. The second stage based on the first-principles density functional theory is used to examine results from the previous step. The proposed polymorph of graphene is mechanically, dynamically, and thermally stable and can be semiconducting with a direct band gap of 0.829 eV.
The intelligent optimization technique is also applied to obtain nano-structures based on molybdenum – $SLMoS_2$ heterostructures with desired mechanical properties.
Some results in this paper are unique and we trust will be verified by other works. The synthesis of the proposed structure is a separate task and goes beyond the area of this work.

ON THE ROLE OF SURFACE TENSION IN MODELS OF NANO-PLATE BENDING

Anatolii Bochkarev*
Faculty Of Applied Mathematics And Control Processes, Saint Petersburg State University, 7/9 Universitetskaya nab., St. Petersburg, 199804 Russia

Summary A von Kármán-type model of nano-plate bending is formulated taken into account the Gurtin–Murdoch surface elasticity and basing on the Kirchhoff hypothesis. Unlike than most of previous related theories, surface tension, usually omitted in the conjugation condition of Young–Laplace law in the transverse direction, is incorporated in 2D motion equations and constitutive relations for membrane forces together with quadratic terms equal of the von Kármán-type strains. A influence of the accounting surface tension is illustrated in comparison with other models on an example of non-linear bending, free transverse vibration, and compressive postbuckling of a strip-like nano-film with simply supported and clamped edges.

INTRODUCTION

The two-dimensional models of plates and shells with allowance for surface stresses, proposed by Gurtin and Murdoch (GM) [1] and supported by the results of atomistic modeling [2], are widely used in problems of nano-mechanics. An integral part of these models is the conjunction condition in the form of Young–Laplace's law, which ensures equilibrium of a negligibly thin surface layer and bulk phase. The work [3] on the non-linear bending of nano-plates was the first one taking into account the GM surface elasticity and identified the basic elements for following related models: effective membrane forces and bending moments, constitutive relations for them, et al. In the same time, this model has an obvious flaw: the conjunction condition of Young–Laplace in the transverse direction, expressed through surface tension, was not considered. Usually it is customary to satisfy this omitted condition through non-zero σ_{33} in Hooke's law. However, the results of [4] showed that this refinement leads to the negligible size effect, thereby confirming the basic principles of plate theory, where σ_{33} is zero. So, most authors prevailed the view that surface stresses affect bending mainly due to the difference in the values of the surface and bulk elastic moduli, and not by surface tension. It was shown in [5, 6] that this is not the case, and surface tension can significantly correct the mechanical properties.

Present study is devoted to the role of surface tension with non-linear terms or without in nano-plate bending. For this purpose, the built in [5] model is considered. It incorporates the conjunction condition of Young–Laplace law in the 2D governing equations in full and takes into account the von Kármán-type non-linearity of surface tension. The solved examples show the effect of surface tension on non-linear bending, transverse free vibration, and compressive postbuckling of a strip-like nano-film with simply supported and clamped edges in comparison with other models.

PROBLEM FORMULATION

An elastic nano-plate is considered, on the top $(+)$ and bottom $(-)$ faces of which there are surface stresses $\boldsymbol{\tau}^{\pm}$ obeying the GM constitutive relations [1]

$$\boldsymbol{\tau}^{\pm} = \tau_0^{\pm}\mathbf{A}^{\pm} + 2(\mu_{\mathrm{s}}^{\pm} - \tau_0^{\pm})\boldsymbol{\epsilon}^{\pm} + (\lambda_{\mathrm{s}}^{\pm} + \tau_0^{\pm})\mathrm{tr}\boldsymbol{\epsilon}^{\pm}\mathbf{A}^{\pm} + \tau_0^{\pm}\nabla_{\mathrm{s}}^{\pm}\mathbf{u}^{\pm} \tag{1}$$

Bulk elastic stresses $\boldsymbol{\sigma}^{\pm}$ on the faces are balanced with surface stresses $\boldsymbol{\tau}^{\pm}$ according to Young–Laplace law [1]

$$\nabla_{\mathrm{s}}^{\pm}\cdot\boldsymbol{\tau}^{\pm} + \boldsymbol{\varphi}^{\pm} = \rho_0^{\pm}\ddot{\mathbf{u}}^{\pm} \pm \mathbf{n}\cdot\boldsymbol{\sigma}^{\pm} \tag{2}$$

Here $\mathbf{u}^{\pm}$ is the displacement, $\nabla_{\mathrm{s}}^{\pm}$ is the nabla-operator, $\boldsymbol{\epsilon}^{\pm} = \mathbf{A}^{\pm}\cdot\boldsymbol{\varepsilon}^{\pm}\cdot\mathbf{A}^{\pm}$ is the surface projection of strain tensor $\boldsymbol{\varepsilon}$, $\mathbf{A}^{\pm}$ is the surface unit tensor, $\lambda_{\mathrm{s}}^{\pm}$ and $\mu_{\mathrm{s}}^{\pm}$ are surface Lame's parameters, $\tau_0^{\pm}$ is the residual surface tension, $\rho_0^{\pm}$ is the surface density, $\boldsymbol{\varphi}^{\pm}$ is the external load – all on the top $(+)$ and bottom $(-)$ faces; $\mathbf{n}$ is a normal to the middle surface of a plate.

The 2D Kirchhoff model for complex bending of nano-plates with taking into account the GM surface stresses (1), incorporating the conjunction condition of Young–Laplace law on nano-plate faces (2) in full, and also considering non-linearity of surface tension, was proposed in [5]. Under the equal surface behaviours of faces, it can be expressed as the von Kármán set

$$\begin{cases} I^*\ddot{u}_\gamma^0 = T^*_{\beta\alpha,\alpha} - \tau_0(w^2_{,\alpha})_{,\beta} + P^*_\beta \\ J^*\ddot{w}_{,\alpha\alpha} - I^*\ddot{w} = D^*\nabla_{\mathrm{s}}^2\nabla_{\mathrm{s}}^2 w - 2\tau_0\nabla_{\mathrm{s}}^2 w - T^*_{\beta\alpha}w_{,\beta\alpha} - m^*_{\alpha,\alpha} - P^*_3 \end{cases} \tag{3}$$

with the constitutive relation for the effective membrane forces

$$T^*_{\beta\alpha} = 2\tau_0\delta_{\beta\alpha} + 2\tau_0(\nabla_{\mathrm{s}}u^0)_{\beta\alpha} + C^*\left((1-\nu_{\mathrm{t}}^*)\varepsilon^0_{\beta\alpha} + \nu_{\mathrm{t}}^*\delta_{\beta\alpha}\varepsilon^0_{\gamma\gamma}\right) \tag{4}$$

where the in-plane strain $\boldsymbol{\varepsilon}^0$ and surface tension $\tau_0(\nabla_{\mathrm{s}}\mathbf{u}^0)$ are expressed through the in-plane displacement of midplane $\mathbf{u}^0$ and together with the first Eq. (3) have the von Kármán-type quadratic non-linearity of deflection w

$$\varepsilon^0_{\beta\alpha} = \frac{1}{2}\left(u^0_{\beta,\alpha} + u^0_{\alpha,\beta} + w_{,\alpha}w_{,\beta}\right),\ \tau_0(\nabla_{\mathrm{s}}u^0)_{\beta\alpha} = \tau_0(u^0_{\beta,\alpha} - ww_{,\beta\alpha}),\ \tau_0(\nabla_{\mathrm{s}}w)_\alpha = \tau_0(w_{,\alpha} + u^0_\beta w_{,\beta\alpha}) \tag{5}$$

Here $D^*, C^*, \nu_{\mathrm{t}}^*, P_i^*, m_\beta^*, I^*, J^*$ are effective flexural and tangential stiffnesses, Poisson's ratio, external forces and moments, static and inertia moment respectively.

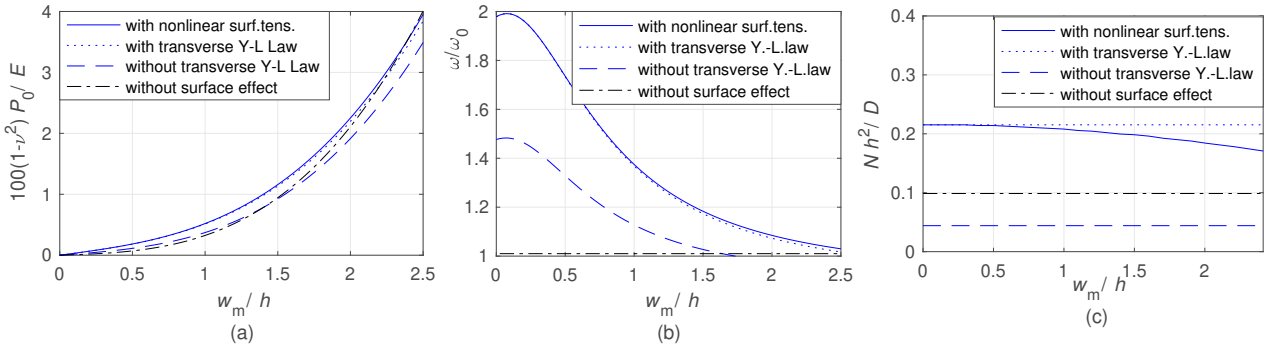

Figure 1: Nano-film with simply supported edges and the thickness $h = 1$ nm: (a) load-deflection ratio under cylindrical bending, (b) frequency-amplitude ratio of free vibration, (c) load-deflection ratio under compressive postbuckling

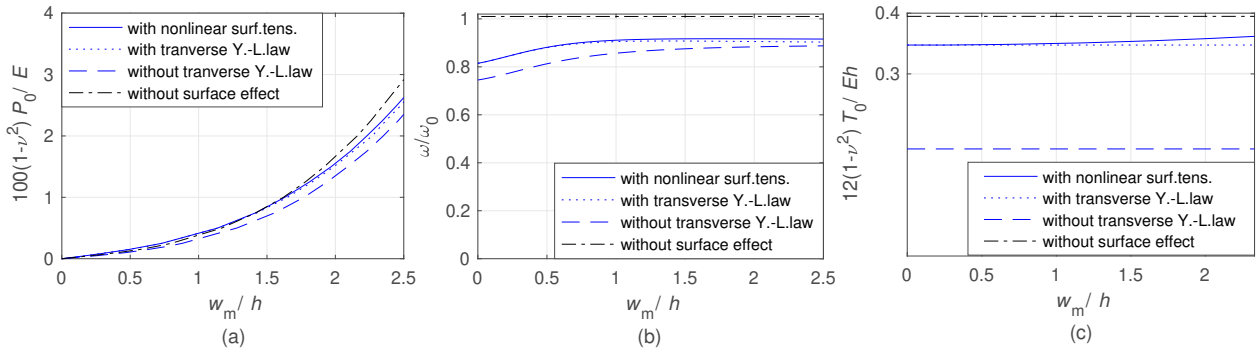

Figure 2: Nano-film with clamped edges and the thickness $h = 1$ nm: (a) load-deflection ratio under cylindrical bending, (b) frequency-amplitude ratio of free vibration, (c) load-deflection ratio under compressive postbuckling

CASE STUDY

Influence of the present surface tension on non-linear cylindrical bending, free transverse vibration and compressive postbuckling of a strip-like nano-film from Al[100] [2] is illustrated in Fig. 1 for simply supported edges and in Fig. 2 for clamped edges in comparison with other models. The considered examples show different directionality of size effect for simply supported and clamped edges. As can see, the 3rd Young–Laplace condition incorporated in the governing equation can significant enhance the size effect in comparison with accounting surface elasticity only as in [3]. Accounting non-linear terms of surface tension gives slight refinement, noticeable at a relative deflection of more than 2 under non-linear bending and free vibration. However, in the 3rd example, accounting linear part of surface tension allows only to find the critical Euler force, whereas accounting its non-linearity allows to consider deformation after the bifurcation point.

CONCLUSIONS

The plate theory proposed by [3] was further developed as an extension of von Kármám non-linear theory of elastic plates incorporated the GM surface elasticity including the non-linearity of surface tension and the conjugation condition of the Young–Laplace law in the transverse direction. As follows from the above examples, accounting surface tension reflects more properly the size effect, and accounting its non-linearity – also previously not described effects.

DISCRETE APPROACH TO MODEL AND TO SIMULATE THE ELASTIC PROPERTIES OF LATTICE MATERIALS

Igor Berinskii *[1]
[1]School of Mechanical Engineering, Tel Aviv University, Tel Aviv, Israel

Summary Elastic properties of two–dimensional cellular lattice materials are studied using a discrete model. The model is based on a representation of the lattice as a set of interacting nodes. A potential of interaction between the nodes is calibrated such that to simulate elastic linking. The analytical homogenization based on Cauchy–Born rule allows determining the elastic properties of the effective continuum corresponding to the specific lattice. On the other hand, the same properties can be found from the numerical simulations based on particle dynamics. It is shown that both ways lead to the same values of elastic components. Hence, particle–based numerical simulations can be used to design various applications of lattice materials including MEMS.

INTRODUCTION

Cellular materials attract the attention of researchers due to their outstanding stiffness and strength as well as enhanced absorption of mechanical energy at relatively small density. Artificial periodic cellular structures can be relatively easy fabricated using modern additive technologies. Due to this, nowadays they are extensively used in MEMS as well as in aerospace, sport, medical, fashion, and other industries. In a high variety of the cellular materials there are such of them, that expand in one or more directions at stretching along the other direction. These materials are called “auxetics”, and their unusual properties are explained by the negative value of Poisson’s ratio along one or several directions.

Computer simulations can help to choose the best cell topology, a number of cells, geometry of struts, material properties. Usually, FEM is used for simulations, however, in some cases, discrete models seem to be more applicable. For instance, such problems include big deformations, buckling, and fracture of cellular materials.

In this work, we consider two auxetic materials with reentrant double arrowheads (DAH), and semi–reentrant honeycombs (SREH) lattices (Fig.1). These lattices are based on the unit cells containing more than one node: such structures are referred to as multilattices. Following the approach proposed in [1] the lattice is represented as a set of particles having both translational and rotational degrees of freedom. Consequently, the interaction between the particles includes both forces and torques. This idea is used both for the theoretical analysis of the elastic properties of the effective continua corresponding to the lattices, and to determine these properties from computational simulations.

ANALYTICAL HOMOGENIZATION

The proposed homogenization procedure is described in [2] and allows finding the components of the stiffness tensor of the effective continuum analytically. The procedure is based on the Cauchy-Born rule: the strain energy of the lattice unit cell is assumed to be equal to the strain energy of the representative volume of the corresponding effective solid material. It is assumed that the nodes in a lattice have elastic connections. In general case, the axial, shear and torsional stiffness constants of these connections can be independent. As a result, the in-plane effective properties of the lattices can be found as the functions of the cells’ geometry and the stiffness constants of the bond. In the specific case considered here, the constants are fitted to simulate the connection by the Euler–Bernoulli rods with the rectangular section. As a result, the axial, torsional, shear and bending stiffness constants are not independent anymore and can be determined through the geometric and elastic parameters of the rod. In turn, these constants and the angles between the rods determine the elastic properties of the effective continuum.

Figure 2: Effective properties of DAH (a) and SREH (b) lattices (N/m) vs angle φ (rad). The results obtained from analytic results are shown with solid (C_{11}) and dashed (C_{22}) lines. The results obtained from numerical calculations are shown with diamonds (C_{11}) and circles (C_{22})

SIMULATIONS

The simulations are provided using particle dynamics. Each particle simulates a node of the lattice. The potential of interaction between the nodes is derived such that to represent the linking with Euler–Bernoulli beams. Initially, the uniform strains are applied to the elements of lattices. Then, the boundary conditions are set. The equations of motion for the translational and rotational degrees of freedom are solved using the Velocity Verlet algorithm. The equilibrium of the system is provided using the Langevin thermostat. As a result, the uniform stress field is obtained in a lattice and the necessary elastic properties can be determined. The components of stress tensor are calculated in two ways. The first way is to find the stress per one node considering the forces acting to the given node from its nearest neighbors. The second approach is to make an imaginary section in the lattice, sum the forces in the links crossing the section and divide the result to the section length. It is shown that both ways give the same or very close results.

RESULTS

The elastic properties of the lattices were determined both analytically and numerically. It was shown that the simulations with fixed boundary conditions may lead to a significant discrepancy between the analytic and numerical results. At the same time, periodic boundary conditions allow reaching a full coincidence (Fig. 2). It was shown, that the lattices can demonstrate highly anisotropic behavior, and due to this, the stiffness in different directions can vary up to several orders. The most typical cases from the practical point of view were considered and the corresponding parameters such as relative thickness, Young's moduli, and Poisson's ratios were calculated. The results were reported in [3].

From a numerical point of view, a case considered in this paper is the most basic. First, only the planar motion of the nodes was taken into account. Second, the linear elastic interaction between the nodes was considered. Also, the small displacement and rotations are presumed. However, the big advantage of the proposed method is its ability for generalization. First of all, much more complicated kinematics corresponding to the large displacements and rotations in three-dimensional motion can be considered. Second, the more complicated constitutive equations can be considered. In the case of large displacements, it seems more reasonable to use non–linear models to simulate hyperelastic materials, soft materials, and others.

NONLINEAR PULL-IN STUDIES OF COUPLED CARBON NANOTUBE RESONATORS: MOLECULAR DYNAMICS SIMULATIONS AND EQUIVALENT CONTINUUM MODELS

Aningi Mokhalingam *[1], Indranil S Dalal[2], and Shakti S Gupta[1]
[1]Department of Mechanical Engineering, IIT Kanpur, Kanpur - 208016, India
[2]Department of Chemical Engineering, IIT Kanpur, Kanpur - 208016, India

Summary In this paper, the static and dynamic pull-in of two coupled single-walled carbon nanotube (SWCNT) resonator is studied using molecular dynamics (MD) and an equivalent continuum model. The SWCNTs are coupled electrostatically and through van der Waals forces. The ReaxFF potential is employed in MD simulations. The distribution of charges due to the externally applied voltage is calculated using the charge equilibrium scheme within the ReaxFF. The SWCNTs are modeled using the Euler−Bernoulli beam theory incorporating the geometric nonlinearities. The Galerkin approach is used to discretize the governing equations of motion. The results from the beam model are in good agreement with the MD simulations within an error of 2%.

INTRODUCTION

Single-walled carbon nanotubes (SWCNTs) are potential candidates for designing nano-electro-mechanical systems (NEMSs), for applications in sensing mass, strain, and pressure/temperature. The SWCNT based resonators consist of either a single or multiple elements. In the single element resonator, the shift in the resonant frequency is measured to identify the perturbations in the system. However, in the multiple-element resonators, which are coupled with either electrically or mechanically, the change in the resonator response amplitudes can be up to three times higher than the shift in the resonant frequency [1]. For the safe operation of such resonators, knowledge of the pull-in voltage is very important. At this pull-in voltage, the elastic forces of the two SWCNTs are overcome by the electrostatic and vdW forces, leading to the collapse of one SWCNT onto the other. Dequesnes et al. [2] studied the static and dynamic pull-in instability of SWCNT based switch using MD simulations and the Euler beam model. In their MD simulations, continuum formulations are used to define the electrostatic and vdW forces. Ouakad and Younis [3] studied the pull-in instability of SWCNT resonator using the Euler-Bernoulli beam model. In this study, the pull-in instability of a SWCNT coupled-resonator is studied using MD simulations and an equivalent continuum model. In the MD simulations, environment-dependent charges are calculated at each time step using the charge equilibrium (QEq) scheme within the ReaxFF [4].

MOLECULAR SIMULATIONS AND CONTINUUM MODEL

In this study, we consider two parallel SWCNTs of (7,7) chirality with length to diameter ($2R$) ratio = 15 separated by $r + 2R$. The atomic interactions between the carbon atoms are defined using the ReaxFF forcefield [4]. The external voltage (V) is applied to the system by providing an offset electronegativity. The two SWCNTs are applied with the electronegativities of $\chi_0 + V/2$ and $\chi_0 - V/2$, where $\chi_0 = 5.7254$ eV is the standard potential parameter for Carbon. To check the accuracy of charge calculations in our simulations, charge distribution in a SWCNT of (5,5) chirality and length of 1.2 nm in infinite space is computed. For a total applied charge of 10 e, the charge distribution computed from the MD simulations is in good agreement with that obtained from earlier DFT calculations [5], within an error of $\approx 6\%$ (see Fig. 1(a)). After the initial setup, the system is brought to a minimum energy configuration using the Polak-Ribiere's conjugate gradient method. Next, the system is thermally equilibrated at 1 K. The natural frequencies are determined by allowing the system to vibrate in the NVE ensemble and using the FFT of the time history of the transverse displacement of the atoms at mid-length of a SWCNT.

In the continuum model, the two SWCNTs are modeled as Euler−Bernoulli beams. The equations of motion of electrostatically charged and closely spaced nanoscale beams of length L and cross-sectional area A, are given as [3]

$$EIu_i'''' + \rho A\ddot{u}_i = EA/2L \int_0^L (u_i')^2 dx\, u_i'' - (-1)^i (F_{elec} + F_{vdW}) \,, \tag{1}$$

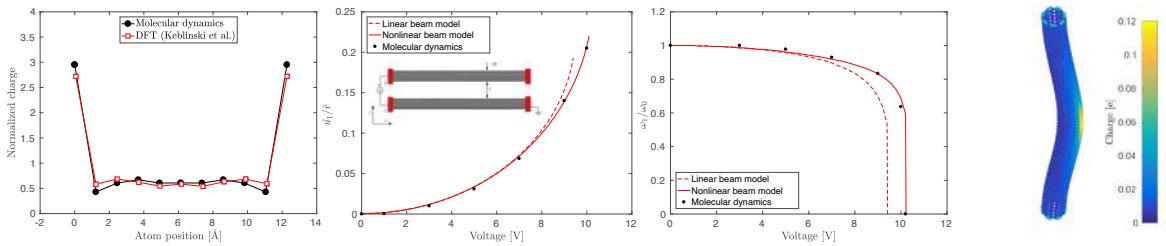
where u_i (i=1 and 2) are the transverse deflections (along y-direction) of the two SWCNTs, E and I are Young's modulus and the second moment of area, respectively, and ρ is the density. The electrostatic force between the two SWCNTs is calculated from the capacitance model [6]. The electrostatic energy is given as $E_{\text{elec}} = \frac{1}{2}C(r)V^2$, where $C(r) = \pi\epsilon_0/(acosh(1 + (r - u_1 + u_2)/2R))$ is the capacitance per unit length, ϵ_0 is the permittivity of vacuum and V is the applied voltage. The electrostatic force per unit length is given by $F_{\text{elec}} = -dE_{\text{elec}}/dr$. The standard Lennard-Jones (LJ) potential is used to define the vdW interactions between the two SWCNTs. The vdW energy per unit length between two parallel SWCNTs is then given by [7] $E_{\text{vdW}} = 1.5\pi\epsilon{\rho_1}^2\sigma^6 R^{-3}[(21/32)A_{12}\sigma^6 R^{-6}((r - u_1 + u_2)/R)^{-9.5} - A_6((r - u_1 + u_2))/R)^{-3.5}]$, where ρ_1 is the areal density, determined as $4/(3\sqrt{3}l_0^2)$, with l_0 as C-C bond length (=

*Corresponding author. E-mail: aningi@iitk.ac.in

0.142 nm), $A_{12} = 0.4735$ and $A_6 = 1.3090$. The LJ parameters for Carbon are $\epsilon = 0.00239$ eV and $\sigma = 0.34$ nm. The vdW force per unit length is given by $F_{\text{vdW}} = -dE_{\text{vdW}}/dr$. The static pull-in instability is calculated by neglecting the inertia term in Eq. (1). The solution for the static problem is approximated as $u_1(x) = \sum_{i=1}^{m} a_i\phi_i(x)$ and $u_2(x) = \sum_{j=1}^{m} b_j\phi_j(x)$, where ϕ_i are the normalized linear undamped mode shapes of the beam and a_i is a scalar constant. The solution is then obtained by substituting the assumed solution into the static governing equation and multiplying with ϕ_n and thereafter integrating within the domain of beams. For calculating the linear frequencies about the static equilibrium position, the solutions of Eq. (1) is assumed as $u(x,t) = u_s(x,0) + u_d(x,t)$ [3], where u_s is the static solution and u_d is the dynamic part. The assumed solution is substituted in Eq. (1) and the nonlinear terms in u_d are neglected. The resulting linear equations are solved to obtain the natural frequencies.

NUMERICAL RESULTS

Here, we compare the pull-in voltages found from MD simulations and solving the continuum model for static and dynamic cases using definition and vanishing first mode frequency criteria, respectively. Also, the results from linear and nonlinear continuum models are compared to highlight the importance of nonlinearity. Figure 1(b) shows the variation of the midplane deflection of SWCNT-1 with the applied voltage for an initial gap of $r = 2$ nm. The estimated pull-in voltages are 10.2 V and 10.1 V from the MD and the nonlinear beam model, respectively. The same, predicted by the linear model is 9.45 V which produces an error of $\approx 7.5\%$ relative to the MD simulations. Thus, the inclusion of stretching nonlinearity is essential in the pull-in voltage calculations. Figure 1(c) shows the variation of first frequency, normalized with the frequency at zero applied voltage, of the SWCNT-1 with the applied voltage. The results from the MD simulations agree well with those determined from the nonlinear beam model within an error of $\approx 2\%$. At $t = 0$ ps, the charge distribution over the two SWCNTs is uniform. However, as the two SWCNTs deflects towards each other, the charge distribution shows higher concentration at the mid-span. At the pull-in state, the charge accumulates about 220% more at the midpoint than the uniform distribution. Also, the atoms, which are in contact with the second SWCNT at the pull-in state, have the charge 150% more than the atoms at the ends (see Fig 1d).



(a) (b) (c) (d)

Figure 1: (a) Comparison between charge distribution obtained from DFT and MD simulations for a CNT (5,5). The normalized charge distribution is defined as the ratio of charge per atom to the average charge. Variation of midpoint deflection and the first mode frequency with the applied voltage in panels (b) and (c), respectively. The charge distribution at the pull-in voltage = 10.2 V is shown in (d).

CONCLUSIONS

The nonlinear static and dynamic pull-in analysis of SWCNT coupled-resonator are studied using MD simulations and an equivalent continuum model based on the Euler-Bernoulli beam theory. Deflection and the fundamental frequency of vibration of the SWCNTs at different voltages from both approaches are found to agree well within an error of less than 2% when geometric nonlinearity is included in the continuum model.

TOWARD A FLOW VELOCITY GRADIENT SENSOR USING A SINGLE MICROBEAM SENSING ELEMENT

Yoav Kessler, Alex Liberzon and Slava Krylov
School of Mechanical Engineering, Tel Aviv University, Israel

Summary In this work we present a novel micro flow sensor, based on a curved microbeam, capable of sensing two distinct locations in space with solely one sensing element. We exploit the critical snap-through (ST) and snap-back (SB) buckling phenomena of the electrostatic actuated and Joule's heated bistable structure, to conduct the measurement. In each cycle of the electrostatic signal, the beam encounters ST during the voltage rise and SB at the voltage drop. Airflow affects these critical points through the convective cooling and the direct aerodynamic forcing. Empirical results demonstrate supreme sensitivity of the device, which potentially could replace currently used larger and more complex multi hot wire based sensors.

INTRODUCTION

Due to an everlasting growing demand for more accurate flow sensors in advanced engineering and scientific systems, a large variety of flow microsensors have been reported in recent years [1,2]. Most of which are based on one of two disciplines; 1. Thermo-resistive heated film or wire, cooled by the forced convection caused by the airflow, or 2. A suspended structure free to deflect by direct lift/drag forcing. Despite a huge effort devoted to miniaturizing "macro" based flow sensors through micro-fabrication technology, it appears to reach a limit in the trade-off between performance and down-scaling. Thus, the next step is to develop and investigate new sensing paradigms, utilizing MEMS (and NEMS) prospects. Recently, a new flow sensing approach, based on the coupling between the flow, electrothermal heating, and the mechanical characteristics of bistable microstructures was introduced [3]. Flow sensing based on stability boundaries monitoring in initially straight beams undergoing static buckling due to thermal stress and cooled by airflow was first demonstrated in [3,4]. Using electrostatically actuated and Joule's heated curved beams, the flow velocity was measured by monitoring critical ST characteristics [5,6]. In this work, we demonstrate two-points flow sensing based on monitoring both the ST and SB events in a bistable microbeam. While ST based sensing was implemented in numerous applications, as far as we know, this is the first demonstration of the ST and SB as the basis of an applicative two-point sensing technique.

Operational principle

The device incorporates an initially curved bistable microbeam positioned within an airflow, Fig. 1. The beam is actuated electrostatically, by an electrode, and electrothermally, by Joule's heating. Competing effects of the Joule's heating and cooling by the airflow along with the direct aerodynamic forcing affect both ST and SB critical voltages, V_{ST} and V_{SB}, which can be therefore related to the flow velocity u. During the operation, the heating voltage V_{ET} is constant, while the actuating voltage V_{ES} is slowly increased up to a value above V_{ST} and then decreased below V_{SB}. For each u, the ST and SB events are identified, the voltages V_{ST} and V_{SB} are registered and the calibration (scale factor) curve relating the critical voltages and u is built.

RESULTS

Two equilibrium curves (built using image processing) corresponding to two different *u* are shown in Fig. 2 (a), (b), respectively. The inset shows the dependence between V_{ST} and V_{SB}, and *u* (the scale factor curve). The dynamics of the beam was also investigated using a reduced order model. The role of the air flow and heating/cooling was studied, and possible performance of the sensor was estimated using the model. Experimental results demonstrate high sensitivity for both critical voltages to the flow. Above a certain value of *u*, V_{SB} becomes higher than V_{ST}. This result is attributed to an interplay between the mechanical, drag force related, and the thermal stress within the beam. The suggested simple and compact device allows measurement of the flow in two closely positioned locations (and therefore of the flow velocity gradient) - the task which is difficult to accomplish using conventional sensors incorporating multiple hot wire assemblies [7].

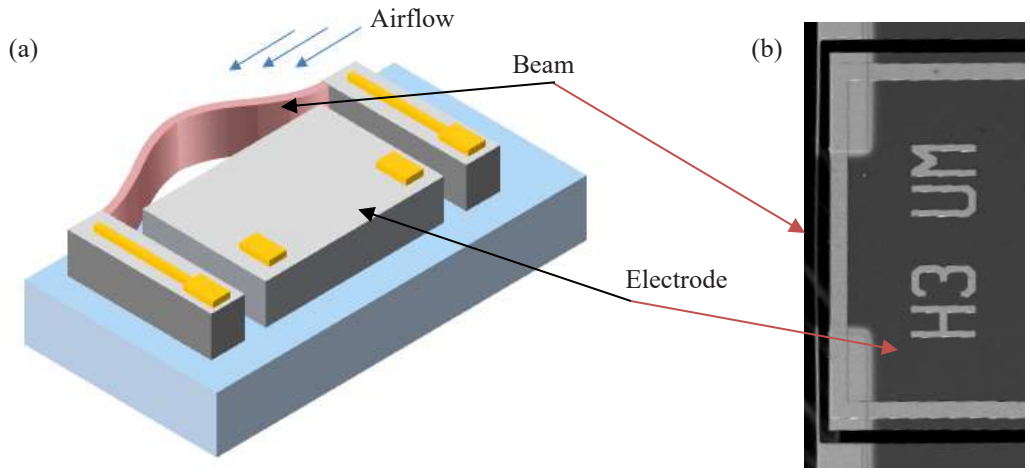

Figure 1: (a) Schematics of the flow sensor. The double-clamped curved microbeam is shown in its initial curved configuration. (b) SEM micrograph of one of the costumed fabricated devices.

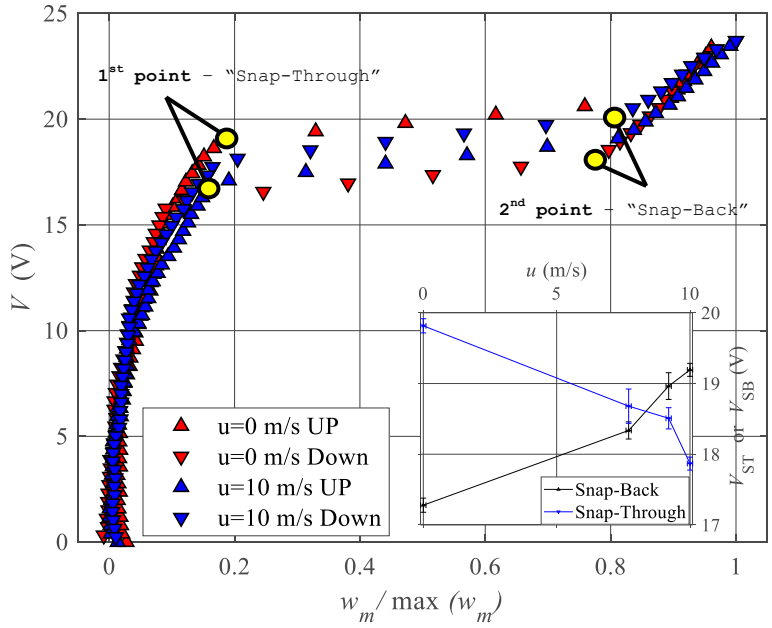

Figure 2: Experimental equilibrium curves of the bistable beam corresponding to two flow velocities (zero and 10 m/s, red and blue markers, respectively), in terms of the ES voltage V_{ES} and the midpoint deflection normalized by the maximal deflection adopted in the experiment. Triangle markers pointing up corresponds to the response to increasing voltages while triangles pointing down are for the decreasing part of the electrical signal. The inset depicts the scale factor curves - snap-through V_{ST} and snap-back V_{SB} voltages versus the air velocity. Error-bars represent the one standard deviation from the mean value at each velocity.

DESCRIBTION OF THE DEFORMATIONS OF GRAPHENE AND GRAPHENE - REINFORCED COMPOSITES IN THE FRAMEWORK OF MOMENT THEORIES

S.H. Sargsyan
Department of Mathematics, Physics and Information Technologies, Shirak State University, Gyumri, Armenia

Summary The paper demonstrates the construction of the discrete and continuum (beam) moment models of the linear atomic chain. Based on the beam model discrete-continuum model of the graphene is constructed. By limit passage the following models are constructed: the model of deformation of graphene in plane as a plane stress state of the moment theory with free rotation; the model of bending-deformation out of plane as a model of bending of the moment theory of elasticity based on the 'shear plus free rotation' principle.

INTRODUCTION

Currently the construction and analysis of mathematical models describing the static and dynamic deformations of nanomaterials, such as graphene or carbon nanotubes is one of the topical problems. In the construction of these models the main focus is on the development of the basic principles of structuring such models, which are in reality most appropriate to their deformations (in the end, the construction of their discrete and continuum models).

If we pay attention only to the existence of graphene or a single-layered carbon nanotube, it is easy to justify that between the atoms of these materials there are not only force but also moment interactions, whereas, force interactions are non-axial. The moment interactions between the atoms of these nanomaterials indicate that their atoms should not be considered as physical points (as in the classical case), but it is necessary to consider them as bodies with small but finite sizes (in this case, as spherical bodies). This implies that atoms, in this case, will possess not only mass, but also moment inertia, as well as not only translational, but also rotational degrees of freedom. Thus, the reasoning of this approach leads to the idea that the moment theories can be taken as basis in constructing both the discrete and continuum models of graphene when describing their deformations.

To construct discrete and continuum models of graphene, a holistic program is implemented in the work, the content of which is stated in the following sections.

CONSTRUCTION OF DISCRETE AND CONTINUUM MODELS OF A LINEAR ATOMIC CHAIN

A linear chain of atoms is considered in the initial undeformed state oriented along axis x. It is assumed that each atom interacts only with its nearest neighbors and its additive energy is the sum of the interaction energies with the left and right neighbors. Small deviations of atoms from the equilibrium position are considered.

Differential equations of equilibrium (or motion) for each atom (which determine the discrete model of a linear chain of atoms) are written in the framework of Euler mechanics (i.e., for a solid, assuming that the chain undergoes deformations of general type). It is assumed that both force and moment interactions of atoms can be energetically described by harmonic (power-law) potentials (this means that the coefficients of these potentials are second order derivatives of the potential function) for the corresponding chain deformations (strain-compression, shift-bending in two perpendicular planes xy, xz and torsion around axis x.). For a discrete model of a linear chain, the corresponding functionals are also compiled (the principle of possible displacements — in the case of statics, or the Lagrangian — in the case of dynamics), on the basis of which the discrete model of a linear chain of atoms in the general case of its deformation is also presented in a variational form. By limit passage in these variational functionals (when $a \to 0$, where $a-$ is the distance between the atoms of the chain), the functionals (of possible displacements in the case of statics or Lagrangian in the case of dynamics) are obtained for the continuum model of a linear chain of atoms. It is established that the continuum model of a linear chain of atoms (both in the case of statics and in the case of dynamics) coincides with the model of a micropolar beam with free displacement and rotation fields. According to this model the motion of a micropolar elastic beam is characterized by the following: a strain-compression scheme; bendings: "shear plus free rotation" in planes xz, yz; torsion around axis x. In a particular plane case, such a model of a micropolar beam was previously constructed (using the asymptotic method of integrating the plane stress state problem of the micropolar theory of elasticity in a thin rectangular region) in [1].

CONSTRUCTION OF DISCRETE-CONTINUUM AND CONTINUUM MODELS FOR THE GENERAL CASE OF DEFORMATIONS OF GRAPHENE

It is assumed that each graphene atom interacts with three nearest neighbors (which are located on three straight lines originating from the point under consideration at angles at 120^0). The elastic interactions between the atom in question and the indicated neighbors are replaced by elastic micropolar beams (the model of which is constructed in section 1). Imagining that the graphene region under consideration is covered by such a beam system that replaces its atomic structure, the model constructed in this way will be a discrete-continuum model of graphene in the general case of its deformation.

On the indicated periodic lattice of graphene, by averaging the total sum (of three terms) of the functionals of elastic micropolar beams (total potential deformation energy in the case of statics or Lagrangian in the case of dynamics), after, by limit passage, the corresponding functionals of the continuum model of statics or dynamics of graphene are constructed. The constructed continuum graphene model is decomposed into two independent models: a) a continuum model of graphene for deformations in plane, b) a continuum model of graphene for the bending deformation out of plane. Both continuum models respectively coincide with the model of plane stress state and the model of bending deformation of the plate (shear plus free rotation), previously constructed in [2]. From general energy considerations, the relationships between the elastic parameters of the discrete model of graphene and the elastic physical constants of the indicated micropolar (moment) elasticity theories are determined.

Generalizing approaches (1), (2), based on moment theories, it is possible to construct discrete and continuum models for other nanomaterials too (nanotubes, fullerenes, etc.). Construction of a discrete-continuum model of nanocomposite (layered) elastic media, obtained by reinforcing a certain elastic medium with two-dimensional graphene-like elements of high strength is demonstrated. In the case, when the number of layers is sufficiently large, a continuum model for the indicated nanocomposite elastic media is constructed by limit passage. Versions of the finite element method for the numerical study of the constructed phased models are developed.

CONCLUSIONS

To sum up, by limit passage from discrete-moment model, a moment beam model of the linear atomic chain is constructed. By substituting atomic interactions of graphene by the constructed model, a discrete-continuum model is constructed. By limit passage a continual-moment model of graphene is constructed as: 1) deformations in plane; 2) bending out of plane. The first model is a plane stress state of the moment theory of elasticity with free rotation, the second theory is the bending based of the moment theory of elasticity based on the ‘shear plus free rotation’ principle. Discrete-continuum and continuum-moment models of graphene reinforced layered nanocomposite are constructed.

EXACT FINITE ELEMENT FORMULATION FOR OUT-OF-PLANE STATIC ANALYSIS OF A CURVED NANOBEAM

Hilal KOC[1]*, Omer Ekim GENEL [1], and Ekrem TUFEKCI[1]
[1]Faculty of Mechanical Engineering, Istanbul Technical University, Istanbul, Turkey

Summary In this study, a new finite element formulation is developed for out of plane static behaviour of curved nanobeams by using nonlocal theory of elasticity. In the formulation, displacement functions that are the results of the exact analytical solution are utilized to formulate the stiffness matrix with the direct method. The exact analytical solution includes effects of small scale, shear deformation and nonlocal effects of shear forces, bending and torsional moments. A static example is handled and compared with similar studies in the literature. With that analysis, a circular nanobeam having uniform cross-section is investigated. The usage of a novel formulation which uses exact analytical solution as shape function does not exist in the literature. This is the first study that is investigated out of plane static behaviour of curved nanobeam with finite element formulation.

INTRODUCTION

Since having superior properties in terms of stiffness, strength, conductivity and low density, nanobeams have been utilised in a wide range of engineering applications. Because of manufacturing imperfections and excessive axial loadings, it is very hard to produce perfect straight nanobeam. [1] states that although most of the studies are about nanobeams having straight axes, in fact, they have curved axes due to their geometrical imprecisions.

In order to be able to model interactions between atoms or molecules properly with interparticle spaces taken into account, in nanostructures, there are some well-known methods. One of them is the molecular dynamics (MD) simulation method. However, compared to molecular dynamics (MD) simulations, high order continuum mechanics-based models are much more computationally cost-effective. Those high order continuum approaches are developed in order to determine the mechanical behaviour of micro/nano-scaled materials while offering simpler and more clear formulations. In nanoscale, effects of gaps between atoms cannot be neglected and a well-developed continuum model should consider these effects as well. Unlike the local theory of elasticity, the nonlocal theory of elasticity approach, which is developed by [2], concerns these effects on structural behaviour.

In the literature, there are numerous analytical studies on static behaviours of nanobeams by using the nonlocal theory of elasticity. In these studies, [3-5] obtained the exact analytical solution of curved nanobeams employing the nonlocal continuum theory. [5] presented a study on out-of-plane static behaviours of curved nanobeams by using the nonlocal theory of elasticity. In addition to analytical studies, there are few studies which investigate static behaviours of nanobeams by combining finite element method and nonlocal theory of elasticity [6-9].

In the present study, a nonlocal finite element formulation based on the exact analytical solution is developed for out-of-plane static behaviour of curved nanobeams. This formulation takes the effects of shear deformation into consideration and obtained results are compared with the literature. To the authors' knowledge, this formulation is the first study in the literature with the scope of mentioned content.

FORMULATION

The exact analytical solution of governing equations for the out of plane behaviour of curved nanobeams with varying curvature and cross-section are obtained in [5]. Effects of shear deformation and bending are taken into account and the solution can be represented as follow:

$$\mathbf{y}(\theta) = \mathbf{Y}(\theta, 0)\mathbf{y}_0 \tag{1}$$

Here, $\mathbf{y}(\theta)$, $\mathbf{Y}(\theta, 0)$ and $\mathbf{y}_0$ are the vector of variables, fundamental matrix and the vector of initial values, respectively. Elements of the fundamental matrix can be found in [5] for constant curvature and uniform cross-section case.

To obtain the stiffness matrix, elements of the fundamental matrix are grouped and expressed as submatrices. Therefore, Equation (1) becomes:

$$\begin{Bmatrix} \boldsymbol{X} \\ \boldsymbol{F} \end{Bmatrix} = \begin{bmatrix} \boldsymbol{A}(\theta_e) & \boldsymbol{B}(\theta_e) \\ \boldsymbol{C}(\theta_e) & \boldsymbol{D}(\theta_e) \end{bmatrix} \begin{Bmatrix} \boldsymbol{X_0} \\ \boldsymbol{F_0} \end{Bmatrix} \tag{2}$$

θ_e is the opening angle of a finite element. After utilising the direct method, the element stiffness matrix is obtained as below:

$$\boldsymbol{K^e} = \begin{bmatrix} \boldsymbol{B}(\theta_e) & \mathbf{0} \\ \boldsymbol{D}(\theta_e) & \mathbf{I} \end{bmatrix}^{-1} \begin{bmatrix} \boldsymbol{A}(\theta_e) & -\mathbf{I} \\ \boldsymbol{C}(\theta_e) & \mathbf{0} \end{bmatrix} \tag{3}$$

NUMERICAL EXAMPLE

The developed finite element formulation is validated with a numerical example and comparison with the literature. In the example, boundary conditions are clamped-free and nonlocal parameter (γ), Young's modulus (E), Poisson ratio

*Corresponding author. E-mail: koch16@itu.edu.tr

(v) values are taken as 1.56 nm, 1 TPa and 0.3, respectively. The opening angle (θ_T) and the factor of shear deformation (k_n) are $\pi/2$ and 6/5, respectively. Slenderness ratio is defined as: $\lambda = R\,\theta_T/\sqrt{I_n/A}$. Here, R is the curvature of the beam; I_n is the area moment of inertia about the normal axis; A is the cross-section area of the beam. In this example, the static analysis of a quarter cantilever beam is performed, Figure 1. Here, the slenderness ratio and curvature values are taken 20 and 5γ, respectively. The magnitude of the binormal force is taken 0.3 nN.

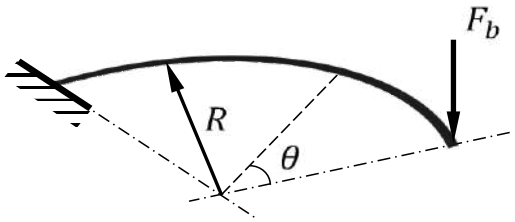

Fig. 1: A circular cantilever beam with uniform cross-section under a binormal force.

Analytical results of the analytical expression from [5] are compared with the ones from the finite element procedure. Due to having a single region, the problem is solved with one curved beam element as defined. The results are presented in Table 1 and it can be seen that finite element and analytical results are in agreement. Here, v is the binormal displacement; Ω_n and Ω_t are the rotation angles about normal and tangential axes, respectively.

Table 1: Comparison of the analytical approach and the finite element formulation

Displacement components	[5]	This study
v [nm]	0.226052	0.226052
Ω_n [rad]	-0.029816	-0.029816
Ω_t [rad]	-0.004049	-0.004049

CONCLUSIONS

In this study, the nonlocal theory of elasticity and initial value method are employed to derive a new finite element formulation in order to investigate out-of-plane static behaviour of curved nanobeams. Effects of small scale parameter, shear deformation, nonlocal effects of bending, torsional moments and shear forces are included in the exact analytical solution of governing equations. While almost all the studies in the literature use some approximate functions as the displacement functions, exact analytical solutions are dealt with as shape functions in the present study. To obtain the stiffness matrix, the direct method is used. To the authors' knowledge, this study is the first because of using exact analytical displacement functions as shape functions and finite element formulation for out of plane static behaviour of curved nanobeams. It is expected that the analysis of complicated nanobeam structures can be simplified with that solution. Thus, it will be possible that complicated nanosystem designs can be truer, more confidential and achieved in a shorter time.

A HIGHER ORDER SHEAR DEFORMATION BEAM MODEL FOR FREE VIBRATION PROBLEMS OF SMART NANOSTRUCTURES

Piotr Jankowski[1], Krzysztof Kamil Żur*[1], and Jinseok Kim[2]
[1]Faculty of Mechanical Engineering, Bialystok University of Technology, Bialystok 15-351, Poland
[2]Department of Mechanical and Aerospace Engineering, Western Michigan University, Kalamazoo, MI 49008-5343, USA

Summary In present study, a model for free vibration problems of elastically supported smart nanobeams made of functionally graded porous material is presented. Reddy third-order shear deformation theory that accounts for a nonlocal strain gradient theory, a power-law distribution for the variation of two material constituents through the nanobeam thickness, and three different porosity distributions as forms of cosine functions is used to develop piezoelectric functionally graded porous nanobeam model. The equations of motion are derived using the dynamic version of Hamilton's principle. The final nonlocal equations of motion are expressed by the displacements.

ABSTRACT

Consider a nanobeam of total thickness $H = h + 2h_p$, where h is the thickness of functionally graded porous nano-core and $2h_p$ is the total thickness of two piezoelectric layers [1-3] (Fig. 1). The nanobeam resting on Pasternak foundation, where K_w is spring stiffness and K_s is shear stiffness.

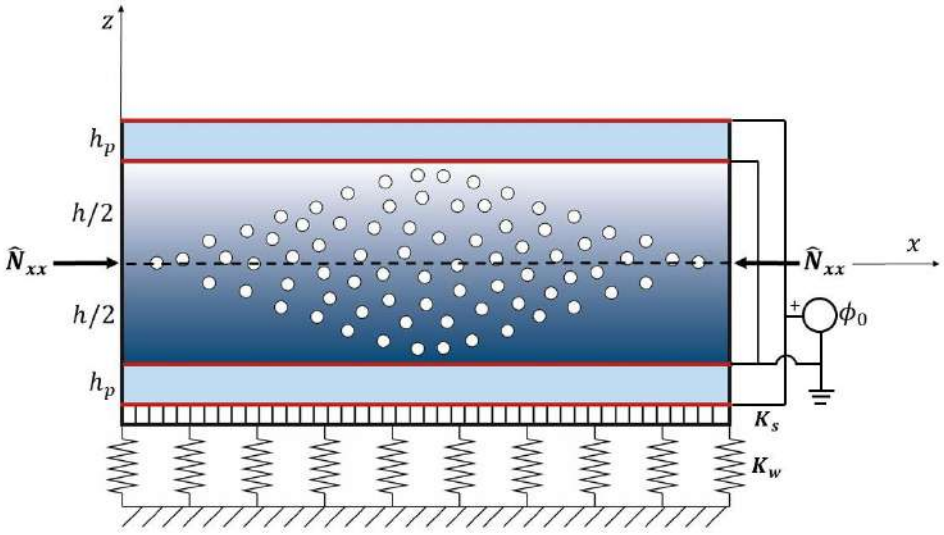

Figure 1. The cross-section and coordinate system of the electro-elastic FGM porous nanobeam subjected to in-plane forces.

The displacement field for the nanobeam under consideration is expressed on the basis on Reddy third-order beam theory [4]:

$$u_x(x,z,t) = u_0(x,t) + z\varphi_x(x,t) - \mathrm{c}_1 z^3\left(\varphi_x(x,t) + \frac{\partial w_0(x,t)}{\partial x}\right), \quad (1a)$$

$$u_z(x,t) = w_0(x,t), \quad (1b)$$

where $\mathrm{c}_1 = \frac{4}{3h^2}$, u_0 is the axial displacement, w_0 is the transverse displacement and φ_x is the rotation of a point on the centroidal axis x of the beam.

Assume that material properties of the FGM nano-core varies through the thickness h according to formula [5]:

$$E(z) = \left[(E_t - E_b)\left(\frac{z}{h} + \frac{1}{2}\right)^g + E_b\right][1 - \Upsilon(z,\vartheta)], \quad (2)$$

where E_t and E_b are Young's modulus values at the top and bottom surface, respectively. The constant g is the power-law index. Moreover, in the study three types of porosity distribution are defined by

$$\text{Type 1: } \Upsilon(\hat{z},\vartheta) = \vartheta cos\left(\frac{\pi z}{h}\right),$$

$$\text{Type 2: } \Upsilon(\hat{z},\vartheta) = \vartheta cos\left[\frac{\pi}{2}\left(\frac{z}{h} - \frac{1}{2}\right)\right], \quad (3)$$

$$\text{Type 3: } \Upsilon(\hat{z},\vartheta) = \vartheta cos\left[\frac{\pi}{2}\left(\frac{z}{h} + \frac{1}{2}\right)\right],$$

where ϑ is porosity coefficient, and $\hat{z} = z/h$ is normalized thickness of the nanobeam.

Figure 2 shows an example of effect of power-law index g, porosity coefficient ϑ, and porosity distribution types Υ on the variation of Young's modulus.

Summary This paper investigates the effect of pre-strains in presence of vacancies as the structural defects on the vibration of circular single-layered silicene sheets (SLSSs) by the use of molecular dynamic (MD) simulations. The Stillinger-Weber potential is used for atomic interactions. The initial velocity is applied to impose the fundamental mode shape of sheets. The results show that increasing the percentage of vacancies decreases the fundamental frequency. Furthermore, increasing the pre-strains and the initial velocity both have increasing effects on the frequencies, however, pre-strain plays a significant role. The results can be considered for tuning the frequency response of silicene, powerfully.

INTRODUCTION

Two-dimensional (2D) materials, consisting of a single layer of atoms on a crystalline lattice, have received many attractions in the last decade thanks to their admirable potentials in the semiconductor, electronics, high resolution sensing, batteries, and composite materials applications. Graphene, as the first 2D material, was isolated in 2004. Thereafter many others were identified e.g. silicene, germanene, stanene, and plumbene in 2012, 2014, 2015, and 2018, respectively [1]. Investigation of the mechanical properties and the responses of these new-born materials is highly cited by the community. Due to the sensing and actuating possibility of 2D materials especially in the dynamic mode, their vibrational behavior have been addressed by the researchers. As the experimental efforts are expensive and challenging, the numerical approaches such as *ab initio*, Monte Carlo, and MD simulations are widely implemented. The mechanical properties of single-layered silicene sheets were investigated by Roman and Cranford [2]. Mahmoudinezhad and Ansari [3] analyzed the vibrational behaviour of the circular single-layered graphene sheets. Jalali et al. [4] studied the capability of tuning the frequency response of graphene sheets by use of out-of-plane defects and calibrated the nonlocal elasticity solution to the MD results. In another work, Jalali et al. [5] explored the effect of porosities on the vibrational behavior of square single-layered graphene sheets by finite element-based molecular structural mechanics. In the present study, the influence of the vacancies and the imposing velocity on the frequency responses of pre-strained circular SLSSs has been investigated by MD simulations.

METHODOLOGY

MD simulations is performed by implementing the well-known open source LAMMP software. The Stillinger-Weber potential is used for interactions between atoms in the circular SLSSs of the radius R. Vacancies are added to the system by uniform removing the atoms from the lattice. The peripheral atoms, the red ones in figure 1, are moved in the radial direction to apply the pre-strain and afterward all the degrees of freedom of the edge are fixed and the system is leaving to be relaxed at the temperature of 1 K. To impose the free vibration, an initial velocity in the form of $V(r) = V_0\cos(\pi r/2R)$ is applied to the atoms for actuating the fundamental mode shape and the system is allowed to vibrate considering an NVE ensemble. After that, using the FTT procedure the fundamental natural frequency of the system is extracted from the transverse displacement of the central atom.

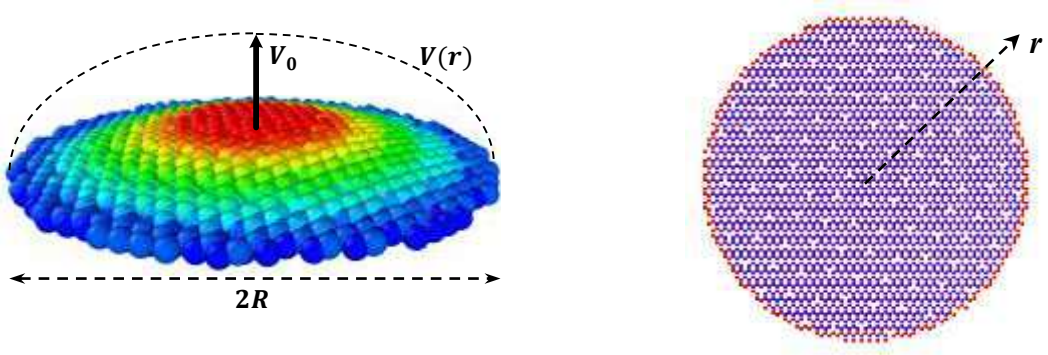

Figure 1. The definitions of the problem and methodology.

RESULTS AND DISCUSSION

In order to assess the sensitivity of the natural frequencies of the circular SLSSs, three influencing parameters i.e. the percentage of vacancies, the pre-strain, and the maximum initial velocity, V_0, have been taken into consideration. The percentage of vacancies is defined as the number of omitted atoms dived by the number of total atoms. The maximum initial velocity is increased in such a way that the sheets resist the tensions during the vibration and no fracture happens. The effect of all the mentioned parameters are explored in details. Figure 2 shows the fundamental natural frequency of the circular SLSSs with respect to the percentage of the vacancies for various initial velocities. As seen the frequencies reduces by increasing the value of vacancies. It means that the reduction in stiffness is higher than the reduction in the total mass due to omitting the atoms from the lattice structure however, this effect decreases by increasing the number of omitted atoms. Besides, raising the initial velocity increases the fundamental frequency for all the percentage of vacancies, which is known as the hardening effect in the classical nonlinear vibration of structures. From the results presented in Figure 3, the pre-strain has a significant increasing influence on the frequency response and by increasing the pre-strain the effect of increasing initial velocity is almost vanished. These results can be proved that the combination of considered parameters can be applied as a powerful tool for tuning the frequency response of silicene as a two-dimensional material.

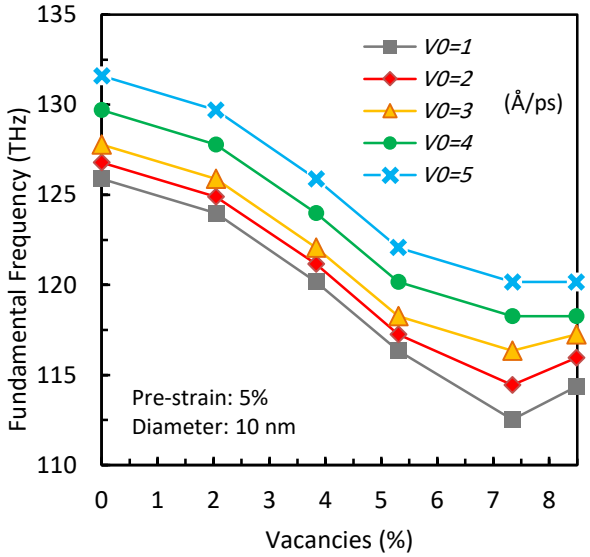

Figure 2. The effect of percentage of vacancies on the fundamental frequency of circular SLSSs for different initial velocities.

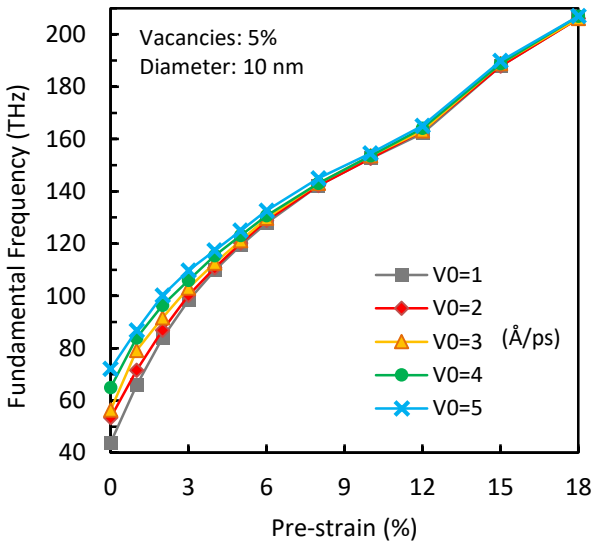

Figure 3. The effect of pre-strain on the fundamental frequency of circular SLSSs for different initial velocities.

CONCLUSIONS

By use of the MD simulations, the vibrational behavior of pre-strained defected circular SLSSs has been explored through an FFT procedure. The percentage of vacancies, the pre-strain, and the initial velocity have been presumed as the influencing parameters. The natural frequency decreases by increasing the percentages of vacancies. In addition, increasing the initial velocity and the pre-strain both lead to significant raising in the frequency of all sheets. It is concluded that by mixing the mentioned parameters, it is possible to tune the frequency response of SLSSs as optimal design.

EXACT FINITE ELEMENT FORMULATION FOR IN-PLANE STATIC ANALYSIS OF A CURVED NANOBEAM

Omer Ekim GENEL [1]*, Hilal KOC[1], and Ekrem TUFEKCI[1]
[1]Faculty of Mechanical Engineering, Istanbul Technical University, Istanbul, Turkey

Summary In this study, a new, exact finite element formulation is proposed for in-plane static analysis of planar curved nanobeams. The shape functions are obtained from exact analytical solutions based on the nonlocal theory of elasticity. The effects of axial extension and shear deformation are taken into account. The stiffness matrix is obtained by using the direct method. The static behaviour of a quarter circular nanobeam having uniform cross-section under normal tip force is analysed and the results are compared with those in the literature.

INTRODUCTION

Nanobeams have a wide range of applications in engineering due to their improved material properties. Mainly, three approaches are employed to investigate the behaviour of nanobeams: molecular dynamics (MD) simulations, hybrid theory and continuum mechanics. The last approach has a less computational cost and is considered as the more effective field in comparison to other approaches. While classical continuum mechanics theory neglects the effect of interatomic gaps, the nonlocal theory of elasticity which is proposed by Eringen [1] takes into consideration this effect and gives reliable results in nanobeam applications.

In the literature, there are numerous studies which investigate in-plane static behaviours of nanobeams by using analytical approaches using the nonlocal theory of elasticity. In analytical studies, the static behaviour of curved nanobeams is investigated and obtained exact analytical solutions by using initial values method [2-4]. The in-plane behaviour of curved nanobeams is investigated and obtained exact analytical solutions by using initial values method [2,3]. In both papers, axial extension and shear deformation are taken into consideration. Compared to analytical studies, the studies which investigate the static behaviour of nanobeams with the finite element method are quite limited [5-8]. For design purposes and considering manufacturing limitations, nanobeams with curved axes are utilised in some applications; therefore, mechanical modelling and analysis of curved nanobeams are crucial in nanoscale engineering applications.

In the presented paper, in order to be able to investigate in-plane static behaviour of curved nanobeams, a finite element formulation, which is used exact analytical solutions based on the nonlocal theory of elasticity as shape functions, is developed. In the formulation, effects of axial extension and shear deformation are taken into consideration. To the best of the authors' knowledge, within the scope of mentioned content, this formulation is considered as the first study in that area in the literature.

FORMULATION

For the in-plane case, governing differential equations of curved nanobeams are given in [2]. The solution of this differential equation system can be expressed as follows:

$$\mathbf{y}(\theta) = \mathbf{Y}(\theta, 0)\mathbf{y}_0 \tag{1}$$

Here, $\mathbf{y}(\theta)$, $\mathbf{Y}(\theta, 0)$ and $\mathbf{y}_0$ are the vector of variables, fundamental matrix and the vector of initial values, respectively. For constant curvature and uniform cross-section case, elements of the fundamental matrix can be found in [2].

To obtain the stiffness matrix, elements of the fundamental matrix are grouped and expressed as submatrices. Therefore, Equation (1) becomes:

$$\begin{Bmatrix} \boldsymbol{X} \\ \boldsymbol{F} \end{Bmatrix} = \begin{bmatrix} \boldsymbol{A}(\theta_e) & \boldsymbol{B}(\theta_e) \\ \boldsymbol{C}(\theta_e) & \boldsymbol{D}(\theta_e) \end{bmatrix} \begin{Bmatrix} \boldsymbol{X_0} \\ \boldsymbol{F_0} \end{Bmatrix} \tag{2}$$

Here, θ_e as the opening angle of a finite element. After application of the direct method, the element stiffness matrix is obtained as below:

$$\boldsymbol{K^e} = \begin{bmatrix} \boldsymbol{B}(\theta_e) & \mathbf{0} \\ \boldsymbol{D}(\theta_e) & \mathbf{I} \end{bmatrix}^{-1} \begin{bmatrix} \boldsymbol{A}(\theta_e) & -\mathbf{I} \\ \boldsymbol{C}(\theta_e) & \mathbf{0} \end{bmatrix} \tag{3}$$

NUMERICAL EXAMPLE

In order to investigate in-plane static behaviour of nanobeams by using finite element method, a quarter circular beam with a uniform cross-section with a force at the tip is analysed. In the example, the nonlocal parameter (γ), Young's Modulus (E) and Poisson's ratio (v) values are taken as 1.56 nm, 1 TPa and 0.3, respectively. The opening angle (θ_T) of the beam is $\pi/2$ and the factor of shear deformation (k_n) is taken as 6/5 for rectangular cross-section. Also, the slenderness ratio is calculated $\lambda = R\theta_T/\sqrt{I_b/A}$. Here, R is the curvature of the beam; I_b is the area moment of inertia about binormal axis; A is the cross-section area of the beam. In the example, static analysis of a quarter circular beam

*Corresponding author. E-mail: genelo@itu.edu.tr

which has uniform cross-section is carried out, Figure 1. Slenderness ratio and curvature are taken as 20 and 5γ, respectively. The external force is taken as 1 nN at normal direction under clamped-free boundary conditions.

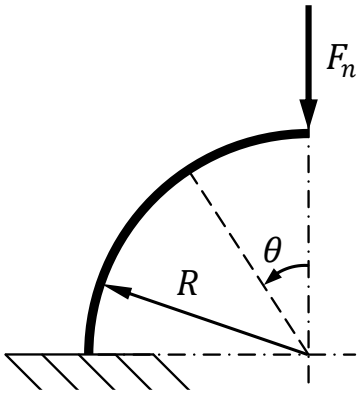

Fig. 1: Quarter circular beam under a tip force.

Due to having only one region, the problem is solved by using one element. Obtained results are compared with [2] and presented in Table 1. As can be seen from Table 1, results which are obtained from finite element formulation are in good agreement with analytical results. Here, w and u are tangential and normal displacements, respectively; Ω_b is the rotation angle about binormal axis.

Table 1: Comparison of the analytical approach and the finite element formulation

Displacement components	[2]	This study
w [nm]	0.213448	0.213448
u [nm]	0.339527	0.339527
Ω_b [rad]	0.053995	0.053995

CONCLUSIONS

In this study, a finite element formulation which uses exact analytical solutions as shape functions is developed for curved nanobeams. These exact analytical solutions are obtained by applying the nonlocal theory of elasticity. In the formulation, effects of axial extension and shear deformation are also considered. The stiffness matrix is constructed by using the direct method. It can be seen from the static example, results which are obtained from developed finite element formulation are in good agreement with the literature. To the authors' knowledge, no study which has abovementioned content has hitherto been published. It is thought that due to taking into account axial extension and shear deformation effects and using exact analytical solutions as shape functions, the presented formulation can be used to develop reliable complex curved nanobeam systems.

MICRO-RESONATORS MAGNETIC SENSOR

Nouha Alcheikh, Sofiane Ben Mbarek, and Mohammad I. Younis *[1]
[1]King Abdullah University of Science and Technology - KAUST, Thuwal, Saudi Arabia

Summary We present a Lorentz-force magnetic sensor based on electrothermally heated resonators operating in air at atmospheric pressure. The sensing mechanism is based on detecting the resonance frequency shift of micro-beams resonators due to the effect of Lorentz forces generated from a magnetic field. By operating near the buckling point of the straight micro-beam, the measured sensitivity, which is controllable by the bias current load, is shown around 1.63/T. To alleviate the dip in frequency near the buckling instability, another sensor is demonstrated based on an initially curved micro-beam, which shows a sensitivity of 0.19/T.

MANUSCRIPT

In recent years, miniaturized sensitive magnetic sensors based on Lorentz-force resonant sensing have received increasing attention[1]. Microelectromechanical Systems (MEMS) magnetic sensors have been explored for various applications, such as biomedical, inertial navigation systems, electronic compasses, telecommunications, and non-destructive testing[2]. They generally rely on two classes of readouts to detect the magnetic field: amplitude modulation (AM) and frequency modulation (FM)[3]. Compared to AM readout, tracking the frequency shift yields high accuracy, high outstanding stability, high sensitivity, low power consumption, and immunity to noise.

In this work, we explore two different kinds of Lorentz-force magnetic sensors, straight and curved micro-beams. The schematic of the micro-sensor is shown in Fig 1(a). The micro-sensors are fabricated from a highly conductive silicon device layer of silicon-on-insulator (SOI) wafer from MEMSCAP. They have a length (L) of 800 µm, a width (b) of 25 µm, and a thickness (h) of 2 µm. The curved micro-beam has a 2.5 µm initial rise (b_0). To generate a DC magnetic field in z-axis, we placed a permanent magnet above the sensor. Under the same value of magentic field +B (+z-axis), we measured the frequency responses of the micro-beam by changing I_{Th}. We repeated the same procedure by applying another direction of -B (-z-axis). As shown in Fig. 1(a), the presence of a permanent magnetic field (B) and with a bias current I_{Th}, which flows through the resonators, generates Lorentz-force in the y-axis. Upon changing I_{Th}, the resonance frequency of the curved micro-beam increases while for the straight beam it continuously decreases until reaching the buckling limit. After buckling, the resonance frequency increases, Figs 1(b,c). Figs 1(d,e) show the measured resonance frequency of the resonators for different values of B. As shown in Fig 1(d), the minimum detectable magnetic field in air at atmospheric pressure is ∓45 mT. Lower values of magnetic field can be detectable by reducing the damping effect by operating the micro-sensor at lower pressure. In addition, the measured results of curved micro-beam show excellent linearity. The insets show the measured frequency shift versus input magnetic field (B) for a constant current (d) and versus various bias currents for a constant B (e). As shown in the figure, for both resonators, the frequency shift for +B is higher compared to –B. The sensitivity of the magnetic sensor is calculated as the relative change in the resonant frequency ($\Delta f/f_0$) over the input magnetic field (B), where f_0 is the frequency of the micro-beams at B=0 T. As shown in the inset of Fig. 1(d), the sensitivities of the curved micro-beam, which is controllable by bias current load, is shown near S= 0.145/T (-B) and S= 0.19/T (+B) at I_{Th} =3 mA. These values of sensitivity are much higher than the values reported in the literature. As can be seen in the inset of Fig. 1(f) and at the buckling point I_{Th} =0.25 mA, the sensitivity increases with the magnetic field, S= 1.63/T (-B). It is expected that the straight beam around buckling is more sensitive than the curved micro-beam. This originates from the high sensitivity of the beam to a small variation of its stiffness in that region. However, it is sometimes desirable to avoid the dip in frequency near the buckling instability; and hence an arch in this case is advantageous. Also, one should note that the performance of the device is dependent on the applied bias current. The sensors show extremely low power consumption of about 2.1 mW and 14.5 µW, for curved and straight micro-beams, respectively. In addition to high sensitivity, the straight micro-beam shows more promising results for low power consumption.

CONCLUSIONS

In conclusion, we proposed highly sensitive Lorentz-force magnetic micro-sensors based on electrothermally heated straight and curved micro-beams. We show that a straight beam operated near the buckling threshold leads to the maximum sensitivity of the device. To alleviate the dip in frequency near the buckling instability, another sensor was demonstrated based on a curved micro-beam, which shows High sensitivity. The micro-sensor demonstrates high sensitivity compared to reported magnetic sensors. The advantages of the proposed sensor are the simplicity of fabrication, lower power consumption, and also scalability.

REMOTE-CONTROLLED SPIN-FLIP PROCESS IN RHOMBIC GRAPHENE NANOFLAKES

Yi Ming Zhang[1], Jing Liu[2], Chun Li *[1,3], Wei Jin[4], Georgios Lefkidis[2,1], and Wolfgang Hübner[2]

Summary We present the configurations and stability of the rhombic graphene nanoflakes (GNFs) with two Ni atoms attached its boundary (Ni_2&GNF) using strict and elaborate geometric modeling. It is shown that the spin-flip process on Ni_2&GNF is highly favored by work of the involved magnetic element and applied strain. The first-principles tensile test predicts that the variation of the C-Ni bond length plays an important role in the spin density distribution, especially for the low-lying magnetic states, and can therefore dominate the spin-flip processes. Furthermore, since the spin is localized on the right Ni atom, when the tensile strain along the right C-Ni bond is applied, the spin processes do not change much with the increasing strain, however, the L-type (strain along the left C-Ni bond) strain strongly influences the local spin-flip process on Ni_R atom. Such phenomenon demonstrates a remote-controlled spin-flip process, which could increase the functionality and the flexibility of the intergated spin-logic in real straintronic devices.

STRUCTURE OPTIMIZATION AND STRAIN MODEL

For simplicity and without loss of generality, in our present work we focus on rhombic graphene nanoflakes with two nickel atoms attached to the boundary of GNFs (Ni_2&GNF). Four initial structures are fully optimized to obtain the equilibrium geometry. The stability of each structure is confirmed after the calculations of normal mode with the absence of imaginary frequencies. After optimization, the GNF with two Ni atoms connected to the adjacent carbon atoms is further studied [Fig. 1(b)]. And Fig. 1(c) shows the strain model we applied, that is, the strain is applied along the left C-Ni bond (L type) and right C-Ni bond (R type).

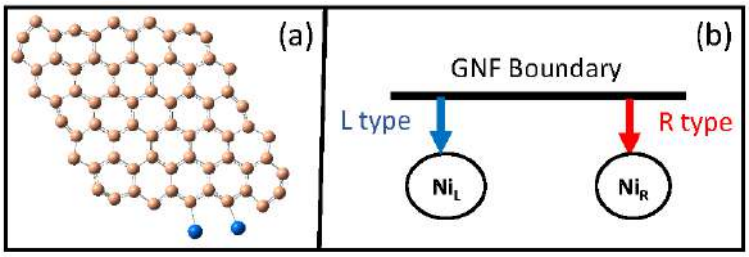

Figure 1: Ni_2&GNF structures and the strain model. (a) Optimized equilibrium structure; (b) Stretching along the C-Ni bonds, noted as L type (left bond) and R type (right bond), respectively.

REMOTE-CONTROLLED SPIN-FLIP PROCESS

Based on the Λ process[1, 2, 3, 4] theoretical model, we need to identify the adequate states with localized spin density, which could be the initial and final states of the spin-flip processes. To this end, we calculate the spin density on each many-body state using a Mulliken population analysis. It is noteworthy that this analysis only gives an estimate of the spin distribution in our structures, while it is enough to detect which atoms and states carry the spin. In our present calculation, the total spin density of the system is around 2, while in the initial structrue and the distorted structures, the Ni_R atom carris about 1.8 on the ground triplet state. It is obvious that the spin density is strongly localized on the Ni_R atom on the ground triplet state (even with the tensile strains). For the purpose of experimental implementation, the initial and final states should be as low as possible in energy, under the prerequisite of its realizability, the $|\downarrow\rangle$ (spin-down) and $|\uparrow\rangle$ (spin-up) states stem from the ground triplet state are chosen as the initial and final states for spin-flip processes. Therefore, the spin-flip processes we mentioned here are actually localized on Ni_R.

Fig. 2 shows the population transfer between the initial and final states via some intermediated states for the ultrafast spin-flip processes achieved on the distorted Ni_2&GNF structures with altering the C-Ni bond length. It is shown that the spin dynamics at the distorted structures can be strongly influenced with the tensile strain along the C-Ni bond. It is obvious that the manipulation scenarios of the two strain types are not identical. For the L-type strain, when 5.0% tensile strain is applied, the fidelity decreases to 81.4%, while the populations of final state under 2.5% and 7.5% strains

*Corresponding author. E-mail: lichun@nwpu.edu.cn

are 98.0% and 96.2%, respectively, indicating that the increasing L-type strain can strongly influence the local spin-flip processes. As for the R-type strain [Figs. 2(d-f)], one can see that the spin-flip processes do not change much with the increasing R-type strain. With the R-type strain increasing from 2.5% to 7.5%, the fidelity increase from 96.1% to 97.7%, while the Rabi oscillation cycles, the number and the occupation of involved intermediate states stay as is. Briefly, L-type strain strongly influences the local spin-flip process on Ni_R atom, while the R-type strain, which is directly applied on the Ni_R atom, seems having no obvious effect. Such phenomenon demonstrates a remote-controlled spin-flip process, which indicates that we can remotely controll the spin information by applying the tensile strain or external field to manipulate the local geometry and electronic properties of the system.

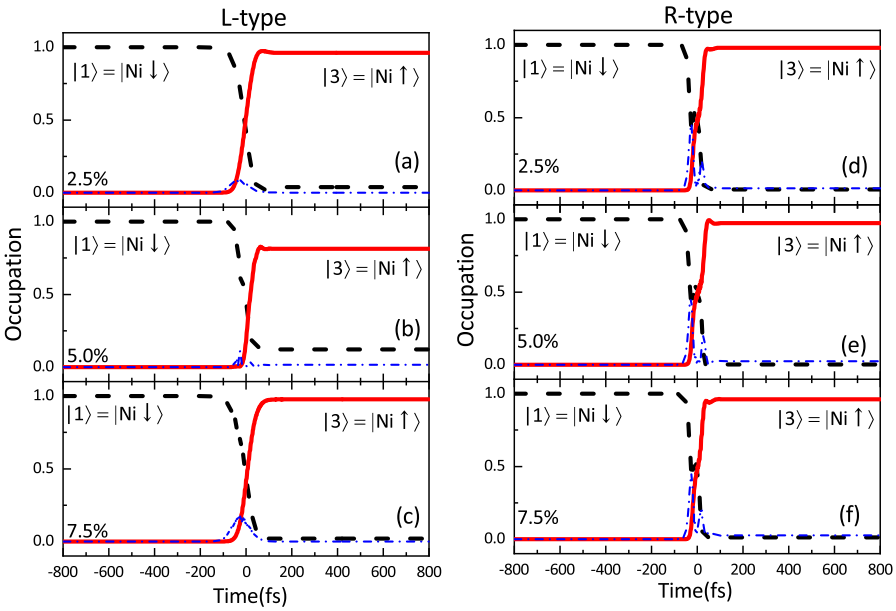

Figure 2: Spin-flip processes achieved in the distorted Ni_2&GNF structures with L-type (left panel) and R-type (right panel) strains, respectively. Time evolutions of the occupations of the initial (dashed black), final (solid red), and intermediate (dash-dotted) states for each spin-flip process are exhibited. Within each panel, the situations for 2.5%, 5.0%, and 7.5% tensile strains along the corresponding C-Ni bond are shown, respectively.

CONCLUSIONS

In summary, the laser-induced ultrafast spin flip on the Ni_2&GNF is investigated using Λ-process-based theoretical model and *ab initio* calculations. In Ni_2&GNF structures, the spin flip process can be modulated by the local strain along the C-Ni bond, and the increasing L-type strain can strongly influence the local spin-flip processes. Since the spin is localized on the right Ni atom, when the tensile strain along the right C-Ni bond is applied, the spin-flip processes do not change much with the increasing strain, however, the L-type (strain along the left C-Ni bond) strain strongly influences the local spin-flip process on Ni_R atom. This phenomenon indicates a remote controlled spin-flip process. Our results reveal the great potential of using the synergistic effect of strain, magnetic field, and laser pulse for active spin control, which could lead to more flexibility for romote spin control and hence functionalization in future carbon-based spintronic devices.

VARIATIONAL PROBLEMS IN PLASTICITY AND BRITTLE FRACTURE OF HETEROGENEOUS MATERIALS

Pierre Suquet*[1] and Jean-Claude Michel[1]
[1]LMA, Aix Marseille Univ, CNRS, Centrale Marseille, Marseille, France

Summary Homogenization results for limit load problems are recalled first. In anti-plane situations the resulting variational principle reduces to finding a minimal cut. This observation makes the link with Schneider's definition of the effective fracture energy of heterogeneous materials. It allows us to use, in the context of brittle materials, the same analytical and computational tools developed to determine the extremal surfaces of ideally plastic heterogeneous materials.

LIMIT LOADS AND MAXIMAL FLOWS

Consider a solid body Ω subjected to body forces $\lambda \boldsymbol{f}$ and surface tractions $\lambda \boldsymbol{F}$ on a part $\partial\Omega_F$ of its boundary, proportional to a load parameter λ,

$$\mathrm{div}\boldsymbol{\sigma} + \lambda \boldsymbol{f} = \boldsymbol{0} \quad \text{in } \Omega, \quad \boldsymbol{\sigma}.\boldsymbol{n} = \lambda \boldsymbol{F} \text{ on } \partial\Omega_F. \tag{1}$$

The body is comprised of a material, possibly heterogeneous, with a limited strength characterized by a *strength* domain $P(\boldsymbol{x})$ (convex set containing $\boldsymbol{0}$ in its interior)

$$\boldsymbol{\sigma}(\boldsymbol{x}) \in P(\boldsymbol{x}) \quad \text{in } \Omega. \tag{2}$$

The limit load is the maximal value of λ for which the two requirements (1) and (2) are compatible. In the above formulation, $\boldsymbol{\sigma}$ is a field of second-order symmetric tensors. Strang [11] noticed that the same formulation applies to the problem of maximal flow through a domain, $\boldsymbol{\sigma}$ being in that case a vector field.

This *static* definition of the limit load (in term of stress fields) admits an equivalent mixed formulation (saddle-point property) and a kinematic formulation (minimum principle)

$$\overline{\lambda} = \sup_{\lambda} \{\exists\, \boldsymbol{\sigma} \text{ satisfying (1) and (2)}\} = \inf_{\boldsymbol{u}} \sup_{\boldsymbol{\sigma} \in P} \frac{\int_\Omega \boldsymbol{\sigma} : \boldsymbol{\nabla u}\, d\boldsymbol{x}}{\int_\Omega \boldsymbol{f}.\boldsymbol{u}\, d\boldsymbol{x} + \int_{\partial\Omega_F} \boldsymbol{F}.\boldsymbol{u}\, ds} = \inf_{\boldsymbol{u}} \frac{\int_\Omega \pi(\boldsymbol{\nabla u})\, d\boldsymbol{x}}{L(\boldsymbol{u})}, \tag{3}$$

with

$$\pi(\boldsymbol{x}, \boldsymbol{e}) = \sup_{\boldsymbol{\sigma} \in P(\boldsymbol{x})} \boldsymbol{\sigma} : \boldsymbol{e}, \quad L(\boldsymbol{u}) = \int_\Omega \boldsymbol{f}.\boldsymbol{u}\, d\boldsymbol{x} + \int_{\partial\Omega_F} \boldsymbol{F}.\boldsymbol{u}\, ds. \tag{4}$$

In the limit load problem $\boldsymbol{u}$ is a vector field, $\boldsymbol{\nabla u}$ is the symmetric part of the gradient of $\boldsymbol{u}$. In the maximal flow problem u is a scalar field and $\boldsymbol{\nabla} u$ is the usual gradient of u. Although limit load analysis is often associated in the literature with plasticity, there is no such restriction in the above formulation which therefore applies to a wide variety of materials, ranging from brittle materials to ideally plastic ones (Salençon [9]). It is therefore not surprising that plasticity and brittle fracture bear common features.

Appropriate numerical schemes have been developed to solve the limit load problem (3) using the static, kinematic or saddle-point formulation (Christiansen [3] among others).

HETEROGENEOUS MEDIA.

Consider now that the body under consideration is highly heterogeneous, characterized by a small parameter ε measuring the size of the heterogeneities. For simplicity only the periodic case will be considered here. Bouchitté and Suquet [1] have shown that the limit as $\varepsilon \to 0$ of the limit load problem is again a limit load problem with two significant differences with respect to the usual homogenization results for convex energies with sufficient growth (here the function π is convex but has only linear growth):

$$\overline{\lambda} = \lim_{\varepsilon \to 0} \lambda^\varepsilon = \mathrm{Sup}\{\lambda \text{ such that } \exists\, \boldsymbol{\Sigma} \text{ satisfying (1)}, \ \boldsymbol{\Sigma} \in P^{hom} \text{ in } \Omega, \ \boldsymbol{\Sigma}.\boldsymbol{n} \in C^{hom} \text{ on } \partial\Omega_F\}, \tag{5}$$

where the homogenized stress domain C^{hom} on the boundary is not directly deduced from the strength domain P^{hom} in the bulk of the body. The discrepancy between the behavior in bulk and on the boundary is uncommon in homogenization.[1]

*Corresponding author. E-mail: suquet@lma.cnrs-mrs.fr

[1]The other noticeable difference, uncommon in homogenization, is that all boundary conditions on the boundary of the volume element are not equivalent in the limit of a large volume element. The periodicity conditions and prescribed affine displacement conditions lead to the same homogenized properties in the limit, but not the conditions of uniform stress on the boundary.

Concentrating on the bulk behavior, the homogenized strength domain is determined by solving a limit load problem on a unit-cell Q,

$$P^{hom} = \{\boldsymbol{\Sigma} \text{ such that } \exists\, \boldsymbol{\sigma},\ \text{such that } \langle \boldsymbol{\sigma} \rangle = \boldsymbol{\Sigma},\ \text{div}\boldsymbol{\sigma} = \mathbf{0} \text{ and } \boldsymbol{\sigma}(\boldsymbol{x}) \in P(\boldsymbol{x}) \text{ in } Q,\ + \text{periodicity conditions}\}, \quad (6)$$

where $\langle . \rangle$ stands for the volume average over a unit-cell (or volume element) V. By duality $P^{hom} = \{\boldsymbol{\Sigma} \text{ such that } \boldsymbol{\Sigma} : \boldsymbol{E} \leq \Pi^{hom}(\boldsymbol{E}) \text{ for all } \boldsymbol{E}\}$, where

$$\Pi^{hom}(\boldsymbol{E}) = \text{Inf} \quad \langle \pi(\boldsymbol{\nabla u}) \rangle, \quad \boldsymbol{u} = \boldsymbol{E}.\boldsymbol{x} + \boldsymbol{u}^*,\ \boldsymbol{u}^* \text{ periodic}. \quad (7)$$

Anti-plane problem. Consider now a unit-cell problem where both the geometry and the material properties are invariant along the direction $\boldsymbol{e}_3$ subjected to anti-plane shear along the directions $(1,3)$ and $(2,3)$. The strength domain$P(\boldsymbol{x})$ is defined by a von Mises criterion $\sigma_{\text{eq}} \leq \sigma_0(\boldsymbol{x})$. Then the variational problem (7) reduces to

$$\text{Inf } \langle \sigma_0 \, |\boldsymbol{\nabla} u| \rangle, \quad u = \boldsymbol{E}.\boldsymbol{x} + u^*,\ u^* \text{ periodic}, \quad (8)$$

where $u(x_1, x_2)$ is now a scalar field (component of the displacement field along $\boldsymbol{e}_3$), $\boldsymbol{E}$ is a vector with 2 components and $\langle . \rangle$ is the average over any cross section of the cylindrical unit-cell. Functions of bounded variation are admissible fields in the variational problem (8). Strang [11, 12] has shown in a similar, but different, problem that the solutions of his similar variational problem are characteristic functions (his problem involves a constraint on $\langle u \rangle$ instead of a constraint on $\langle \boldsymbol{\nabla} u \rangle$). Assuming that the same property holds true in the present problem, (8) is equivalent to the *minimal cut* problem:

$$\text{Inf} \int_S \sigma_0(\boldsymbol{x})\, ds, \quad S \subset V, \int_S \boldsymbol{n}\, ds = \boldsymbol{E}. \quad (9)$$

LINK WITH SCHNEIDER'S DEFINITION OF FRACTURE ENERGY OF BRITTLE MATERIALS [10]

Extrapolating a mathematical homogenization result of Braides *et al* [2], Schneider [10] suggested that the energy required to fracture a volume element of a heterogeneous brittle material is given in any dimension ($N = 2$ or 3) by the variational problem (9). How this definition is related to the *effective toughness* of Roux and Hild [8] or Hossain *et al* [4] remains to be clarified (it is probably only relevant in the weak pinning regime of [8]). Then, again at the expense of extrapolating Strang's result, this effective surface energy can be determined by solving the variational problem (8).

In this framework, it is therefore clear that the effective fracture energy can be determined by the very same computational schemes used to determine the effective strength domain (or extremal surface [13]) of an ideally plastic material, or more generally of materials with limited strength. Different algorithms can be used to that end, in particular those developed a number of years ago by Michel *et al* [5, 6]. Similarly, analytical upper bounds from this fracture energy can be deduced either from direct investigation of minimal surfaces through (9) (see for instance Willot [14]) or from nonlinear homogenization techniques based on linear comparison composites (Ponte Castañeda and Suquet [7]).

DUCTILE FAILURE MECHANISMS IN PURE METALS AND ALLOYS

Jianing Xie[1], Kyuminl Eom[1], and Krishnaswamy Ravi-Chandar*[1]
[1]Department of Aerospace Engineering and Engineering Mechanics, University of Texas, Austin, USA

Summary Ductile failure in structural materials has been a problem of longstanding interest, both from the fundamental scientific and applied technological perspectives. While different failure models – ranging from phenomenological to computational models to mechanism based micromechanical models – have been proposed and used, there is still an active debate concerning the predictive capabilities of these models. In this work, we describe the results of a multiscale, multimodal experiments utilizing interrupted testing protocol, quantitative optical and scanning electron microscopy, and x-ray tomography to identify and quantify the deformation and failure mechanisms that are at the root of ductile behaviour in both high purity metals and in engineered alloys. This investigation reveals that very large deformations occur without observable damage at scales above about one micron and above.

INTRODUCTION

Modeling of the inelastic response of metallic materials, such as the commercial alloy Al 6061-T6, is of significant interest in numerous applications in the aerospace, automobile, and naval industries. These models must encompass the early stages of deformation as well as the later stages leading up to failure. Typical models are based on phenomenological descriptions of the constitutive response during the early stages of deformation, and on micromechanical models of damage nucleation and growth (such as the Gurson model) during the later stages that generate softening of the material response triggered by the damage. Calibration of these models is typically based on measurements of the macroscopic response of the material and is an inherently non-unique process. While there are numerous investigations that implement such models in simulations, there are very few investigations that provide an experimental evaluation, both of the calibration of the models and of their use in predicting the deformation and failure in structural applications. In this work we seek to determine the mechanisms relating to the deformation and failure of pure metals as well as alloys that include second phase particles as impurities through a multiscale, multimodal investigation prior to engaging in the selection and calibration of models of the deformation and failure behavior. Interrupted testing protocol is used for macroscale observations and x-ray tomography, and *in situ* loading in a scanning electron microscope are used for continuous and noninvasive monitoring of surface deformation and interior damage. The presence of mechanisms leading to material softening become apparent with these observations, as well as the strain range over which such mechanisms initiate and evolve.

MATERIALS AND METHODS

Oxygen-free high-conductivity (OHFC) copper, pure tantalum, Al 6061-O and Al 6061-T6 are used as examples of high purity metals, materials with different strain hardening characteristics, and materials with second phase particles, spanning a range of fcc and bcc metals. Tests were performed under uniaxial tension, pure shear, and compact tension geometries to explore a range of macroscopic states of stress or constraint. Thus, nominal triaxialities in the range of zero to about three can be explored in these tests; it should be noted that the triaxiality is a local field and could only be estimated through a proper calculation of the stress field through finite element analysis of the nonhomogeneous deformation fields. Two types of interrupted tests were performed. In the first type, the test was halted at specific points along the loading path, and the specimen was the examined in an x-ray tomography system to identify and characterize potential interior damage in the form of voids or cracks at a spatial resolution of about 5 microns. The specimens were then returned to the test machine and subjected to further loading along the original load path and subjected to further x-ray tomographic inspection at selected deformation levels until final failure. In the second type of tests, the specimen recovered at a specific deformation level was sectioned across the thickness and polished for metallographic inspection; these images of the grain structure were used to identify the local strain levels using the procedure indicated in Ghahremaninezhad and Ravi-Chandar [1]. This metallographic inspection permits the observation of damage as well, but with a lower resolution than the x-ray tomography. Interpretation of the experimental observations in terms of constitutive model and damage evolution requires an inverse modeling approach that couples the experiments with finite element simulations. The simulations were performed in a hybrid experimental-computational procedure using MATLAB optimization tools and ABAQUS finite element software for modeling the response of the specimen.

RESULTS

Two different mechanisms of failure are observed in the different materials considered in this work. In the polycrystalline alloys that include a dispersion of second phase particles, we confirm through a combination of microscopy and x-ray tomography, that such particles act as nucleation sites for eventual failure [2]. The progression of these nuclei into a collection of growing and coalescing voids is traced to explore how such growth leads to a localization of the damage over a spatial extent of only about 10 microns (see Figure 1). In polycrystalline materials of high purity

* Corresponding author: ravi@utexas.edu

such as the OHFC copper [4] and pure tantalum [5], the absence of such second phase impurities deprives the material of the mechanism of void nucleation to evolve towards failure; in this case, failure occurs predominantly by the alternating slip mechanism identified for single crystals by Orowan [6] and in polycrystals by Ghahremaninezhad and Ravi-Chandar [3]. Secondary damage in the form of voids at the grain boundaries is also observed [4]. These results indicate that plastic flow is the failure mechanism!

The implication of these observations is that all deformation mechanisms (and damage processes, if any) occur at length scales smaller than a micron, and could/should be captured through a homogenized model, embedded in the stress-strain relation. The experiments also indicate that a robust strain-based failure criterion for the onset of fracture could be quite efficient in modelling ductile failure. The presentation will demonstrate such modeling through a hybrid experimental-computational procedure for constitutive and damage modeling.

Figure 1. X-ray absorption image of an aluminium alloy specimen indicating the localization of damage into an interior microcrack.

CONCLUSIONS

The onset of deformation and damage mechanisms is examined in two high purity metals OFHC copper and tantalum, and in two structural alloys Al-6061-O and Al 6061-T6. Interrupted and in situ tests were performed to assess the evolution of damage under conditions of different triaxiality. Muliscale, multimodal evaluation of damage was assessed using optical and scanning electron microscopy in the destructive tests and x-ray tomography for non-destructive assessment of the geometry of damage. Two different mechanisms of damage – void nucleation, growth and coalescence as well as alternating slip mechanism – were identified in materials with second phase particles and pure metals, respectively. Calibration of a constitutive model and a strain-based failure model based on these measurements of the local strain levels is shown to be an effective way to model ductile failure.

HOW IS DUCTILITY ACHIEVED IN MG ALLOYS ?

Summary The ductility of an alloy is usually determined at the continuum level with phenomenological flow and hardening rules. Pure Mg has a very low ductility yet certain dilute solid-solution alloys can have much larger ductility, making such alloys suitable for structural applications. Here, the mechanism of low-ductility in pure Mg is first identified, a mechanism for enhancing ductility by changing the fundamental behaviour of dislocations in the hcp metal is then proposed, and the dependence of operation of the mechanism on solute type is determined. The theory, using inputs from first principles, then predicts solutes and concentrations necessary for high ductility, and good agreement is found for essentially all alloys studied to date. The theory is then used to identify entirely new multi-component alloy compositions that are predicted to be ductile and do not involve the Rare-Earth Elements (Y, Ce, Nd, Gd, …) that are most frequently found to enhance ductility. This work highlights the role of sub-continuum level modelling that is essential in guiding design of new alloys.

BACKGROUND

For accurate modeling of polycrystalline metals, it is essential to understand the dislocation-based mechanisms that control the plastic flow on the different slip systems in metal alloys. Current approaches fit standard crystal plasticity models to experimental data [1]. Such models implicitly assumes that all plasticity occurs by normal glide and hardening mechanisms, and addresses only differences in crystallographic slip systems. Such approaches may thus misrepresent the underlying dislocation phenomena that operate in a given material. Crystal plasticity parameters can be fit to experimental data on any given alloy, but provide no insight into how to change the material to achieve different, and improved, performance.

Pure Mg is a hexagonally-close-packed metal with a number of different slip systems having different critical Burgers vectors and different stresses for activation (basal (<a>, prismatic <a>, pyramidal I and II <c+a>), where a and c are the lattice vectors for the hcp structure and <...> indicates the Burgers vector. Pure Mg has a very high hardening rate and low ductility (a few %). This has now been identified as mainly due to a thermodynamically favorable transition of the <c+a> pyramidal II dislocations to an immobile structure that is dissociated on the basal plane [2] (Fig. 1a). This behavior is typically represented indirectly in crystal plasticity by using a high critical resolved shear stress for <c+a> slip, and does not reflect the underlying dislocation process. Alloying generally improves ductility considerably; for instance, Mg-1at%RE (RE=Y, Tb, Dy, Ho, Er) alloys show high ductility (20-30%) [3], as compared to most commercial Mg-Al-Zn alloys at similar grain size. Again, crystal plasticity can be fit to the measured behavior, but the mechanisms that change the material from low-ductility to high-ductility at alloying levels as low as 0.03% for Ce, are not identified. Prevailing concepts for ductility in alloys include the reduction of plastic anisotropy due to solute strengthening, the nucleation of <c+a> from basal I1 stacking faults, the prevention of the detrimental <c+a> transformation to sessile structures, and the weakening of strong basal texture by some solute/particle mechanisms. Experiments and modeling do not strongly support any of these concepts, however. Thus, the achievement of high ductility in Mg alloys relies on some new phenomenon.

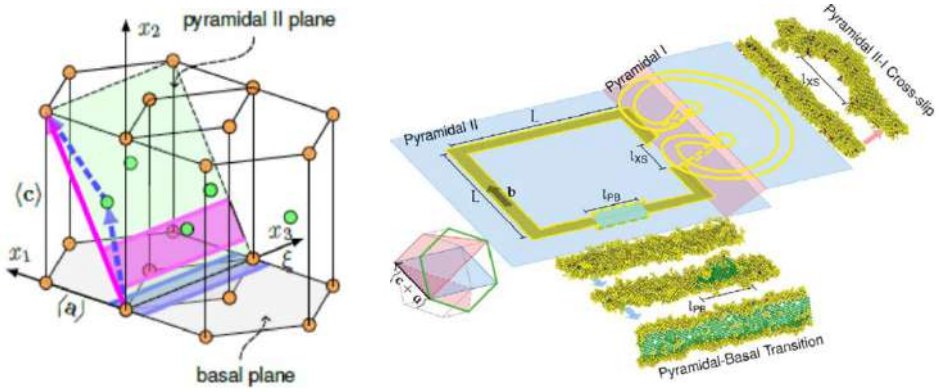

Figure 1. (a) Schematic of the hcp lattice showing the Pyramidal II plane in green, the Burgers vector for the Pyr. II <c+a> dislocation (pink arrow), the easy-glide dissociated Pyr. II <c+a> edge dislocation lying on the Pyr. II plane (pink), and the lower-energy basal-dissociated Pyr. II <c+a> edge dislocation (purple). (b) Schematic of the two competing processes: the undesireable Pyramidal to Basal transition along Pyr. II <c+a> edge segments and the desirable cross-slip of the Pyr. II <c+a> screw segments onto the (higher energy) Pyr. I plane followed by cross-slip back on to the Pyr. II plane, leading to isolation of the Pyr. II edge segments and multiplication of Pyr. II <c+a> dislocations; from Ref. 4, reprinted with permission from AAAS.

DUCTILITY IN Mg ALLOYS

We have recently introduced a new mechanism for achieving high ductility in Mg alloys [4]. The mechanism is that of pyramidal cross-slip of dislocations from the lower-energy Pyr. II plane to the higher energy Pyr. I plane (Fig. 1b). This process accelerates pyramidal dislocation multiplication and limits the undesirable transition of the Pyr. II dislocation to an immobile dislocation, enabling dislocation motion of the mobile pyramidal dislocations, and associated plastic strain. This process essentially turns Mg into a more-normal metal with sufficiently easy slip and multiplication on at least 5 slip systems as required for global plastic strain. The process does not operate effectively in pure Mg because the energy barrier for the cross-slip is much larger than that for the transition to the immobile structure. The process only becomes operative if its rate can sufficiently exceed the rate of the undesirable transition, which requires a reduction of the energy barrier for the cross-slip.

An analytical theory for the cross-slip energy barrier was developed [4]. The dominant role of the solutes was postulated to be in changing the Pyramidal I and II stacking fault energies, which then changes the relative energies of the Pyr. I and II dislocations. Solutes that reduce this energy difference will reduce the barrier and facilitate cross-slip. First-principles calculations reveal that the Rare Earth Elements are by far the most effective in reducing the cross-slip barrier, and hence are predicted to enhance ductility at low concentrations. The particular role of Ce is identified, with the model predictions showing ductility being achievable at the low Ce concentrations observed in experiments. Equally important is the finding that several other solutes, particularly Ca, Mn, and K, can be effective for enabling high ductility while the common solutes Al and Zn are unable to reduce the barrier sufficiently to achieve the ductility condition.

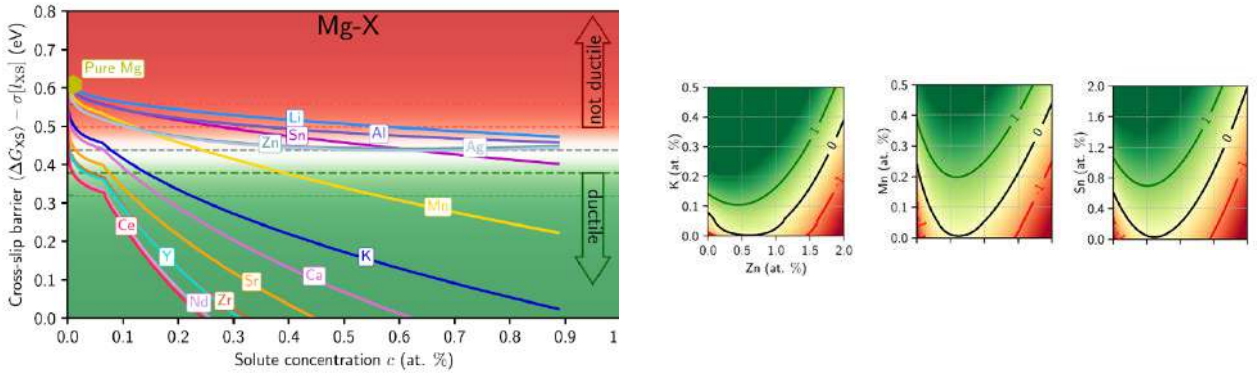

Figure 2. (a) Cross-slip barrier (predicted) as a function of solute type and concentration for binary Mg alloys. Ductility is predicted if the cross-slip barrier falls below ~0.38 (indicated by the heavy dashed green line). The Rare Earth solutes, Ca, K, Mn, and Zr can ductilize Mg at very low concentrations (<0.3%) whereas the common alloying elements Zn and Al cannot reach the necessary condition at any concentration. (b) Example predictions of ductility for ternary Mg-Zn-X alloys (X=K, Mn, Sn), where green shading indicates the ductile regime of compositions. The theory predicts that, while Zn is unfavorably in general, an addition of 0.5at% enables ductility in multicomponent alloys at lower concentration of the third element X. Zn at 0.5% is commonly used in existing alloys. Adapted from Ref. 5 with Permission of Elsevier.

The theory has been extended to multiple dilute solutes, e.g. ternary Mg-X-Y and quarternary Mg-X-Y-Z alloys, enabling validation of other experimental trends (Fig. 2b). In particular, ductility can be achieved at very low levels of K, Mn, and Sn with a small addition of ~0.5% Zn. The ductility of other alloys, especially Al-Ca-Mn alloys recently studied, is predicted in good agreement with experiments. Extensive details of the model and applications, and further predictions on a wide range of ternary and quarternary alloys without Rare Earth elements can be found in Ref. 5.

CONCLUSIONS

Achieving ductility in Mg involves the study of dislocation-level phenomena at scales well below typical continuum level models for polycrystalline alloys. Attaining quantitative results then requires modelling at the level of first-principles to determine the role of specific alloy chemistry in controlling the dislocation-scale phenomena. The ductility in Mg alloys is, furthermore, related to rate-dependent thermally-activated processes, that requires additional understanding of the energy barriers for the relevant processes. This example demonstrates the importance of sub-continuum modelling to drive the design of new alloys with desired plastic flow properties.

PREDICTING THE VISCOPLASTIC BEHAVIOUR OF GLASSY POLYMERS VIA SHEAR TRANSFORMATION ZONE DYNAMICS

Summary The large deformation response of polymeric glasses is predicted by making use of shear transformation zone (STZ) theory. The STZ model requires the calibration of only five parameters to predict the complete uniaxial stress-strain response of glassy polymers, including the yield, softening, and hardening regime. Due to the simulated heterogeneous nature of the inelastic deformation, the framework also provides insight into the origin of micro shear band formation and of macroscopically observed phenomena such as non-linear unloading behaviour, Bauschinger and anisotropy effects, and rejuvenation/ageing evolutions. Future avenues involving the response of polymeric glasses at small and intermediate length scales are outlined.

INTRODUCTION

The deformation and failure behaviour of glassy polymers is complex. When deformed in uniaxial compression or tension at a temperature below the glass transition temperature, the measured stress-strain curve of a polymeric glass typically has, in the absence of failure, an initial linear, (visco-)elastic regime, followed by yield, strain softening, plastic flow, and strain hardening. In addition, the deformation response is sensitive to temperature and rate of deformation, physical ageing, and processing and/or deformation history. Other phenomena include pressure-dependent yield, the Bauschinger effect, and the Kohlrausch (or rate-reversal) effect upon unloading [1]. Sophisticated three-dimensional (visco)elastic-(visco)plastic continuum constitutive models have been developed to predict the large deformation response of glassy polymers [2-5]. Most of these frameworks are based on the one-dimensional constitutive model of Haward and Thackray [6], who decomposed the post-yield stress into a viscous intermolecular resistance and an entropic intramolecular resistance. These large deformation models generally give excellent fits to measured uniaxial stress-strain curves, but they rely on a large number of (often phenomenological) calibration parameters and do not allow the prediction of the inherently heterogeneous nature of inelastic deformation which is thought to be responsible for more complex phenomena such as the non-linear unloading behaviour and the Bauschinger effect. Molecular dynamics (MD) simulations have been used to elucidate the discrete molecular deformation mechanisms leading to the heterogeneous inelastic behaviour of polymeric glasses. The results of MD calculations suggest that plastic deformation of polymeric glasses is caused by thermally activated molecular rearrangements and conformational changes of a collection of polymer chains parts. Given the inherent restrictions in time and length scale of atomistic simulations, the practical use of MD methods is however limited when attempting to predict intermediate scale deformation phenomena such as micron-sized shear bands which may be observed in thin adhesive joints or fibre-reinforced polymer (FRP) composites.

The use of a mesoscale numerical model based on shear transformation zone (STZs) dynamics offers a practical avenue to bridge the state-of-the-art continuum and atomistic simulation approaches. The STZ framework was originally developed by Argon [7] to predict the deformation behaviour of metallic glasses. We have used the implementation by Homer and Schuh [8] of Argon's theory to develop a mesoscale finite element model for polymeric glasses. A first version of the model was presented by Chevalier *et al*. [1]. The scope of this contribution is twofold. We first discuss the effect of some modifications of the framework. In addition, we explore the use of the model when predicting the viscoplastic response of polymeric glasses in more complex loading scenarios and at small length scales. The paper is structured as follows. We first summarise the key ingredients of the STZ framework. Then, we briefly outline the implementation in Abaqus and the calibration of the finite element model to experimental results. We conclude by identifying some cases of interest for future work.

THE STZ FRAMEWORK

It is assumed that the elementary deformation mechanism giving rise to macroscopic plastic deformation in a polymeric glass is a pure shear deformation of an STZ. This STZ may correspond to part of a molecular chain or an assembly of such chain parts. Although we do not need to detail the nature of the collection of molecular changes leading to the shear transformation, one may think of these as conformational molecular changes including slipping of chains, dihedral twists and flips of chain parts. Inelastic deformation is a result of transformation of STZs due to these conformational changes and the elastic interaction of these transformations with the surrounding matrix. Following Argon's theory, we assume that shear zone transformations are thermally-activated. The activation attempt rate is governed by the competition between the free Helmholtz energy barrier ΔF for deformation of the STZ and the available mechanical energy given the STZ's stress state. The magnitude of the energy barrier may be calculated via Eshelby's inclusion theory, it comprises: (1) the transformation strain due to constrained shearing of the

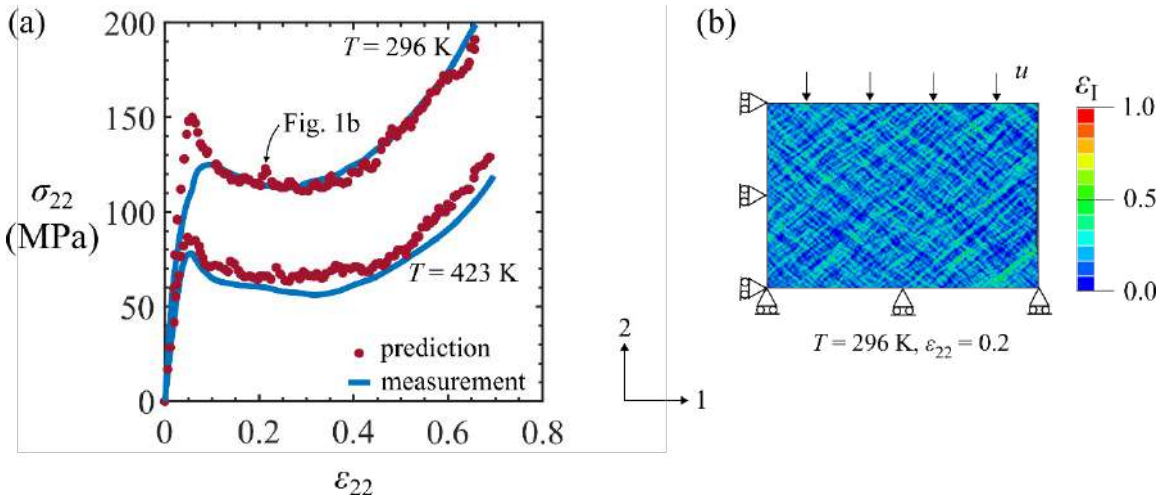

Figure 1. Predictions made by the STZ-based finite element model: (a) Calculated stress-strain versus measured stress-strain curves of an RTM6 epoxy in uniaxial compression at a strain rate equal to 10^{-2} s^{-1} at two testing temperatures. (b) Predicted maximum principal strain field for the $T = 296$ K response shown in (a) at $\varepsilon_{22} = 0.2$. Simulations are conducted for a square model geometry with boundary conditions shown in (b), details on the measurements are included in the work of Chevalier *et al*. [1].

STZ in the surrounding matrix, (2) the strain energy in the matrix and the inclusion due to the temporarily dilation of the STZ and (3) the intermolecular potential energy for shearing the STZ freely. The last two components are assumed to be sensitive to a local chain mobility parameter, which is a measure for the local excess energy for molecular conformational changes. A fourth energy component is added to the energy barrier to account for the finite extensibility of the polymer chains between the crosslinks; the energy contribution for stretching the STZ 'network' is computed by making use of a hyperelastic material model.

We have implemented the STZ framework in a commercial finite element (FE) software package (Abaqus) via a series of user subroutines. The glassy continuum is discretised by means of plane strain quadratic triangular elements. We assume that every element gives rise to one STZ, and that an STZ is comprised of this central element and its neighbouring (node-sharing) elements. Uniaxial compression tests were conducted on an RTM6 epoxy at different testing temperatures ($296\ \text{K} \leqslant T \leqslant 423\ \text{K}$) below the glass transition temperature at a true strain rate equal to 10^{-2} s^{-1}. The measured stress-strain curves for $T = 296$ K and $T = 423$ K are shown in Fig. 1a. The five fitting parameters of the FE model were calibrated to the measured strain-strain curves at different testing temperatures; the predicted response for $T = 296$ K and $T = 423$ K at a strain rate equal to 10^{-2} s^{-1} is included in Fig. 1a. The predicted curves are in good agreement with the measured ones. Interaction of individual STZ transformations at yield leads to the formation of shear bands. The nucleated shear bands start to propagate upon continued macroscopic deformation, resulting in the predicted softening response beyond the yield point. It is emphasised that the simulated heterogeneous stress and strain distributions in the deformed polymeric glass results in the prediction of anisotropic effects.

CONCLUDING REMARKS AND FUTURE AVENUES

The STZ model provides insight into the relation between the heterogeneous nature of viscoplastic flow in polymeric glasses and complex macroscopically observed deformation phenomena. In addition, it is anticipated to be a useful tool to study the deformation and failure of glassy polymers at intermediate length scales (in the order of 0.1 to 10 μm). Future work will therefore include (i) the use of the model to predict constrained plastic deformation at the crack tip in a thin adhesive joint, (ii) the use of the model to predict the stress (re)distribution in a polymer matrix close to a broken fibre in an FRP. More fundamental changes to the framework are also explored in order to predict the effect of physical ageing and mechanical rejuvenation on the viscoplastic response.

ENRICHED COMPUTATIONAL LIMIT ANALYSIS IMPLEMENTATION FOR LARGE-SCALE 3D TRUSS-FRAME STRUCTURES

Rosalba Ferrari[1], Giuseppe Cocchetti[2], and Egidio Rizzi *[1]
[1]Università degli studi di Bergamo,Dipartimento di Ingegneria e Scienze Applicate viale G. Marconi 5, I-24044 Dalmine (BG), Italy
[2]Politecnico di Milano, Dipartimento di Ingegneria Civile e Ambientale piazza L. da Vinci 32, I-20133 Milano, Italy

Summary The present short note compactly presents some new developments of recently proposed algorithms toward the computational Limit Analysis of 3D truss-frame structures. They concern the definition of the interaction yield domain in the space of the static generalized variables of the plastic joint, where localized plastic activations may take place. First results on a steel frame are presented, showing the enriched computational tools to reveal rather effective, toward structural optimization and form finding purposes.

Keywords: Computational Limit Analysis; evolutive elastoplastic response; kinematic (upper-bound) theorem; collapse load multiplier; plastic collapse mechanism; truss-frame structures; interaction domain.

INTRODUCTION

Two new algorithms of computational Limit Analysis (LA) have been recently proposed by the authors toward achieving an effective description of elastoplastic material non-linearity at the cross-section level, within large-scale 3D truss-frame structures [1-5]. The first LA algorithm is apt to trace a fully exact evolutive piece-wise linear elastoplastic response of the structure, up to plastic collapse, by reconstructing the true sequence of activation of made-available plastic joints (as a generalization of plastic hinges), within the true spirit of LA [1-2,4-5]. The second LA algorithm develops an independent kinematic iterative approach apt to directly determine the plastic collapse state, in terms of collapse load multiplier and plastic mechanism, based on the upper-bound theorem of LA [3,5].

The two LA algorithms are found to much effectively run and perform, even for computational models of quite a large size (for multi-storey reinforced concrete frames and a monumental historic bridge, in its structural parts or whole structure), by achieving good corresponding matches in terms of the estimate of the load-bearing capacity and of the collapse characteristics of the structure. Moreover, the kinematic algorithm displays a rather dramatic effective performance, as a "direct method" of LA, in truly precipitating from above onto the collapse load multiplier and in rapidly adjusting to the collapse mode, in very few iterations, by a considerable saving of computational time, with respect to the complete evolutive elastoplastic analysis, though of course without attempting to reconstruct the whole load-displacement response curve.

ENRICHED COMPUTATIONAL PROCEDURE

In the considered implementations, the algorithms so far adopted a simple boxed-form Rankine-type interaction domain in the space of the generalized static variables, to characterize the yield domain of the plastic cross-section joint. In the present work, the above-mentioned algorithms for the LA analysis of 3D truss-frame structures are enriched by dedicated additional computational features. In particular, the procedures are adapted to deal with more general forms of the yield domain of the plastic joint (see e.g. of the Orbison type), as a multi-facet linearized yield surface or by approximating the latter through appropriate ellipsoids, thus combining axial force and bending moments interaction (and possibly couple also other generalized variable internal actions), in this way further enlarging the potentialities of the LA algorithms, especially toward describing the response of truss-frames in practical terms and toward real application scenarios.

Specifically, in the present work focus is placed on the formulated kinematic approach [3,5], as it shall deserve a particular attention for its both straightforward implementation and elevated speed of convergence, being now enriched with computational features allowing for axial force and bending moment interaction. In particular, a six-story space frame adopted in [3] has been here re-considered as a benchmark case study, and preliminary analyses have been conducted so far by considering the yield domain of the plastic joint of the frame to be modelled through an ellipsoid.

NUMERICAL TESTS

As often assumed in elastoplastic frame analysis, in the considered implementation the permanent kinematic discontinuities in each beam element, commonly referred to as "generalized plastic strains", are assumed to be concentrated in so-called "plastic joints", located at the beam finite element edges. These consist of the axial and the transverse relative rotations, and the axial relative displacement for each joint, totalling to 8 plastic kinematic variables for each beam element. Accordingly, the internal actions activating the plastic strains at each plastic joint are axial force, torque and

*Corresponding author. E-mail: egidio.rizzi@unibg.it

two bending moments (shear effects are assumed to be negligible). The (hyper-)ellipsoid that defines the activation of the limit plastic behaviour is herein considered to be tangent to each couple of planes orthogonal to the axis of one static variable (i.e. it is considered to be strictly inscribed into a box describing a Rankine-type domain, as earlier considered in the references above, see Fig. 1(a)).

The considered six-story frame is depicted in Fig. 1(a). The structure is subjected to a uniform vertical floor pressure of 4.8 kN/m^2, leading to a uniform distributed load of 64.2 kN/m along the spandrel beams and of 128.4 kN/m along the central beams. Wind load is represented by horizontal forces of 26.7 kN acting in the y-direction at every beam-column joint of the front elevation. All loads are affected by common load multiplier μ_c. Material yield limits are taken as $\sigma_y = 250$ MPa and $\tau_y = \sigma_y/\sqrt{3} = 144.3$ MPa; the plastic section moduli for the determination of the yield limits defining the principal axes of the ellipsoid refer to the AISC structural steel shapes reported in Fig. 1(a) itself.

The obtained numerical results in terms of collapse load multiplier and associated collapse mechanism are reported in Fig. 1(b). Such results may be compared to those obtained by the same direct kinematic approach, by considering a Rankine-type boxed-form yield domain, actually leading to a higher though quite similar collapse load multiplier [3]. This shall mean that the considered interaction is not much activated, at least for the devised loading condition. The dramatic convergence curve on the collapse load multiplier is also plotted in Fig. 1(c), showing that few iterations are sufficient for the prediction of the collapse state.

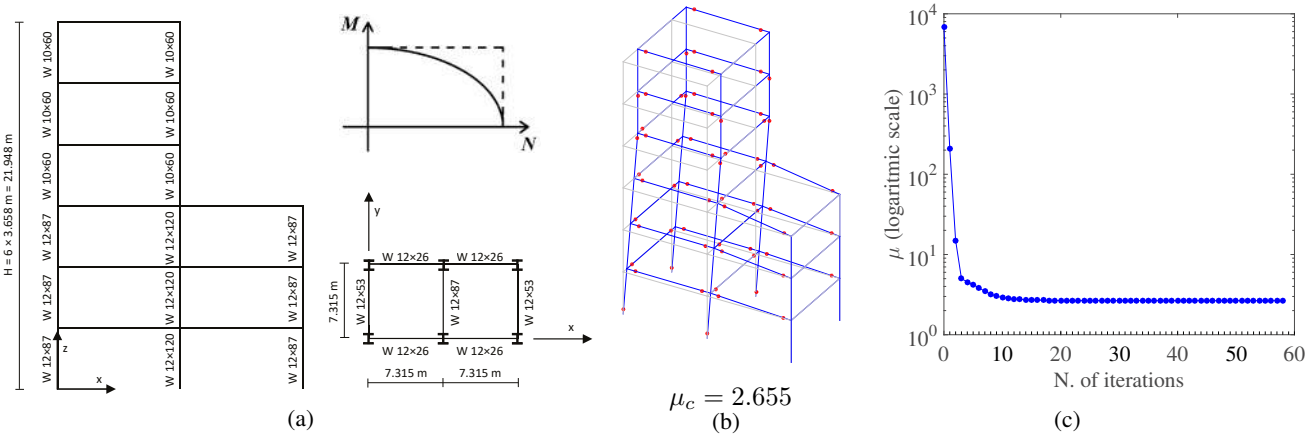

Figure 1: (a) six-story frame and N-M ellipsoidal interaction domain; (b) collapse mechanism and (c) relevant convergence curve.

Also in this case, the algorithm has confirmed to display a quick and easy convergence (Fig. 1(c)). In fact, it took just 58 iteration to get to the solution, demanding less that 1.5 s of computing time, thus showing a very similar computational performance as compared to that pointed out in [3], despite for the added complexity in the description of the yield domain. Moreover, only about 10 iterations are already enough to achieve a good estimate of the collapse load multiplier (Fig. 1(c)). The algorithm has been implemented and run as a non-compiled code within a MATLAB®environment, under a Windows 10 operating system, on a Dell laptop endowed with an Intel Core i7-6500U Processor, clock at 2.50 GHz and 16 GB RAM.

CONCLUSIONS

The present contribution shall much widen out the scopes of the present line of research and additionally open up the way for a further adoption of such advanced computational LA tools, with LA aiming at regaining a new momentum within modern and effective optimization analyses of structural design and form-finding problems.

SHOCK-INDUCED GRADIENT NANO-GRAINED MICROSTRUCTURES IN SILVER

Mauricio Ponga*[1] and David Funes Rojas[2]
[1]Department of Mechanical Engineering, University of British Columbia, Vancouver, Canada

Summary We study the dynamic recrystallization of Silver single crystals nanocubes subject to supersonic impact velocities. Our study shows that upon the impact, a rich, architected microstructure develops in the nanocubes due to the severe plastic deformation imposed by the impact. The resulting microstructure, called gradient nano grained structure, has shown to provide excellent mechanical properties. By doing systematic numerical experiments, we provide a pathway to control the recrystallization by impacting the particles in preferred orientations.

INTRODUCTION

Architecting materials from its microstructural features is one path to achieve extraordinary mechanical properties. Recently, heterogeneous microstructure has been receiving much attention. In a heterogeneous microstructure, the features (grains) exhibit large gradients in their sizes in different parts of the specimens. Materials exhibiting heterogeneous architectures can combine properties that otherwise would be mutually exclusive. This type of architecture is ubiquitous in many materials, including bones, shells, and cellulose materials. However, this type of architecture has not been explored in structural materials until recently. Examples of heterogeneous structure in structural materials have been developed in Copper using the mechanical surface grinding [1, 2], in Copper and other metallic materials using chemical deposition [3], and in semiconductors using shock loading [4]. Controlling the microstructure of crystalline structural materials represents a pivotal milestone to unlock the combination of different properties, *a priori* opposed to each other.

One type of architected microstructure that has been promising in improving the mechanical properties of structural materials is based on gradient-nano-grained structure (GNG). The microstructure of GNG materials is characterized by a smooth transition in the grain size. The grain sizes usually vary from the nano-to-micro scale. However, a key distinctive feature in GNG materials is that this change in grain size happens smoothly and, thus, elastic mismatching is reduced in comparison with other nano-architected microstructures. As a result, GNG materials have shown to combine traditionally mutually exclusive properties such as high-yield stress with high ductility [1, 4, 5]. Thus, GNG materials have areas of traditional strain hardening (micro grains) combined with areas of strain-softening (nanograins). This combination has shown to achieve strength levels compared with nano grained materials, while retaining the ductility of coarse materials [1, 4, 5]. GNG materials offer tremendous opportunities to exploit the properties of metal and push the envelope of structural materials.

Despite the tremendous efforts made to develop and control the microstructure of GNG materials, a fundamental understanding of the parameters that play a critical role remains unclear. This lack of understanding is especially true in the context of GNG materials made through severe plastic deformation and shock loading. Interesting experimental work carried out by Thevamaran *et al.* [5, 6] subjected Silver (Ag) single crystal micro-cubes of different sizes to supersonic impacts. Upon the impact, an extreme plastic deformation generated dynamic recrystallization of the micro-cube, showing the development of a GNG structure. Interestingly, Thevamaran *et al.* [6] have shown that upon the impact, the material transition into a martensitic phase-transformation from 3C face-centered cube (FCC) structure to a 4H hexagonal closed packed structure (HCP). Following the work of Thevamaran *et al.* [6], we systematically investigate through atomistic simulations the key factors that drive the dynamic recrystallization in micro-cubes under high-velocity impacts. Our goal is to better understand the deformation mechanisms in order to be able to control and manipulate the production of an optimized GNG structure.

METHODOLOGY

We perform a set of molecular dynamics (MD) simulations were we impacted single-crystal nanocubes made of 3C FCC silver at different speeds against an impenetrable target. We model the material using the interatomic potential developed by [7]. For all the cases, the impact occurs along the crystallographic direction [100]. The nanocubes size was 65 nm in the side and containing around 16 millions of atoms. The cubes were first stabilized at $T = 300$ K using an NVT ensemble for 30 ps. Next, the cubes were given an initial velocity in the range of $v_i = 200 - 600$ m·s^{-1}. The cubes impacted into an impenetrable wall that modeled with a Lennard-Jones potential. The spatial-temporal evolution of the stress and temperature was tracked down, to understand the shock behavior of the impact. In order to predict the evolution of dislocation density, we also developed a dynamic recrystallization model that was calibrated to our MD simulations. The model takes into account the wave propagation behavior of the shock load and treats the mobile and immobile dislocation densities.

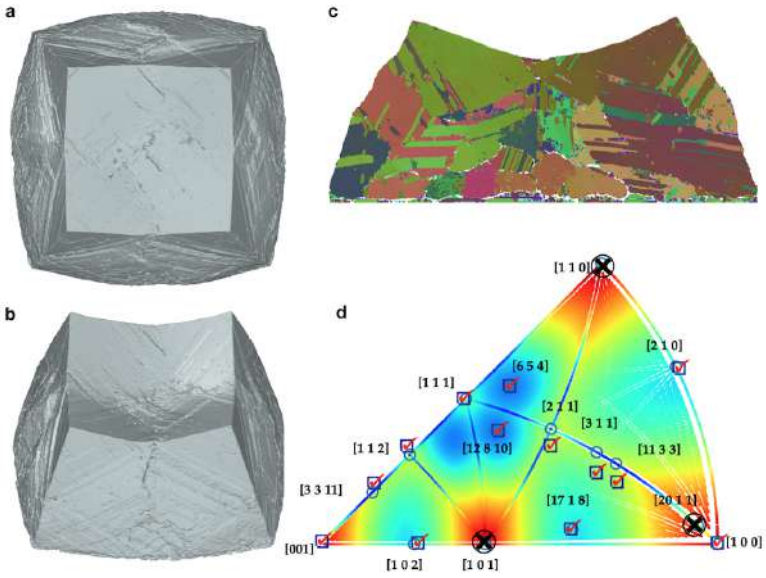

Figure 1: View of the nano-cubes after the impact. a) and b) external view. c) View of the grains. d) Stere0graphic projection for an fcc lattice. Locations with checkmarks indicate a high probability of GNG transformation.

RESULTS

Our simulations revealed that the nano-cubes recrystallize after the impact due to dislocation emission, and the plastic deformation generated during the collision. This is shown in Figure 1(a) and (b). The new grains formed in a sub-nanosecond scale, an illustration of high dynamic effects, where the stresses achieved values up to 20 GPa in compression. The resulting microstructure possesses geometrical features similar to the experiments, where small -nanosized- grains are placed in the impacted surface and with larger grains as one moves away from the impacted surface, as shown in Figure 1(c). Our simulations revealed that in order to obtain dynamic recrystallization, simultaneous activation of slip systems is required. Based on the numerical results, we concluded that at least eight slip systems need to be equally activated. The simultaneous activation occurs when the Schmid's factor of the eight slip systems are similar to each other, with a standard deviation smaller than 0.10. Figure 1(d) shows a stereographic projection with the orientations that produce a GNG recrystallization (indicated with a checkmark) in an fcc lattice for Ag.

The exact grain-size and grain-distribution of the resulting GNG structure strongly depend on the type of metal and the impact velocity. Our analysis shows that the ratio of kinetic energy transformed into temperature, and the ratio of kinetic energy transformed into plastic deformation are strongly dependent on the melting temperature and the stacking-fault energy. Melting is an unwanted effect, as it would degrade the rich microstructure. For each metal, there is an impact speed that produces a maximum density of dislocations and, therefore, the more exotic microstructures without reaching the melting temperature.

CONCLUSIONS

We have systematically investigated the high-velocity impact of Ag nanocubes. Our simulations showed that upon the impact, an avalanche of dislocation was emitted, and the single-crystal recrystallized. This process happened on a sub-nanosecond scale, due to the tremendous high strain rate of the shock load. We showed how the recrystallization depends on the orientation before the impact. For some preferred orientations, the GNG transformation was more likely. Thus, our simulations offer a pathway to control microstructure in metallic materials during high-velocity impact. Our results are relevant in manufacturing methods, such as cold spray.

A HOMOGENIZATION-BASED DAMAGE MODEL FOR STIFFNESS LOSS IN DUCTILE METAL-MATRIX COMPOSITES

K. Dorhmi[1], L. Morin*[1], K. Derrien[1], Z. Hadjem-Hamouche[1], and J.-P. Chevalier[1]
[1]PIMM, Arts et Metiers Institute of Technology, CNRS, Cnam, Paris, France

Summary A homogenized model that describes the progressive loss of stiffness observed experimentally on ductile metal-matrix composites is derived. Damage is supposed to be driven by plastic deformation using a Gurson-type model accounting for the nucleation and growth of voids. Completed by appropriate evolution equations of the microstructure, this model of plasticity is used to update the elastic properties that are described by a mean-field homogenization scheme. The complete incremental model is implemented numerically and applied to the prediction of stiffness loss. The model predictions are in very good agreement with experimental results on Al-SiC composites, cast irons and steel composites.

INTRODUCTION

Metal-matrix composites are attractive materials due to their enhanced mechanical properties; in structural applications, a classical property that is aimed at is the specific modulus, which is defined as the ratio between the elastic modulus E and the density ρ (E/ρ). However, structural metal-matrix composites are limited in real applications because they may lose their improved elastic properties when they are processed by plastic deformation (such as metal forming and rolling). Indeed, the presence of particles with high volume fraction promotes the nucleation of damage in the form of particle cracking and interface decohesion on the metal matrix, which may lead to a decrease of the elastic modulus.

The aim of this work is to derive a micromechanical model for ductile metal-matrix composites that is able to describe the progressive loss of stiffness observed during plastic straining, based on microstructure changes.

A TWO-STEP HOMOGENIZED MODEL FOR ELASTIC-PLASTIC METAL-MATRIX COMPOSITES

In metal-matrix composites, damage nucleation can arise from three sources [1]: (i) the decohesion of the interface between reinforcements (primary particles) and the matrix, (ii) the cracking of reinforcements and (iii) the nucleation within the matrix on second-phase particles. In this work, damage is supposed to be driven only by plastic deformation so no microstructure modifications are induced by elastic strains. The elastic behavior is thus supposed to depend on the microstructure (distribution and volume fraction of various phases) at a given instant while the plastic behavior is supposed to induce damage through the nucleation and growth of voids due to plastic straining .

Homogenization of elastic properties The macroscopic elastic properties are derived using the mean-field scheme of Mori-Tanaka. We investigate the overall behavior of a 3-phase composite made of an isotropic matrix characterized by its shear and bulk moduli μ_m and κ_m, reinforced by isotropic spherical particles characterized by its shear and bulk moduli μ_p and κ_p, and containing spherical voids. The volume fractions of the matrix, particles and voids are respectively denoted by f^m, f^p and f^v, where $f^m + f^p + f^v = 1$. The bulk modulus $\overline{\kappa}$ and shear modulus $\overline{\mu}$ of the composite are given by

$$\left\{\begin{array}{ll} \overline{\kappa} & = \kappa_m \dfrac{f^m(\kappa_m + \alpha_m(\kappa_p - \kappa_m)) + f^p\kappa_p}{f^m(\kappa_m + \alpha_m(\kappa_p - \kappa_m)) + f^p\kappa_m + \dfrac{f^v}{1-\alpha_m}(\kappa_m + \alpha_m(\kappa_p - \kappa_m))} \\ \overline{\mu} & = \mu_m \dfrac{f^m(\mu_m + \beta_m(\mu_p - \mu_m)) + f^p\mu_p}{f^m(\mu_m + \beta_m(\mu_p - \mu_m)) + f^p\mu_m + \dfrac{f^v}{1-\beta_m}(\mu_m + \beta_m(\mu_p - \mu_m))} \end{array}\right. , \left\{\begin{array}{ll} \alpha_m & = \dfrac{3\kappa_m}{3\kappa_m + 4\mu_m} \\ \beta_m & = \dfrac{6}{5}\dfrac{\kappa_m + 2\mu_m}{3\kappa_m + 4\mu_m} \end{array}\right. \quad (1)$$

Homogenization of plastic properties We consider Gurson's macroscopic yield criterion [2]

$$\Phi(\boldsymbol{\Sigma}) = \frac{\Sigma_{eq}^2}{\sigma_0^2} + 2q_1 f^v \cosh\left(\frac{3q_2\Sigma_m}{2\sigma_0}\right) - 1 - q_3(f^v)^2 \leq 0, \quad (2)$$

where Σ_{eq} is the macroscopic equivalent von Mises stress, Σ_m is the macroscopic mean stress and σ_0 is the yield stress of the matrix. The evolution equation of the porosity corresponding to void growth is classically deduced from the incompressibility of the matrix:

$$\dot{f}_{\text{growth}} = (1 - f^v)\,\text{tr}\,\mathbf{D}^p, \quad (3)$$

where $\mathbf{D}^{\text{p}}$ is the plastic Eulerian strain rate. Nucleation of voids is supposed to follow a strain-controlled model:

$$\dot{f}_{\text{nucleation}} = \frac{f_N}{s_N\sqrt{2\pi}}\exp\left[-\frac{1}{2}\left(\frac{\overline{\epsilon} - \epsilon_N}{s_N}\right)^2\right] \times \dot{\overline{\epsilon}} \quad (4)$$

where f_N, ϵ_N and s_N respectively represent the volume fraction, average nucleation strain and standard deviation [3].

*Corresponding author. E-mail: leo.morin@ensam.eu.

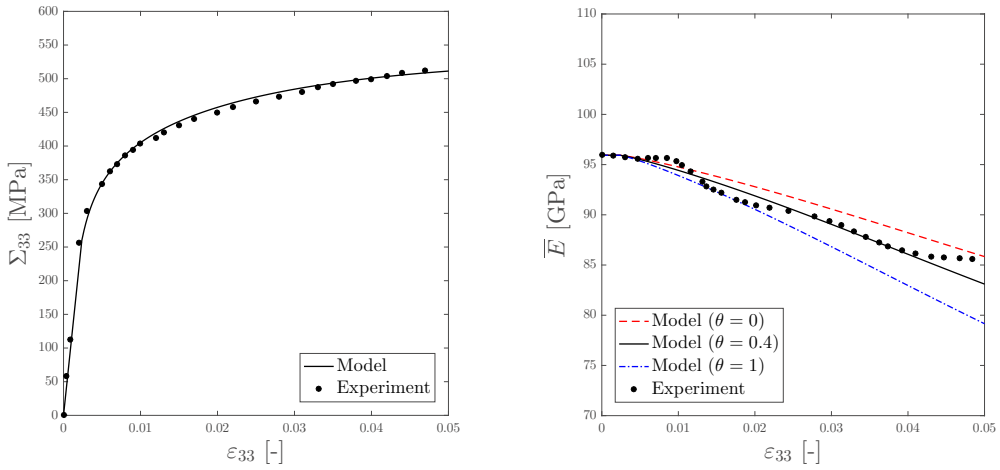
Evolution of the microstructure The evolution laws of the microstructure parameters are supposed of the form

$$\begin{cases} \dot{f}_v &= \dot{f}_{\text{growth}} + \dot{f}_{\text{nucleation}} \\ \dot{f}_p &= -\theta \dot{f}_{\text{nucleation}} \\ \dot{f}_m &= -\dot{f}_{\text{growth}} - (1-\theta)\dot{f}_{\text{nucleation}}, \end{cases} \tag{5}$$

where θ corresponds to the overall nucleation ratio that permits to distinguish nucleation within the matrix and the particles. In the case of decohesion of matrix/particles interfaces, the overall nucleation ratio takes the value $\theta = 1$, while in the case of second-phase particles nucleation, the overall nucleation ratio takes the value $\theta = 0$. In the case of a combination of several mechanisms, the parameter θ will take a value between 0 and 1.

APPLICATION TO STIFFNESS LOSS DURING PLASTIC DEFORMATION

The model's predictions are investigated in problems involving loss of stiffness. Experimental tension tests results from the literature are considered for several heterogeneous materials including Al-SiC composites, cast irons and Fe-TiB_2 composites. Model predictions are investigated with a single (homogeneous) element subjected to an axisymmetric proportional loading with major axial stress Σ_{33}, under conditions of fixed stress triaxiality $T = \Sigma_m/\Sigma_{eq} = 1/3$ (since tensile tests are considered). Two quantities are studied: (i) the evolution of the axial stress Σ_{33} versus the axial strain ε_{33} (the stress-strain curve) and (ii) the evolution of the macroscopic Young's modulus $\overline{E}$ versus the axial strain ε_{33} (the loss of stiffness) (see Figure 1 for Al-SiC composites with a volume fraction of particles of 15 %). In all cases considered, the model, calibrated with physical values of internal parameters, is in very good agreement with experimental data of the literature and permits to predict the influence of progressive damage on elastic modulus.



(a) (b)

Figure 1: Comparisons between experimental and model's predictions in the case of a 15%-SiC Al-SiC composite: (a) stress-strain curves and (b) stiffness loss.

CONCLUSION

A new micromechanical model for prediction stiffness loss in metal-matrix composites is presented. The elastic properties depends on the volume fraction of the present phases (matrix, particles and voids) which may evolve during plastic straining due to void nucleation and growth. Applied to several materials (Al-SiC, cast irons and Fe-TiB_2) the model has permitted to reproduce loss of stiffness in tensile tests.

A MICROSTRUCTURALLY AND EXPERIMENTALLY MOTIVATED DISTORTIONAL HARDENING PLASTICITY MODEL

Knut Andreas Meyer*[1], Andreas Menzel[2,3], Johan Ahlström[1], and Magnus Ekh[1]
[1]Industrial and Materials Science, Chalmers, Gothenburg, Sweden
[2]Institute of Mechanics, TU Dortmund, Dortmund, Germany
[3]Solid Mechanics, Lund University, Lund, Sweden

Summary Plastic deformations cause yield surface distortion in most metals. Consequently, many models have been developed to capture this phenomenon. Starting from simulations of physical mechanisms at the microscale, we discuss the different modeling components of such models. The behaviors of models with those components are then compared to experimental observations of yield surface evolution due to large shear strains in pearlitic steel. By combining the observations from simulations of physical mechanisms with experimental results, a new model formulation is suggested. In contrast to several models in the literature, it guarantees a convex yield surface. Finally, we propose a novel experiment that enables a straight forward calibration procedure for the anisotropy parameters.

INTRODUCTION

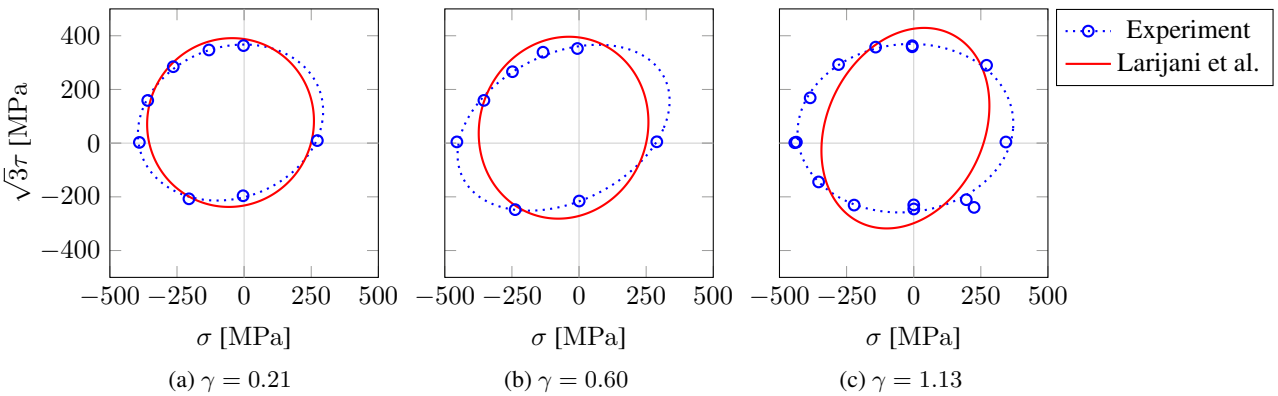
Different mechanisms on the microstructural level give a material its macroscopic behavior. In this contribution, we study some mechanisms that influence anisotropy. The goal is to advance our understanding of both the physical mechanisms and which model components that are important to account for to accurately describe the macroscopic behavior.

We first consider a material consisting of isotropically hardening phases, with different initial yield strengths. In line with the Masing-model [1], the yield surface of this material translates. But it does not distort. Hence, standard kinematic hardening can describe this simple stress partitioning very well. Another explanation for the Bauschinger effect is the polarization of the dislocations [2]. This mechanism can be simulated by crystal plasticity with a back-stress on each slip system. It turns out that after a small predeformation, a high curvature of the yield surface in the loading direction is present. This result is in accordance with experimental findings in the literature, see e.g. Hu et al. [3].

A common motivation for distortional hardening is that the microstructure aligns with the deformation. This substructure evolution is often modeled as a strain-driven process, potentially also including the notion of plastic spin. We first show that for elastic inclusions to influence the yielding anisotropy, the behavior of the interface between the matrix and inclusions is essential. Additionally, the realignment of crystal grains also affects the yield surface shape.

EVALUATION OF SUBSTRUCTURE EVOLUTION

Based on the analysis in the previous section, it seems natural to propose a model in which the substructure evolution governs the distortional hardening. Fully pearlitic steels are well-suited materials to evaluate this approach, as they consist of hard cementite lamellas embedded in a softer ferrite matrix. The model by Larijani et al. [4] directly models the evolution of the yield criterion by considering areal affine reorientation of the cementite lamellas. In Figure 1, we compare the results with this model to our experimental results. But this strain-driven evolution cannot capture the experimentally observed yield surface evolution. Hence, a purely strain-driven evolution seems to be insufficient, and a different modeling strategy is required.



(a) $\gamma = 0.21$ (b) $\gamma = 0.60$ (c) $\gamma = 1.13$

NEW MODEL FORMULATION

An alternative approach to the strain-driven evolution discussed in the previous section is a stress-driven evolution. This approach has proven successful in several studies and is chosen for the present model. We use the idea of a transformed stress state from Karafillis and Boyce [5], which guarantees a convex yield surface. Combined with a von Mises yield criterion, this approach results in a quadratic, Hill-type, yield surface, as in Shi et al. [6], but with ensured convexity. Furthermore, following Qin et al. [7], we introduce a second isotropic hardening stress. This component replaces the dynamic hardening in e.g. [6], making it easier to determine parameter bounds. Finally, we modify the flow rule to simplify the parameter identification procedure.

Model formulation

In this section, we present the key features of the model but omit many details due to space constraints. The yield function Φ is formulated by transforming the Mandel stress $\boldsymbol{M}$:

$$\Phi = \sqrt{\boldsymbol{M}_{\text{red}} : \hat{\mathbf{C}} : \boldsymbol{M}_{\text{red}}} - Y \leq 0, \quad \boldsymbol{M}_{\text{red}} = \boldsymbol{M} - \sum_{i=1}^{N_{\text{back}}} \boldsymbol{M}_{\text{kin},i}, \quad \hat{\mathbf{C}} = \frac{3}{2}\mathbf{C}^{\text{T}} : [\boldsymbol{I} \underline{\otimes} \boldsymbol{I}] : \mathbf{C} \tag{1}$$

where Y is the isotropic yield limit that evolves with plastic deformation. The evolution of $\mathbf{C}$, controlled by the material parameters b and c, is perpendicular to the loading direction $\boldsymbol{N}$ ($\dot{\lambda}$ is the plastic multiplier):

$$\mathbf{C} = \left[[1-b]\mathbf{I}^{\text{dev}} + b\mathbf{C}_{\text{l}}\right], \quad \dot{\mathbf{C}}_{\text{l}} = -c\dot{\lambda}\left[\mathbf{N}_{\perp}^{\text{T}} :: \mathbf{C}_{\text{l}}\right]\mathbf{N}_{\perp}, \quad \mathbf{N}_{\perp} = \mathbf{I}^{\text{dev}} - \boldsymbol{N} \otimes \boldsymbol{N}^{\text{t}}, \quad \boldsymbol{N} = \boldsymbol{M}_{\text{red}}^{\text{t}} / \left|\left|\boldsymbol{M}_{\text{red}}\right|\right| \tag{2}$$

Experimental calibration

Proportional loading, which is described by $\boldsymbol{N} = \pm\boldsymbol{N}_1$, leads to a constant $\mathbf{N}_{\perp}$. For this case, an analytical solution to the evolution of $\mathbf{C}$ exists:

$$\mathbf{C}(t) = \mathbf{I}^{\text{dev}} + \frac{b}{7}\left[\exp\left(-7c\lambda(t)\right) - 1\right]\mathbf{N}_{\perp,1}, \quad \lambda(t) = \int_0^t \dot{\lambda}\mathrm{d}t' \tag{3}$$

The yield limit, Y_2, in the loading direction $\boldsymbol{N}_2$, perpendicular to $\boldsymbol{N}_1$, is then

$$Y_2 = Y\left[1 - \frac{b}{7}\left[1 - \exp\left(-7c\lambda(t)\right)\right]\right]^{-1} \tag{4}$$

where Y is the yield limit in the $\boldsymbol{N}_1$ direction. Y_2 can be measured during a proportional loading experiment. By using a normalized flow rule, i.e. $\boldsymbol{L}_{\text{p}} = \dot{\lambda}\left(\partial\Phi/\partial\boldsymbol{M}\right) / \left|\left|\partial\Phi/\partial\boldsymbol{M}\right|\right|$, $\lambda(t)$ can be obtained from the experiment. The parameters b and c can then be identified directly, without the need for an inverse modeling optimization procedure.

Equation (4) shows that the cross hardening in the present model does not differentiate between monotonic and cyclic proportional loading. This feature is shared with other stress-driven models in the literature. To investigate the validity of this modeling assumption, an experiment comparing the cross-hardening during monotonic and cyclic proportional loading could shed new light on our understanding of distortional hardening. Such experiments will be conducted and presented at the conference.

CONCLUSIONS

A new model for distortional hardening has been developed. It is based on simulations of the physical mechanisms at the microscale, as well as on experimental findings. With the current understanding, a stress-driven approach seems to be the best option. However, results from proposed experiments, which we will present at the conference, will further advance our understanding of this subject.

MESOSCALE LATTICE CONTINUUM: DIFFUSION, CREEP AND PLASTICITY

Sinisa Dj Mesarovic and Sasa Kovacevic,
School of Mechanical and Materials Engineering, Washington State University, Pullman, WA 99164-2920, USA

Summary At high temperatures, the interior of each grain in a polycrystal suffers: (1) dislocation glide, (2) climb, and (3) diffusion of vacancies. Grain boundaries undergo: (4) growth/disappearance, as a result of vacancy diffusion, and, (5) crystallographic reorientation/mismatch, as a result of dislocations arriving to the boundaries either by glide or by climb. All the above deformation mechanisms are naturally described in the lattice continuum framework, whereby the lattice represents the material. Climbing edge dislocations are lattice sink/source which must be reflected in the continuity equation and the transport theorem. The transport theorem for grains with lattice growing or disappearing lattice at different grain boundary faces results in the direct formulation of the boundary condition for vacancy diffusion flux in terms of the boundary velocity (different from the lattice velocity). The field equations for each grain are derived by means of the principle of virtual power. The resulting polycrystal initial/boundary value problem consists of elasticity-plasticity-diffusion field equations in each crystalline domain with moving boundaries, coupled through the boundary conditions.

KINEMATICS OF THE LATTICE CONTINUUM

We consider isothermal process in a single crystal with conserved mass, a single species of atoms and vacancies, without interstitials. The lattice velocity field is an Eulerian variable $\mathbf{v}(\mathbf{x},t)$, and the lattice velocity gradient $\mathbf{L}$ $\mathbf{v}$ is defined. The velocity field characterizing the continuum carries with itself the lattice density N, so that, in contrast to the standard mass continuum and its material derivative, we define the *lattice derivative* as the time derivative following the lattice. Similarly, the transport theorem takes the specific form [1-3].

In addition the lattice density N, the lattice point currently located at $\mathbf{x}$, carries the vacancy concentration c and the deformation gradient $\mathbf{F}$, which evolves as $D\mathbf{F}/Dt$ $\mathbf{L}$ $\mathbf{F}$. Deformation gradient in a newly grown lattice being thus defined, the reference position $\mathbf{X}$ of a newly grown lattice point is formally defined by integrating dX $\mathbf{F}^{-1}$ $d\mathbf{x}$.

Let N_0 be the number of lattice point per unit volume of the undeformed lattice. Then the number of lattice points per unit volume of the deformed lattice is N N_0/F; F $\det\mathbf{F}$.

The deformation gradient tensor can be decomposed into the plastic deformation gradient $\mathbf{F}^p$ and the elastic-compositional deformation gradient $\mathbf{F}^*$. The decomposition is multiplicative and formally identical to the standard (glide-only) elastic-plastic decomposition: $\mathbf{F}$ $\mathbf{F}^*$ $\mathbf{F}^p$. We envision a sequential application of the two gradients (Figure 1). First, the plastic deformation gradient is applied to the reference configuration to produce the intermediate (isoclinic) configuration $\mathbf{F}^p:\mathbf{X}$ $\mathbf{x}$. In contrast to standard crystal plasticity based on dislocation glide, here F^p $\det\mathbf{F}^p$ 1; lattice planes are lost/created, resulting in the translational motion of the parts of the lattice, but lattice symmetries and orientation are preserved. The elastic-compositional deformation gradients accounts for lattice stretching (compositional and elastic strains) and rotation, but the connectivity of lattice points is preserved.

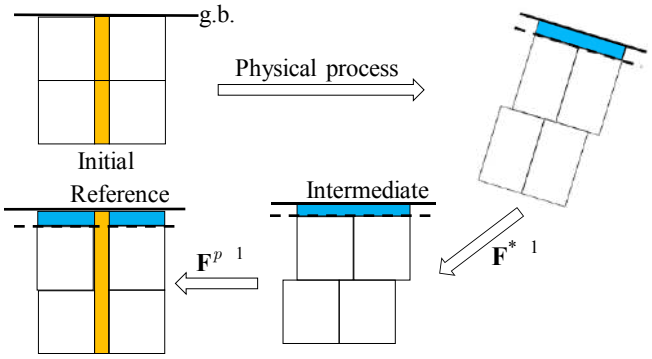

Figure 1. Illustration of elastic-plastic decomposition when the reference configuration is not the initial configuration. The initial element (upper left) at the grain boundary (g.b.) is transformed into the current configuration (upper right). The physical deformation process includes: loss of lattice planes through dislocation climb (yellow), dislocation glide along the horizontal pane, creation of new lattice planes at the boundary (blue), elastic-compositional lattice stretching, and, rotation.

The Eulerian deformation rates are additive:

$$\mathbf{L}\quad\mathbf{L}^*\quad\mathbf{L}^p\quad\mathbf{F}^*\ \mathbf{F}^{*\ -1}\quad\mathbf{F}^*\ \mathbf{L}^p\ \mathbf{F}^{*\ -1};\quad\mathbf{L}^p\quad\mathbf{F}^p\ \mathbf{F}^{p\ -1}. \tag{1}$$

The slip system is described by a triad of unit orthogonal vectors: the slip direction $\mathbf{s}$ $\mathbf{b}/|\mathbf{b}|$, the slip plane normal $\mathbf{m}$, and $\mathbf{t}$ $\mathbf{s}$ $\mathbf{m}$. The plastic velocity gradient on intermediate configuration $\mathbf{L}^p$ accounts for changes in lattice topology and is defined from the elementary slip system state variables: true slip rates $\hat{}$ and climb rates s :

$$\tilde{\mathbf{L}}^p\quad\sum\ \hat{}\ \mathbf{s}\ \mathbf{m}\quad\sum\ s\ \mathbf{s}\ \mathbf{s};\quad\mathrm{tr}\tilde{\mathbf{L}}^p\quad s\quad\sum\ s\ . \tag{2}$$

The boundaries of the crystal serve as vacancy sources and sinks. Upon defining the vacancy flux **J**, *relative to the lattice*, we obtain the diffusion equation for vacancy concentration as

$$Dc/Dt \quad F^* \quad \mathbf{J} \quad (1 \quad c)s \tag{3}$$

The *boundary velocity* **V** is defined on the boundary and is independent of the lattice velocity field, with the normal component V_n **V n**. Then, the boundary lattice growth rate is g V^n **n v**. For a variable crystal domain, with lattice growing/vanishing at the boundary, the local mass conservation condition implies absence of boundary diffusion by requiring that lattice growth/disappearance at the boundary be directly related to the normal atomic flux. The *creep velocity gradient* is the rank-2 tensor, constant within the domain Ω, and defined on the basis of the difference between the boundary velocity **V**, and the lattice velocity at the boundary:

$$\mathbf{C} \quad \frac{1}{} \quad \frac{F^* J_n}{1 \quad c} \mathbf{nn} d \quad ; \quad F^* \quad \det \mathbf{F}^*; \quad c \quad \text{vacancy concentration} . \tag{4}$$

GOVERNING EQUATIONS AND ANALYSIS

Upon defining the compositional strain as eigenstrain and the strain energy density (c), we formulate the power balance with linear dissipation. Then, application of the principle of virtual power yields the governing equations. In addition to the standard stress (quasi-) equilibrium and velocity or traction boundary conditions, we obtain coupled, moving-boundary diffusion problem with an unusual boundary condition on the moving boundaries:

$$\frac{Dc}{Dt} = BF^* \nabla^2 \frac{\partial \Phi}{\partial c} - (1-c)s \quad \text{in } \Omega(t) ; \quad \frac{1-c}{F^*} g = B\mathbf{n} \cdot \nabla \frac{\partial \Phi}{\partial c} = H \frac{F^* t_n}{1-c} - \frac{\partial \Phi}{\partial c} \quad \text{on } \partial\Omega(t) , \tag{5}$$

where B and H are bulk and boundary mobility coefficients.

Several approximations and asymptotic solutions are developed in [1], including linearized elasticity and periodic gran arrangements. Specifically, for small elastic deformation, small departures from equilibrium vacancy concentration and linear (Vegard's law) eigenstrain, the diffusion equations take the simplified form:

$$\frac{c}{t} = B\nabla^2 \frac{}{c} \quad \text{in } \Omega(t); \quad B\mathbf{n} \cdot \nabla \frac{}{c} = V_n = H \; t_n \quad \frac{}{c} \quad \text{on } \partial\Omega(t) , \tag{6}$$

where / c 3 p $(c \quad c_0)$, p is the pressure, t_n is normal traction, is the Vegard's law coefficient and c_0 is the equilibrium vacancy concentration at the given temperature. The following can be deduced:

- The secondary creep rate estimate corresponds to the standard Nabarro-Herring model.
- The volumetric creep is small.
- Equilibrium under deviatoric stresses is not possible without the inclusion of surface energy and then, only for grains with high aspect ratio.
- The main features of the primary creep are qualitatively understood.

In this paper we present numerical simulations of Nabarro-Herring model with emphasis of stress evolution along the grain boundaries which, although subjected the microscopically uniform tractions, exhibit stress concentrations as the result of non-uniform vacancy concentration.

CONCLUSIONS

The lattice continuum theory developed in [1 , 2, 3] represents natural and intuitive framework for analysis of diffusion in crystals and lattice growth/loss at the boundaries. The formulation includes the definition of the Lagrangean reference configuration for the newly created lattice, transport theorem and mass conservation. The latter connects the creep rate tensor, constant within a crystal, to the normal diffusional flux at the boundaries. Dislocation plasticity, including climb and glide is readily accommodated through the decomposition into elastic-compositional and plastic deformation pseudo-gradients. The special case of Nabarro-Herring creep under isothermal conditions has been analyzed. The governing equations are developed with coupled diffusion and elasticity.

The list of unresolved issues and directions for future research include:

- Inclusion of surface energy and surface stresses.
- Inclusion of boundary diffusion for Coble creep.
- Related to the above issues is the question of vacancy nucleation without subsequent absorption by the lattice. The activation energy of such process will be much higher than the one characterizing the nucleation with lattice absorption. A dependence of surface energy of the vacancy content (excess volume) appears to be the key component of such process.

AN INCREMENTAL VARIATIONAL PROCEDURE FOR ELASTO-PLASTIC COMPOSITES WITH COMBINED ISOTROPIC AND KINEMATIC HARDENING

Antoine Lucchetta*[1], François Auslender[2], Michel Bornert[3], and Djimédo Kondo[1]
[1]Université Pierre et Marie Curie, Institut Jean le Rond d'Alembert, Paris, France
[2]Université Clermont Auvergne, Institut Pascal, Clermont-Ferrand, France
[3]Université Paris-Est, Laboratoire Navier, Marne-la-Vallée, France

Summary In this study, we first investigate the nonlinear behavior of elasto-plastic composites with isotropic and linear (or nonlinear) kinematic hardening. To this end, we rely on the incremental variational principles introduced by Lahellec and Suquet [4]. We also take advantage of the formulation recently proposed by Agoras et al. [1]. The proposed model, named *Double Incremental Variational* procedure (DIV), consists in a double application of the variational procedure (VP) of Ponte Castañeda [8]. These two applications of the VP lead to a thermo-elastic Linear Comparison Composite (LCC) with an homogeneous polarization inside the phases. The effective behavior can then be estimated by the classical linear homogenization schemes. New theoretical results are also provided and they are in good agreement with numerical computations at both local and macroscopic scales.

ELASTO-PLASTIC COMPOSITES WITH ISOTROPIC AND KINEMATIC HARDENING

We consider a Representative Volume Element Ω of a composite material made of N phases $(r = 1, \ldots, N)$ with volume fraction $c^{(r)}$. The phases are generalized standard materials (GSM) having an elasto-plastic local behavior described by the conventional J_2 theory of plasticity combined with both linear kinematic hardening and isotropic hardening. This corresponds to a material with internal variables $\boldsymbol{\alpha} = (\boldsymbol{\varepsilon}^p, p)$ describing the irreversible phenomena, where $\boldsymbol{\varepsilon}^p$ is the plastic strain and p the cumulated plastic strain, and with two convex potentials whose expressions are detailed in [6]:

- The free-energy density $w^{(r)}(\boldsymbol{\varepsilon}, \boldsymbol{\varepsilon}^p, p)$ where $\boldsymbol{\varepsilon}$ denotes the local strain
- The dissipation potential $\varphi^{(r)}(\dot{\boldsymbol{\varepsilon}}^p, \dot{p})$ which depends on the indicator function of the convex $\mathcal{C} = \{(\dot{\boldsymbol{\varepsilon}}^p, \dot{p}) / g(\dot{\boldsymbol{\varepsilon}}^p, \dot{p}) = \dot{\varepsilon}^p_{eq} - \dot{p} \leq 0\}$.

Following Lahellec and Suquet [4], an incremental approximation of the constitutive equations for a classical GSM is obtained by using an implicit Euler-scheme at all time increments of duration Δt of a prescribed loading history. Then, two local potentials are introduced: first the incremental potential $J^{(r)}$ defined as $J^{(r)} = w^{(r)} + \Delta t\, \varphi^{(r)}$ which is nonuniform per phase. Second, the condensed free-energy $w^{(r)}_\Delta$ which is defined as the infimum of $J^{(r)}$ with respect to $\boldsymbol{\alpha}$ and leads to the expression $\boldsymbol{\sigma} = \partial w^{(r)}_\Delta / \partial \boldsymbol{\varepsilon}$ for the local stress field in phase r. Finally, the condensed effective free-energy $\tilde{w}_\Delta$ is defined in variational form as $\tilde{w}_\Delta(\boldsymbol{E}) = \inf_{\boldsymbol{\varepsilon} / \langle \boldsymbol{\varepsilon} \rangle = \boldsymbol{E}} \langle w_\Delta(\boldsymbol{\varepsilon}) \rangle$. Thanks to previous relation and using Hill's macro-homogeneity condition, the macroscopic stress $\boldsymbol{\Sigma} = \langle \boldsymbol{\sigma} \rangle$ is obtained as $\boldsymbol{\Sigma} = \partial \tilde{w}_\Delta / \partial \boldsymbol{E}$ (see [4]).

As the dissipation potential is non quadratic, a linearized incremental potential $J^{(r)}_L$ is introduced which depends on a set of per-phase uniform viscosities $\eta^{(r)}_{\varepsilon^p}$ one for each phase r. The application of the VP of Ponte Castañeda [8] provides an approximation of $\tilde{w}_\Delta$ associated with stationarity conditions. The resolution of these conditions leads to an expression for these unknows and to the definition of a thermo-elastic LCC with intraphase heterogeneous properties. Thanks to the VP introduced by Lahellec et al. [3], this heterogeneous LCC is approached by a homogeneous one.

This model has been further extended to an elastoplastic matrix with combined nonlinear kinematic and isotropic hardening. To develop the DIV formulation to nonlinear kinematic hardening, we considered for the matrix phase the Chaboche model which is a regularization of the Armstrong-Frederick one [2] in the framework of GSM (see [7]). In this case, the dissipation potential depends on the state variable, in addtion to their rates. This required to reformulate the incremental variational principles introduced by Lahellec and Suquet [4].

APPLICATIONS AND DISCUSSIONS

We applied this procedure to the case of a composite comprised of an elasto-plastic matrix exhibiting both types of hardenings and reinforced by elastic spherical particles. Both phases are supposed isotropic. The Hashin-Shtrikman lower bound is used to homogenize the LCC with per-phase homogeneous properties, assuming an isotropic phase distribution. As an example of application, let us consider composite materials composed of an elastoplastic matrix with isotropic and linear (or nonlinear) kinematic hardening reinforced by elastic spherical inclusions. These composites are submitted to a uniaxial cyclic isochoric extension along axial direction e_3, such that the macroscopic strain tensor reads $\boldsymbol{E}(t) = E_{33}(t)(-\frac{1}{2}(\boldsymbol{e}_1 \otimes \boldsymbol{e}_1 + \boldsymbol{e}_2 \otimes \boldsymbol{e}_2) + \boldsymbol{e}_3 \otimes \boldsymbol{e}_3)$. The materials mechanical parameters are as in [5].

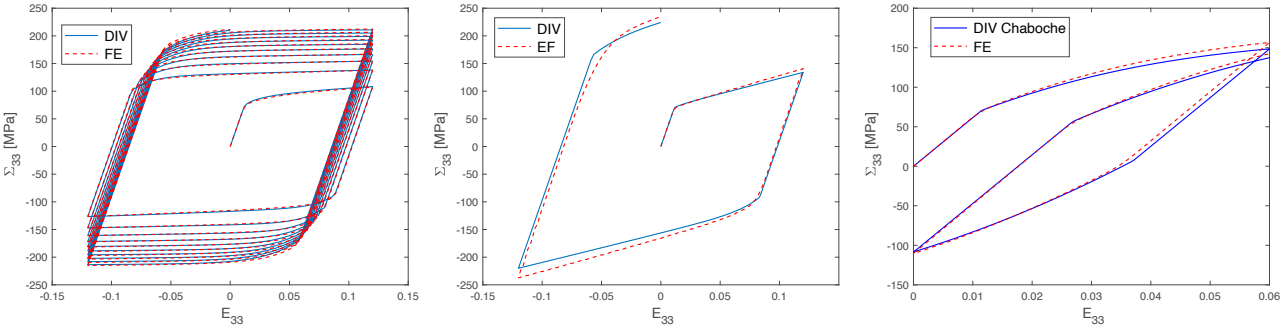
Figure 1: Elastically reinforced composite with an ideally-plastic matrix. $c^{(1)} = 0.17$. (a) Macroscopic axial stress, (b) Average axial stress in the matrix, (c) Average axial stress in the inclusion.

Fig.1 compares the predictions of the DIV formulation to that of RVP (*Rate Variational Procedure*) by Lahellec et Suquet [5], to FFT simulations for a composite comprised of an ideally-plastic matrix. Firstly, RVP and DIV predictions are very close and both of them provide accurate results for of the macroscopic stress and the average stress in the matrix. Moreover, they capture the Bauschinger effect. Is is also noted that although the DIV and RVP approaches qualitatively reproduce the trends of the FFT simulations, they overestimate the average stress in the inclusion. We note that the model has been similarly validated for composites comprised of a matrix with isotropic or linear kinematic hardening (see [6]).



(a) (b) (c)

Figure 2: Macroscopic axial stress of elastically reinforced composites comprised of an elastoplastic matrix with (a) Isotropic hardening submitted to 10 radial loading cycles, (b) Isotropic and linear kinematic hardening, (c) Isotropic and nonlinear kinematic hardening.

We finally provide some results for composites with a matrix exhibiting combined hardening. Fig.2 represents the variation of the macroscopic stress of composite comprised of a matrix with (a) isotropic hardening,(b) isotropic and linear kinematic hardening and (c) isotropic and nonlinear kinematic hardening. In these three cases a close agreement is observed between the DIV approach and FE simulations. It is noted that the proposed models also capture the Bauschinger effect. In particular for isotropic hardening, the model reproduces this effect at each cycle. Moreover, we observe that in general the average stress in the matrix is in good agreement with the FE simulations and the predicted average stress in the inclusion reproduces qualitatively the FE simulations (see [6] and [7]).

Summary Following an extensive experimental campaign carried out on a cold-rolled Ti-6Al-4V titanium alloy grade within a wide range of (low and high) strain rate, temperature and loading cases (tension, compression, shear), an advanced constitutive model is built within the irreversible thermodynamics framework following the internal variable procedure. Some key aspects such as texture-induced anisotropy (which manifests through orthotropy, kinematic hardening and tension/compression asymmetry), rate dependence, strain hardening and thermal softening are consistently accounted for. Material constants are calibrated using the software Zset and the model has been implemented in the commercial finite element computation code LS-DYNA. The latter has been employed to conduct numerical simulations at the structural scale for evaluating the predictive performances of the numerical version of the model.

INTRODUCTION

Due to their high specific impact resistance, Ti-6Al-4V titanium alloys are widely used as protection material for ballistic applications. In aircraft engine fan, they accordingly constitute promising candidates for the leading edge of multi-component blades regarding bird ingestion. During the latter, impacted blades undergo complex loading path and history involving notably large strain, high strain rate and load reversal. In the context of aerospace structure engineering-oriented numerical simulation-aided design, an advanced constitutive model able to account for all the above mentioned parameters is therefore required.

We are here interested in a Ti-6Al-4V titanium alloy grade provided in the form of cold-rolled plate. An extensive experimental campaign has been carried out on it within a wide range of (low and high) strain rate, temperature and loading cases (tension, compression, shear). Experimental results have evidenced that its behaviour is strongly dependent on orientation, rate and temperature, and is subject to isotropic and kinematic hardening as well as tension-compression asymmetry, see Figs.1-2.

In view of describing the above mentioned effects, an advanced constitutive model is built within the irreversible thermodynamics framework following the internal variable procedure. In particular, some key aspects such as texture-induced anisotropy (which manifests through orthotropy, kinematic hardening and tension/compression asymmetry), rate dependence, strain hardening and thermal softening are consistently accounted for. Material constants are calibrated using the software Zset and the model has been implemented in the commercial finite element computation code LS-DYNA. The latter has been employed to conduct numerical simulations at the structural scale for evaluating the predictive performances of the numerical version of the model.

The salient features of the constitutive model will be presented, in particular those related to anisotropic plasticity and rate dependence, as will be shown some numerical simulations involving complex loading cases.

CONSTITUTIVE MODELLING

As mentioned previously, the internal variable procedure is herein applied within the irreversible thermodynamics framework to model the thermo-mechanical behaviour of the Ti-6Al-4V grade under consideration. Plastic anisotropy involves a loss of collinearity between the plastic strain rate and the stress deviator. As the plastic strain rate is derived from the transformed equivalent stress according to the normality rule in the context of non-associate plasticity adopted herein, plastic anisotropy effects are accounted for in the expression of the transformed equivalent stress. Yield function $f\left(\hat{\underline{\underline{\Sigma}}},r\right)$ and plastic potential $F\left(\hat{\underline{\underline{\Sigma}}},r\right)$ accordingly read

$$(1) \qquad f\left(\hat{\underline{\underline{\Sigma}}},R\right)=\sigma_{eq}\left(\hat{\underline{\underline{\Sigma}}}\right)-R\left(\kappa,T\right)=\sigma_{v}\left(\kappa\right)\geq 0 \;\; ; \;\; F\left(\hat{\underline{\underline{\Sigma}}},R\right)=f\left(\hat{\underline{\underline{\Sigma}}},R\right)+g\left(\underline{\underline{X}}\right)$$

where $\hat{\underline{\underline{\Sigma}}}$ and $R\left(\kappa,T\right)$ represent the transformed stress and radius of the elasticity domain subject to isotropic hardening and thermal softening, κ and T the isotropic hardening variable (or accumulate plastic strain) and temperature, and $g\left(\underline{\underline{X}}\right)$ a function of the kinematic hardening force $\underline{\underline{X}}$. $\sigma_{eq}\left(\hat{\underline{\underline{\Sigma}}}\right)$ and $\sigma_{v}\left(\kappa\right)$ are the transformed equivalent stress and strain rate induced over stress (or viscous stress).
It is reminded that in the present case plastic anisotropy manifests through (i) loading direction dependence, (ii) kinematic hardening, and (iii) strength differential. Combining Karafillis and Boyce [1] and Cazacu et al. [2] approaches for orthotropy coupled with kinematic hardening on the one hand and orthotropy coupled with strength asymmetry on the other hand, the expression of the transformed equivalent stress $\sigma_{eq}\left(\hat{\underline{\underline{\Sigma}}}\right)$ is of the form

$$(2) \qquad \sigma_{eq}^{a}\left(\hat{\underline{\underline{\Sigma}}}\right)=\frac{1}{m_{0}^{a}}\left[\left(\left|\hat{\Sigma}_{1}\right|-k\hat{\Sigma}_{1}\right)^{a}+\left(\left|\hat{\Sigma}_{2}\right|-k\hat{\Sigma}_{2}\right)^{a}+\left(\left|\hat{\Sigma}_{3}\right|-k\hat{\Sigma}_{3}\right)^{a}\right] \;\; ; \;\; \hat{\Sigma}_{i}=eig\left(\hat{\underline{\underline{\Sigma}}}\right) \;\; ; \;\; \hat{\underline{\underline{\Sigma}}}=\underline{\underline{\underline{\underline{A}}}}:\left(\underline{\underline{s}}-\underline{\underline{X}}\right)$$

where $\underline{\underline{s}}$ is the Cauchy stress deviator and $\underline{\underline{\underline{\underline{A}}}}$ the orthotropy tensor. eig stands for eigenvalue. a is a positive constant and k takes positive or negative values depending on the strength asymmetry. In addition to involving nonlinear kinematic hardening, function $g\left(\underline{\underline{X}}\right)$ is coupled with $R\left(\kappa,T\right)$ via common materials constants to better describe loading paths with load reversals, see e.g. [3].
Material constants have been calibrated using the software Zset, see Fig.2 for loading direction and strain rate effects. The above outlined advanced model has then been implemented into the commercial finite element computation code LS-DYNA to conduct numerical simulations at the structural scale. The predictive performances of the numerical version of the model have been shown.

CONCLUDING REMARKS

Following an extensive experimental campaign carried out on a cold-rolled Ti-6Al-4V titanium alloy grade within a wide range of (low and high) strain rate, temperature and loading cases (tension, compression, shear), an advanced constitutive model has been built within the irreversible thermodynamics framework following the internal variable procedure. It accounts for texture-induced anisotropy (which manifests through orthotropy, kinematic hardening and tension/compression asymmetry), rate dependence, strain hardening and thermal softening, and is expected to apply to a wide class of strongly nonlinear metals and alloys.

MODELLING PRIMARY CREEP REGENERATION IN A MARTENSITIC 10%CR STEEL

Xiaolong Li[1,2], Stuart Holdsworth[1], Edoardo Mazza[1,2], and Ehsan Hosseini[*1]
[1]Empa, Swiss Federal Laboratories for Material Science and Technology, Dübendorf, Switzerland
[2]Department of Mechanical and Process Engineering, ETH Zürich, Zürich, Switzerland

Summary Primary creep regeneration is an important phenomenon observed for some materials loaded under stress-varying creep conditions. A Chaboche-type unified viscoplastic constitutive model has been developed in this study for representation of the PCR behaviour of a 10%Cr martensitic steel at 600 °C. It has been shown that the developed model can well represent the experimental observations from a comprehensive stress-varying creep testing program and successfully describe the sensitivity of the PCR response to various loading parameters.

INTRODUCTION

For some materials under creep loading, a stress reversal might clear the previous strain hardening memory and lead to regeneration of the primary creep stage upon reloading, i.e. creep re-priming or primary creep regeneration (PCR). PCR significantly increases the accumulated inelastic strain for components operating under cyclic creep loading conditions, and therefore might strongly affect their predicted lifetimes by the strain-based ductility exhaustion method [1]. Different approaches have been employed for consideration of the PCR in mechanical integrity assessment of high-temperature components. As an example, [2-4] assumed that the accumulation of a minimum of 0.01% reverse inelastic strain clears the previous strain hardening history and therefore results in re-occurrence of the primary creep stage upon reloading. The recently generated experimental records from a set of stress-varying creep experiments for two high-temperature steels [5-7] indicated that such simple representations cannot realistically describe the PCR phenomenon. For example, it has been experimentally shown that, depending on the reverse loading conditions, the strain-hardening memory might only partially be cleared or the creep rate after a load reversal might be even higher than that of the primary creep stage. This study presents a new variant of the Chaboche viscoplastic constitutive model, devised from [8, 9], for realistic representation of the PCR response of a 10%Cr steel under different loading conditions at 600 °C.

EXPERIMENTAL DETAILS

Ten stress-varying and two constant-load creep tests were designed to study the PCR behaviour of the 10%Cr steel and its sensitivity to different loading parameters at 600 °C. Fig. 1 shows an example of the loading profile and readers are referred to [6] for more details.

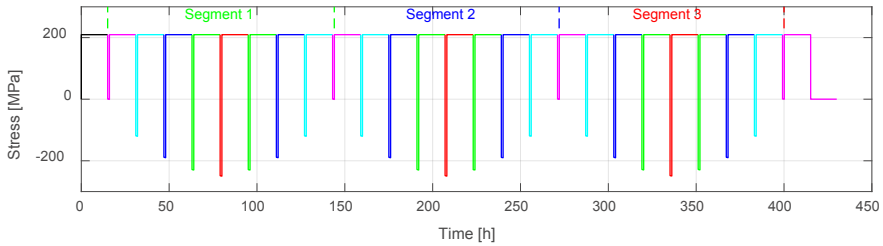

Figure 1. An example of the applied loading profiles for stress-varying creep tests.

MODEL DESCRIPTION AND RESULTS

The following presents the 1D representation of the developed unified viscoplastic constitutive model:

$$\dot{\varepsilon}_{vp} = \sum_{i=1}^{2} A_i \left(\left|\sigma - \Sigma X\right| / D\right)^{n_i} sign\left(\sigma - \Sigma X\right), \quad \Sigma X = \sum_{i=1}^{3} X_i \tag{1}$$

$$\dot{X}_i = C_i \dot{\varepsilon}_{vp} - \gamma_i \left|\dot{\varepsilon}_{vp}\right| X_i - K_i X_i, \quad X_i\big|_{t=0} = 0, \quad \gamma_i = \gamma_{i,\infty} + \left(\gamma_{i,0} - \gamma_{i,\infty}\right)\exp\left(-w_i \left|\varepsilon_{vp}\right|\right), \quad i = 1-3 \tag{2}$$

$$\dot{D} = C' \left|\dot{\varepsilon}_{vp}\right| - \gamma' D \left|\dot{\varepsilon}_{vp}\right| - K' D, \; D\big|_{t=0} = D_0, \quad \gamma' = \gamma'_{\infty} + \left(\gamma'_0 - \gamma'_{\infty}\right)\exp\left(-w' \varepsilon_{vp}^{eq}\right) \tag{3}$$

where σ, X and D are the applied stress, back stress and drag stress, respectively, $\dot{\varepsilon}_{vp}$ is the viscoplastic strain rate, and ε_{vp}^{eq} is the accumulated viscoplstic strain. Calibration of the model and determination of the material parameters (e.g. A_i, n_i, C_i, γ_i) were based on the experimental observations from the twelve conducted experiments.

Fig. 2 compares the experimental and model represented strain evolutions for two of the examined stress profiles, which demonstrates the capability of the developed model for describing different levels of PCR depending on the parameters of the stress profile.

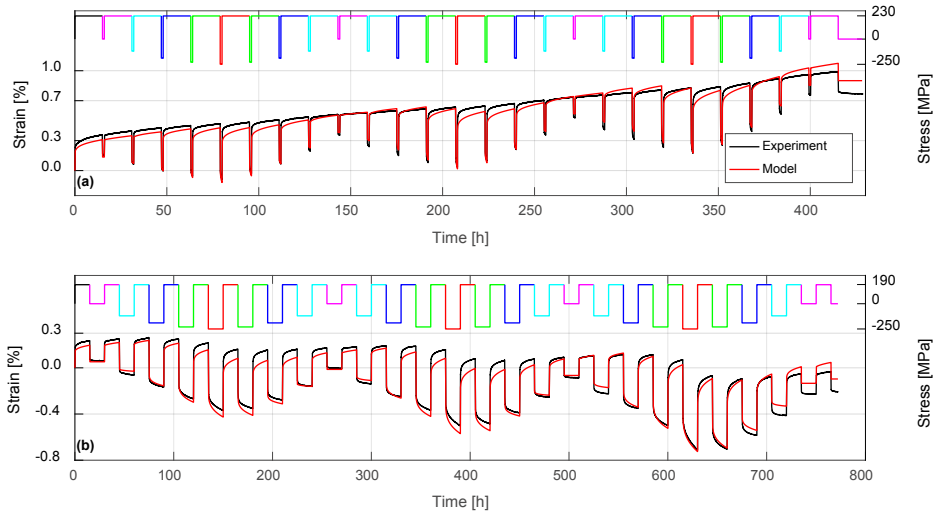

Figure 2. Comparison of the experimental and model represented strain evolutions for two of the examined stress profiles for the 10%Cr steel at 600 °C.

The model was then employed for prediction of the strain evolution for an independent benchmark test for the 10%Cr steel at 600 °C. The satisfactory consistency of the modelling and experimental strain profiles, shown in Fig. 3, demonstrates the predictive capability of the developed model formulation.

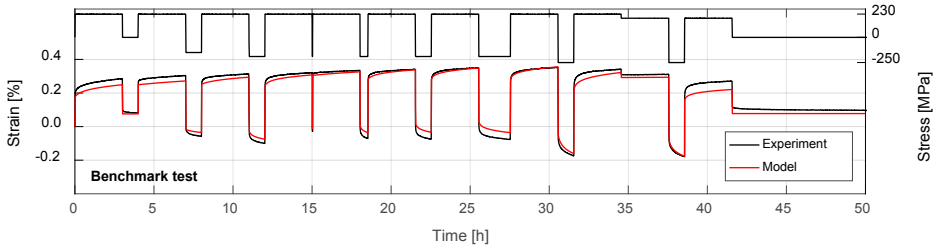

Figure 3. Comparison of the experimental and model-predicted strain evolutions for the conducted independent benchmark test for the 10%Cr steel at 600 °C.

CONCLUSIONS

A unified viscoplatic constitutive model has been developed for representation of the creep behaviour of a 10%Cr steel under stress-varying creep loading conditions at 600 °C. It has been demonstrated that the model can well represent the PCR phenomenon and its sensitivity to parameters of the loading profile.

MICROSTRUCTURE-SENSITIVE FFT-BASED MODEL OF CREEP OF POLYCRYSTALLINE METALS

Ricardo Lebensohn*[1], M. Arul Kumar[1], Nathan Bieberdorf[1], and Laurent Capolungo[1]
[1]Los Alamos National Laboratory, Los Alamos, NM, USA

Summary We present a physics-based model to predict creep in polycrystalline metals, with application to steels. The model is an extension of the dislocation glide-based elasto-viscoplastic (EVP) Fast Fourier Transform (FFT) full-field crystal plasticity formulation, to consider other deformation mechanisms (dislocation climb, diffusion, diffusion- and plasticity-mediated cavitation) at temperatures and stresses relevant to in-service conditions of steels parts in thermal power plants. Upon calibration to reproduce the temperature and stress dependencies of primary, secondary, and tertiary creep for different steels, the model can be used to generate material response across a wide range of operating conditions.

INTRODUCTION

The development of high-strength steels has for decades improved the efficiency and safety of thermal power plants operating under more demanding in-service conditions. Safely employing these materials requires some a priori knowledge of their lifespan. In the case of the thermal creep, however, experimentally verifying the material's time-to-rupture is not always feasible, as operating conditions are generally chosen to produce lifespans on the order of years and decades. Instead, experimental campaigns are conducted at artificially elevated stresses and temperatures, and empirical relations are used to correlate the resultant short time-to-rupture to more realistic operating conditions. But, as temperature and stress are lowered, a different set of deformation mechanisms are expected to dominate the material's behavior. As a consequence, these empirical extrapolated lifetime predictors lack physical basis to predict performance outside of the deformation regime for which they were calibrated.

As a contribution to improve modelling and simulation tools available for engineering analysis and material design, we present a physics-based model to predict thermal creep of steels with sensitivity to the material's microstructure. The model is an extension of an efficient full-field crystal plasticity formulation for dislocation glide, to other relevant deformation regimes. Upon calibration to reproduce the temperature and stress dependencies of primary, secondary, and tertiary creep, the model can be used to generate material response across a wide range of operating conditions.

MODEL

FFT-based methods were developed in the 1990's by Moulinec and Suquet and initially applied to composite materials [1], in which the source of heterogeneity is related to the spatial distribution of phases with different mechanical properties. Later, this methodology was adapted to polycrystals [2], where the heterogeneity is related to the spatial distribution of crystals with anisotropic mechanical properties. This extension exploits the superior numerical performance of crystal plasticity (CP) solved by FFT-based methods, compared with CP Finite Elements. The CP-FFT implementation showed a large reduction of the computational time and the feasibility of solving complex and detailed polycrystalline unit cells. Since then, numerous numerical implementations of the FFT-based method for polycrystals have been developed, for different constitutive descriptions of the behavior of each single crystal material point, including elasto-viscoplasticity [3]. However, in the latter EVPFFT implementation, single-crystal plasticity is considered to occur by dislocation glide only, and the constitutive relation describing the contribution of individual slip systems to plastic strain-rate is given by a power-law relating the ratio between the resolved shear stress on each slip system (given by the projection of the applied stress on the Schmid dyadic tensor), and a critical stress that implicitly contains the dependencies with temperature, strain-rate and deformation history, i.e. strain hardening. This semi-phenomenological constitutive description is insufficient to capture temperature dependence explicitly, and other deformation mechanisms that become relevant, and, at sufficiently lower stresses and higher temperatures, even dominant, during thermal creep. For the ranges of stresses and temperatures of interest, these mechanisms are [4]: for primary and secondary creep, dislocation climb and grain boundary diffusion, and diffusion- and plasticity-mediated damage at grain boundaries in the tertiary creep regime.

In order to overcome these limitations, the EVPFFT formulation and its numerical implementation have been extended to consider: a) crystallographic dislocation climb, using the model of Lebensohn et al. [5], based on the consideration of a newly-defined dyadic climb tensor, which contracted with the applied stress gives the driving force for climb; b) Wen et al. [6]'s model crystal plasticity model, to consider explicit temperature-dependent and microstructure-sensitive dislocation mobility and dislocation density evolution in the climb-and-glide regime; c) a space-resolved constitutive description of Coble creep to model the vacancy-mediated plasticity at grain boundaries. Consideration and proper calibration of all these mechanisms provide a physics-based, temperature-dependent and microstructure-sensitive description of the behavior of steels in the primary and secondary creep regimes, as illustrated in the Results section.

In order to describe the material's behavior in the tertiary creep regime, void nucleation and growth by coupled viscoplastic and diffusive processes driven by local stresses generated in the secondary creep regime are considered. At local (grain boundary voxel) level, the interplay between porosity on local slip activity is accounted for using

homogeneized analytical expressions obtained for a voided rate-sensitive, single crystal matrix [7] and the interplay between porosity on local diffusion kinetics is described using rate-sensitive isotropic dilatational plasticity homogenization [8].

RESULTS

In the primary and secondary creep regimes, Figure 1 shows calibration/validation cases, for different temperatures and applied uniaxial stresses. All calculations were performed on a 32x32x32 polycrystalline unit cell with random texture and austenite single crystal elastic and plastic properties. For the different temperatures, we used one or two stresses for calibration of the single crystal properties and the solid curves for the other two stresses are predictions of the model for primary and secondary creep, which are compared with the corresponding dash lines representing the steady-state secondary creep rate, after [9] for 650C (Fig. 1a), [10] for 700C (Fig. 1b), and [11] for 750C (Fig. 1c).

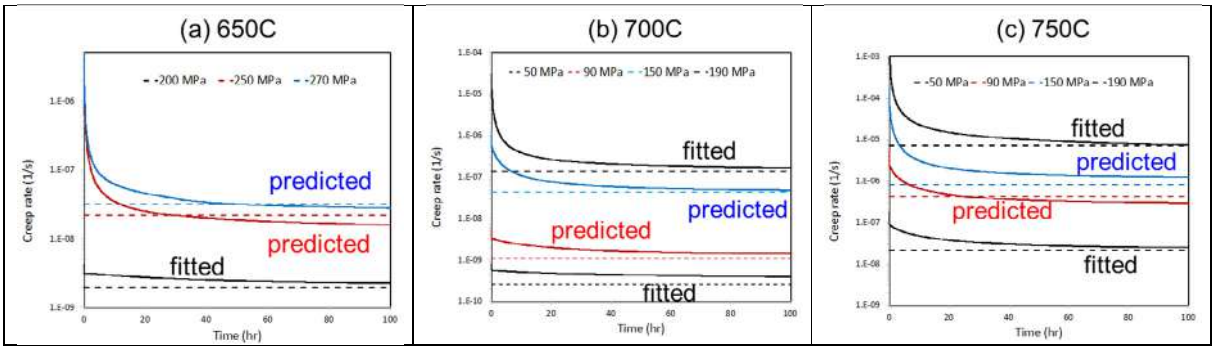

Figure 1: Calibration/validation of the constitutive model parameters to reproduce existing primary and secondary creep experiments of 347 steel for different temperatures and uniaxial stress states.

Summary This work provides an alternative derivation of the homogenization scheme for viscoelastic composites proposed by Lahellec and Suquet, see [1]. This derivation clearly shows that the scheme can be interpreted as a model reduction in the sense that the final estimate preserve the two-potential structure providing a macroscopic free energy and dissipation potential involving a finite number of internal variables (the per phase average and the fluctuations of the internal variable local field).

FRAMEWORK

Inelastic composites exhibiting short-memory effects at the microscale display long-memory effects at the macroscale. Consequently, microscopic constitutive descriptions based on finite sets of internal variables give rise to macroscopic constitutive descriptions with an infinity of internal variables, see [2]. This can be shown in the case of material described in the framework of generalized standard materials by the constitutive relations on the form :

$$\boldsymbol{\sigma} = \frac{\partial w}{\partial \boldsymbol{\varepsilon}}(\boldsymbol{x}, \boldsymbol{\varepsilon}, \boldsymbol{\alpha}), \quad \frac{\partial w}{\partial \boldsymbol{\alpha}}(\boldsymbol{x}, \boldsymbol{\varepsilon}, \boldsymbol{\alpha}) + \frac{\partial \varphi}{\partial \dot{\boldsymbol{\alpha}}}(\boldsymbol{x}, \dot{\boldsymbol{\alpha}}) = 0, \tag{1}$$

where $\boldsymbol{\varepsilon}$ and $\boldsymbol{\alpha}$ denote the infinitesimal and inelastic strains relative to a stress-free reference configuration, $\boldsymbol{\sigma}$ denotes the Cauchy stress, the dot over a variable denotes a time derivative, and the potential functions w and φ are, respectively, the Helmholtz free-energy density and the dissipation potential of the solid. The homogenized response relates the macroscopic stress $\overline{\boldsymbol{\sigma}}$ to the macroscopic strain $\overline{\boldsymbol{\varepsilon}}$, which are the averages of the local stress and strain fields over the representative volume element. This relation can be written in terms of the macroscopic free-energy density and dissipation potential as (e.g., [2])

$$\overline{\boldsymbol{\sigma}} = \frac{\delta \overline{w}}{\delta \overline{\boldsymbol{\varepsilon}}}(\overline{\boldsymbol{\varepsilon}}, \boldsymbol{\alpha}), \quad \frac{\delta \overline{w}}{\delta \boldsymbol{\alpha}}(\overline{\boldsymbol{\varepsilon}}, \boldsymbol{\alpha}) + \frac{\delta \overline{\varphi}}{\delta \dot{\boldsymbol{\alpha}}}(\dot{\boldsymbol{\alpha}}) = 0, \tag{2}$$

where

$$\overline{w}(\overline{\boldsymbol{\varepsilon}}, \boldsymbol{\alpha}) = \min_{\boldsymbol{\varepsilon} \in \mathcal{K}(\overline{\boldsymbol{\varepsilon}})} \langle w(\boldsymbol{x}, \boldsymbol{\varepsilon}, \boldsymbol{\alpha}) \rangle \quad \text{and} \quad \overline{\varphi}(\dot{\boldsymbol{\alpha}}) = \langle \varphi(\boldsymbol{x}, \dot{\boldsymbol{\alpha}}) \rangle \,. \tag{3}$$

In these expressions, $\mathcal{K}(\overline{\boldsymbol{\varepsilon}})$ is the set of kinematically admissible strain fields with average $\overline{\boldsymbol{\varepsilon}}$, $\langle . \rangle$ denotes volume averaging over the representative volume element, and the δ operator denotes a functional derivative. Expression (2) shows that the effective behavior of the composite material is defined by an infinity of internal variables which are the local internal variables of each material point.

This fact has motivated several attempts to generate approximate macroscopic descriptions based on reduced sets of effective internal variables that provide a partial but hopefully accurate characterization of the evolving microscopic state of the composite. One of the earliest attempts consisted in assuming that the inelastic strain within each phase of the composite is uniform and therefore expressible in terms of a finite set of internal variables, see [3]. While attractively simple, it is known that this approximate scheme, commonly referred to as "transformation field analysis", can be severly inaccurate when the local fields exhibit strong spatial fluctuations (e.g., [4]). In view of this observation, Michel and Suquet, see [4] and [5], refined the approximation by assuming non-uniform inelastic strain fields that can be expressed as a linear combination of a finite number of predefined fields, so that the amplitudes constitute a finite set of internal variables for which evolution laws can be provided. This refinement significantly improves the accuracy of the approximation but introduces the need to carry out full-field numerical computations. In this work we proposed an other way of improvement of the TFA method which relies on mean-field homogenization.

EFFECTIVE INTERNAL VARIABLE FORMULATION

To ease the exposition, we restrict attention to viscoelastic phases characterized by Maxwell potentials of the form (for the phase r)

$$w^{(r)}(\boldsymbol{\varepsilon}, \boldsymbol{\alpha}) = \frac{1}{2} (\boldsymbol{\varepsilon} - \boldsymbol{\alpha}) . \boldsymbol{L}^{(r)} (\boldsymbol{\varepsilon} - \boldsymbol{\alpha}) \quad \text{and} \quad \varphi^{(r)}(\dot{\boldsymbol{\alpha}}) = \eta^{(r)} \dot{\boldsymbol{\alpha}} . \dot{\boldsymbol{\alpha}}, \tag{4}$$

*Corresponding authors. E-mail: martin.idiart@ing.unlp.edu.ar, lahellec@lma.cnrs-mrs.fr

where $\boldsymbol{L}^{(r)}$ is positive-definite tensor of elastic moduli and $\eta^{(r)}$ the viscous modulus. Upon an implicit Euler scheme time discretisation, [1] shown that the evolution law $(2)_2$, in view of the convexity of the macroscopic potential, is equivalent to [1]

$$\min_{\boldsymbol{\alpha}} \left[\overline{w}(\overline{\boldsymbol{\varepsilon}}, \boldsymbol{\alpha}) + \Delta t \overline{\varphi}(\frac{\boldsymbol{\alpha} - \boldsymbol{\alpha}_n}{\Delta t}) \right] \tag{5}$$

The estimate is derived by bounding the macroscopic dissipation potential $\overline{\varphi}$ by two potentials $\overline{\varphi}^+$ and $\overline{\varphi}^-$ who only depend on the inelastic strain field $\boldsymbol{\alpha}(\boldsymbol{x})$ through their phase averages $\langle \boldsymbol{\alpha} \rangle^{(r)}$ and the square root of the intraphase fluctuations $\tilde{\alpha}^{(r)} = \left\langle (\boldsymbol{\alpha} - \langle \boldsymbol{\alpha} \rangle^{(r)}).(\boldsymbol{\alpha} - \langle \boldsymbol{\alpha} \rangle^{(r)}) \right\rangle^{(r)^{1/2}}$ of each phases :

$$\overline{\varphi}^{\pm} \left(\frac{\langle \boldsymbol{\alpha} \rangle^{(1)} - \langle \boldsymbol{\alpha}_n \rangle^{(1)}}{\Delta t}, ..., \frac{\tilde{\alpha}^{(1)} \pm \tilde{\alpha}_n^{(1)}}{\Delta t}, ... \right) = \sum_{r=1}^{N} c^{(r)} \eta^{(r)} \left[\frac{\langle \boldsymbol{\alpha} \rangle^{(r)} - \langle \boldsymbol{\alpha}_n \rangle^{(r)}}{\Delta t} . \frac{\langle \boldsymbol{\alpha} \rangle^{(r)} - \langle \boldsymbol{\alpha}_n \rangle^{(r)}}{\Delta t} + \left(\frac{\tilde{\alpha}^{(r)} \pm \tilde{\alpha}_n^{(r)}}{\Delta t} \right)^2 \right] \tag{6}$$

It is not shown here but these reduce potentials are found with the Cauchy-Schwartz inequality which gives bounds for $\left\langle (\boldsymbol{\alpha} - \langle \boldsymbol{\alpha} \rangle^{(r)}).(\boldsymbol{\alpha}_n - \langle \boldsymbol{\alpha}_n \rangle^{(r)}) \right\rangle^{(r)}$. It appears that two different estimates can be derived by switching the sign $\pm$. The form (6) suggests that the bound corresponding to the negative sign should be adopted to be consistent with the time continuous limit $\Delta t \to 0$, so that the last term could be seen as the discretised time derivative of $\tilde{\alpha}^{(r)}$. Choosing the sign $-$, we finally found the following estimate for the effective constitutive relations :

$$\overline{\boldsymbol{\sigma}} = \frac{\partial \hat{w}}{\partial \overline{\boldsymbol{\varepsilon}}} \left(\overline{\boldsymbol{\varepsilon}}, \overline{\boldsymbol{\alpha}}^{(1)}, ..., \tilde{\alpha}^{(1)}, ... \right), \quad \min_{\substack{\overline{\boldsymbol{\alpha}}^{(r)} \\ \tilde{\alpha}^{(r)}}} \left[\hat{w} \left(\overline{\boldsymbol{\varepsilon}}, \overline{\boldsymbol{\alpha}}^{(1)}, ..., \tilde{\alpha}^{(1)}, ... \right) + \Delta t \overline{\varphi}^{-} \left(\frac{\langle \boldsymbol{\alpha} \rangle^{(1)} - \langle \boldsymbol{\alpha}_n \rangle^{(1)}}{\Delta t}, ..., \frac{\tilde{\alpha}^{(1)} - \tilde{\alpha}_n^{(1)}}{\Delta t}, ... \right) \right]. \tag{7}$$

The above formulae simplify considerably when the composite is made up of isotropic phases. In this case, the tensors of elastic moduli are given by $\boldsymbol{L}^{(r)} = 3\kappa^{(r)}\boldsymbol{J} + 2\mu^{(r)}\boldsymbol{K}$ where $\boldsymbol{J}$ and $\boldsymbol{K}$ are the standard fourth-order isotropic bulk and shear projection tensors, $\kappa^{(r)}$ and $\mu^{(r)}$ are the bulk and shear moduli. We obtain the reduced expression for the macroscopic free-energy density which can be estimated by the classical mean field homogenization method :

$$\hat{w} \left(\overline{\boldsymbol{\varepsilon}}, \overline{\boldsymbol{\alpha}}^{(1)}, ..., \tilde{\alpha}^{(1)}, ... \right) = \min_{\in \mathcal{K}(\overline{\boldsymbol{\varepsilon}})} \sum_{r=1}^{N} c^{(r)} \left[\frac{9}{2} \kappa^{(r)} \left\langle \varepsilon_m^2 \right\rangle^{(r)} + \mu^{(r)} \left[\left(\left\langle \boldsymbol{\varepsilon}_d \right\rangle^{(r)} - \overline{\boldsymbol{\alpha}}^{(r)} \right) . \left(\left\langle \boldsymbol{\varepsilon}_d \right\rangle^{(r)} - \overline{\boldsymbol{\alpha}}^{(r)} \right) + \left(\left(\left\langle \boldsymbol{\varepsilon}_d^2 \right\rangle^{(r)} - \left\langle \boldsymbol{\varepsilon}_d \right\rangle^{(r)} . \left\langle \boldsymbol{\varepsilon}_d \right\rangle^{(r)} \right)^{1/2} - \tilde{\alpha}^{(r)} \right)^2 \right] \right] \tag{8}$$

where $\varepsilon_m = \mathrm{tr}\boldsymbol{\varepsilon}/3$ and $\boldsymbol{\varepsilon}_d = \boldsymbol{\varepsilon} - \varepsilon_m$. $\boldsymbol{I}$ denote the mean and deviatoric parts of the strain, respectively, $\boldsymbol{I}$ denotes the second-order identity tensor, and $\mathrm{tr}\boldsymbol{\alpha}^{(r)} = 0$.

CONCLUSIONS

In this paper we give an alternative derivation of the EIV estimate proposed by [1]. These new derivation has several advantages including : (i) it clearly shows the structure of the effective constitutive relation and the set of internal variables used to describe it ($\overline{\boldsymbol{\alpha}}^{(r)}$ and $\tilde{\alpha}^{(r)}$ for each phases). (ii) it gives some criterion to choose between the different roots arising when using the EIV estimate. The proposed method is sufficiently general to be used to derive the RVP estimate, firstly proposed by [6] then by [7], which is based on a dual formulation of equations (1).

NUMERICAL STUDY OF INFLUENCE OF THERMAL RECOVERY ON THE RESIDUAL STRESS STATE AFTER MELTING AND SOLIDIFICATION

Martin Kroon*[1] and MB Rubin[2]
[1]Department of Mechanical Engineering, Linnaeus University, Vaxjo, Sweden
[2]Faculty of Mechanical Engineering, Technion, Haifa, Israel

Summary A thermomechanically consistent Eulerian plasticity model with work hardening is adopted for studying the residual mechanical state resulting from loading at elevated temperatures. The isotropic plasticity model includes the standard effect of work hardening as well as thermal recovery. The results indicate the importance of modeling thermal recovery for accurate prediction of residual stresses for problems dealing with melting and solidification.

INTRODUCTION

Controlling welding and 3D printing processes requires models for melting and solidification which include volumetric expansion and contraction. Melting during heating causes the material to loose resistance to distortional deformation with the melted material behaving more like a fluid than a solid. Solidification during cooling causes the material to regain resistance to distortional deformation with inhomogeneous shrinkage developing undesirable residual stresses. This paper discusses a thermodynamically consistent phenomenological model that is developed using an Eulerian formulation based on the work of Eckart [1] and Leonov [2] who proposed an evolution equation for elastic deformation directly.

THEORETICAL FRAMEWORK

The velocity is $\mathbf{v} = \dot{\mathbf{x}}$, with $\mathbf{x}$ being the position vector in the current configuration, and the velocity gradient $\mathbf{L}$ and the rate of deformation tensor $\mathbf{D}$ are defined in standard ways. Moreover, within the context of the Eulerian formulation of viscoplasticity developed in Rubin [3], the elastic dilatation is $J_{\rm e}$. Also, the elastic distortional deformation is determined by the symmetric, positive definite, unimodular tensor $\bar{\mathbf{B}}_{\rm e}$, which is determined by the evolution equation

$$\dot{\bar{\mathbf{B}}}_{\rm e} = \mathbf{L}\bar{\mathbf{B}}_{\rm e} + \bar{\mathbf{B}}_{\rm e}\mathbf{L}^{\rm T} - \frac{2}{3}(\mathbf{D}:\mathbf{I})\bar{\mathbf{B}}_{\rm e} - \Gamma\bar{\mathbf{A}}_{\rm p}, \quad \Gamma \geq 0, \tag{1}$$

where $\mathbf{I}$ is the second order unit tensor. In these equations, Γ is a non-negative function, and the direction of inelasticity is determined by the tensor $\bar{\mathbf{A}}_{\rm p}$, defined by

$$\bar{\mathbf{A}}_{\rm p} = \bar{\mathbf{B}}_{\rm e} - \left(\frac{3}{\bar{\mathbf{B}}_{\rm e}^{-1}:\mathbf{I}}\right)\mathbf{I}. \tag{2}$$

For an elastically isotropic material, the Helmholtz free energy is taken in the form

$$\psi = \psi(J_{\rm e}, \alpha_1, \theta), \quad \alpha_1 = \bar{\mathbf{B}}_{\rm e}:\mathbf{I}, \tag{3}$$

where α_1 is a scalar pure measure of elastic distortional deformation, and θ is the absolute temperature.

An overstress model is used to characterize the rate-dependent inelastic response with the inelastic distortional deformation rate controlled by the function Γ which is specified by the overstress form

$$\Gamma = a_1 \langle g \rangle, \quad a_1 \geq 0, \tag{4}$$

where a_1 is a temperature-dependent function that controls rate-dependence, and $\langle g \rangle$ denotes the Macaulay brackets. The yield function g is specified by

$$g = 1 - \frac{R_{\rm h}\kappa}{\gamma_{\rm e}}, \quad R_{\rm h}(\theta) \geq 0, \tag{5}$$

where $R_{\rm h}$ is a function of the temperature that influences the temperature dependence of the yield strength, and $\gamma_{\rm e}$ is a measure of effective elastic distortional deformation. Let κ be a scalar measure of hardening determined by the evolution equation

$$\dot{\kappa} = m_1\Gamma(\kappa_s - \kappa) - m_2(\kappa - \kappa_a), \quad m_1 \geq 0, \quad m_2 \geq 0, \quad \kappa_s > \kappa_a > 0, \tag{6}$$

where m_1 controls work hardening, m_2 controls thermal recovery, and $\kappa_{\rm a}$ is a constant that controls the minimum annealed value of κ.

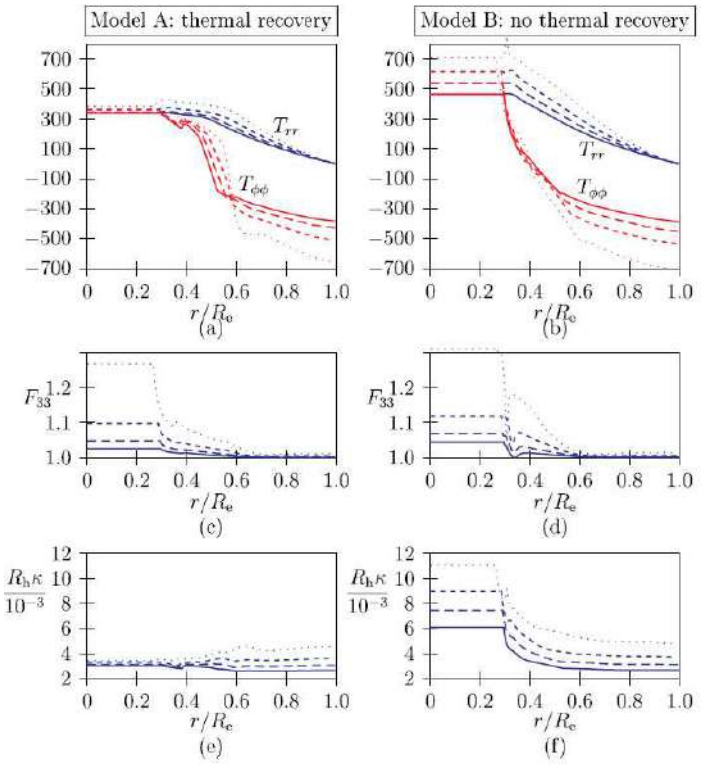

Figure 1: Solutions to the disk problem for different numbers of heating cycles: 1 cycle (solid lines), 2 cycles (dashed lines), 4 cycles (short dashed lines), and 10 cycles (dotted lines). Solution is shown in terms of stress components (T_{rr} and $T_{\phi\phi}$), relative thickness change (F_{33}), and material hardening ($R_h\kappa$). Comparison between the standard case with thermal recovery (a,c,e) and a solution for the simplified model without thermal recovery (b,d,f).

NUMERICAL EXAMPLE

Consider a thin, circular disk. The disk has an initially uniform thickness and consists of two parts: an inner part with radius R_i and an outer part with external radius R_e. The disk is modelled as a 2D structure, and a state of generalized plane stress is assumed. No external forces are acting on the disk, and all mechanical processes in the disk are driven by an inhomogeneous temperature distribution in the disk. The initial temperature distribution at time $t = 0$ is a uniform temperature, $T(R) = T_0 = 20°C$. During the analysis, the temperature in the disk first increases linearly with time, such that at $t = t_c$, the central part of the disk has reached a melted state at the temperature $T = T_m$, where T_m is the melting temperature of the material. At this point in time, the rim of the disk has increased to a lower temperature T_e with the temperature decreasing linearly from T_m at $R = R_i$ to T_e at $R = R_e$. After the maximum temperature distribution has been reached, the temperature field is decreased along the same temperature path, and at the end of the analysis, the disk has the same uniform temperature distribution as in the beginning of the analysis, i.e. $T(R) = T_0$.

Fig. 1 explores the influence of several consecutive heating cycles, each with $t_c = 10s$. Solutions are shown for 1 (solid lines), 2 (dashed lines), 4 (short dashed lines), and 10 (dotted lines) heating cycles. Results are shown in terms of the radial and hoop Cauchy stress components, the thickness component of the deformation gradient, and the accumulated hardening.

For Model A (with thermal recovery), the residual stresses in the inner part of the disk are of the order of 350-400MPa, and these stresses are negligibly affected by an increasing number of heating cycles. The residual hoop stress shows the strongest sensitivity to the number of cycles with its magnitude near the outer edge of the disk increases from about 400MPa to almost 700MPa from 1 to 10 heating cycles.

The predictions of Model B (with no thermal recovery) indicate that the residual stresses continue to increase with each cycle both in the inner region and along the outer edge of the disk. For 10 cycles, the residual stresses are of the order of 700MPa in both the inner part of the disk and along its outer edge. The huge difference in stress levels between the cases with and without thermal recovery is explained by the big differences in accumulated hardening shown in figures (e) and (f).

STABLE PHENOMENOLOGICAL DESCRIPTIONS OF ELECTROMECHANICAL CREEPING IN POLYCRYSTALLINE FERROCERAMICS

Martín I.Idiart*[1,2] and Cristian J. Bottero[1]
[1]Centro Tecnológico Aeroespacial/Departamento de Aeronáutica,Facultad de Ingeniería,Universidad Nacional de La Plata, La Plata,Argentina
[2]Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET),Argentina

Summary Ferroceramics display nonlinear creep effects under both electrical and mechanical loadings at room temperature. These effects have been described by certain phenomenological theories that additively decompose the strain and the dipole density into reversible parts associated with elasticity and dipole perturbations, and irreversible parts associated with dipole switching, and generate constitutive relations from suitably chosen free-energy densities and dissipation potentials. It is shown in this work that the creeping responses predicted by those theories can be unstable, and it is argued that these instabilities are unphysical artifacts of the theories arising from the use of non-convex free-energy densities. Motivated by these findings, a novel class of convex free-energy densities is proposed and employed to generate stable responses reproducing the essential features of ferroelectric creeping.

Ferroceramics display nonlinear creep effects under both electrical and mechanical loadings at room temperature [7, 5]. Various phenomenological theories with the capacity to describe such effects have been proposed.

A particularly attractive class of multiaxial theories hinges upon an additive decomposition of the deformation and the electric polarization into reversible contributions from elasticity and molecular polarizability, on the one hand, and irreversible contributions from ferroelectric switching, on the other hand [6, 8, 9]. The measures of irreversible deformation and irreversible polarization are thus identified as internal variables, and corresponding evolution laws are derived from postulated thermodynamic potentials in accordance with the framework of generalized standard materials. The resulting laws are able to reproduce essential features of ferroelectric responses such as electric hysteresis loops, nonlinear stress-strain curves, butterfly loops, and dipole rotation, and are amenable to numerical implementation into efficient finite-element codes [9]. Rate effects are introduced by assuming dissipation potentials of degree greater than one in the internal rates. It has been recently recognized, however, that the free energies often employed in these theories are non-convex functions of the internal variables and that, consequently, the predicted responses can exhibit unrealistic material instabilities even for simple loading histories such as electric cycling under colinear mechanical tractions [1]. The offending non-convexity is always introduced —perhaps inadvertently— in the attempt to capture the expected contribution of switching to straining via an algebraic connection between the deformation and the irreversible polarization. Some of these theories have also been found to produce evolution equations with no solution [10]. The first part of this work provides predictions for the evolution of polarization and deformation in unpoled specimens subject to uniaxial electric and mechanical step loadings. The evolution laws are numerically integrated in time following an implicit Euler scheme. The resulting polarization and deformation are found to develop an appreciable misalignment relative to the applied loading, which confirms the issues alluded to above.

Motivated by these findings, a novel class of convex free-energy densities is proposed in the second part of the work. For conciseness, we restrict attention to ceramic systems with tetragonal perovskite structure below their Curie temperature and subject to isothermal electromechanical loadings such that the influence of inertia, magnetism and the potential presence of mobile charges can be neglected. It is further assumed that the polycrystalline microstructures are untextured. The theoretical framework borrows ideas from the various microelectromechanical and hybrid theories for polycrystalline ferroceramics already available in the literature (e.g., [3, 11]). These theories consider the switching process as a phase transformation between ferroelectric domain variants, and thus identify the volume fractions of the multiple variants as internal variables. The measures of deformation and polarization are then related indirectly via these volume fractions, whose evolution is dictated by suitably chosen thermodynamic potentials. Realistic predictions can be generated by considering some hundreds of variants, albeit with an equally large number of internal variables. A similar constitutive framework is employed here. Thus, the internal state of the material is initially characterized by an infinite-dimensional internal variable representing the orientation distribution function of ferroelectric domains. A class of convex thermodynamic potentials in terms of this internal variable is then posited, and constitutive relations within the framework of generalized standard materials are derived. However, the functional form of the dissipation is selected in such a way that it effects an order reduction of the constitutive description whereby the infinite-dimensional internal variable is reduced to finite-dimensional internal variables representing irreversible polarization and irreversible deformation due to ferroelectric switching, preserving at the same time the generalized standard structure of the theory. Existance and stability of the predicted material response are thus ensured [2]. As a result of this order reduction, an integral —rather than algebraic— connection between the deformation and polarization due to switching is obtained. Predictions for the evolution of polarization and deformation in unpoled specimens subject to uniaxial electric and mechanical step loadings are reported. Once again, the evolution laws are numerically integrated in time following an implicit Euler scheme. In contrast to the previous predictions, the resulting polarization and deformation are found to remain aligned with the applied loading for the entire history, in agreement with physical expectations.

LINEAR AND NONLINEAR ELASTIC-VISCOELASTIC MODELING OF HIGHLY POROUS POLYMERS

Zahra Hooshmand Ahoor and Kostas Danas *
LMS, Ecole Polytechnique, Institut Polytechnique de Paris, Palaiseau, 91128, France

Summary In this study, a modification of the random sequential adsorption (RSA) algorithm is proposed to generate virtual microstructures with random distributions of non-overlapping elliptical voids in two-dimensions. Due to polydispersity, we can reach very high porosities up to 90vol%. The calculation of the effective elastic and viscoelastic response of the porous unit cells is performed through the finite element (FE) analysis with periodic boundary conditions. We compare the elastic results with the corresponding Hashin-Shtrikman (HS) bounds and study in detail the effect of viscoelasticity upon the nonlinear response of the porous materials. Such materials can be readily 3D-printed and used as designed in applications.

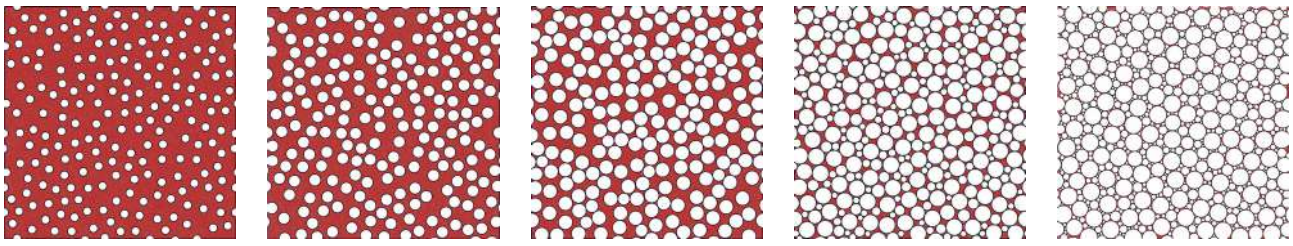
INTRODUCTION

In this work, we study numerically and whenever possible analytically the effective elastic and nonlinear elastic-viscoelastic response of two-dimensional (plane-strain) porous materials. Emphasis is put on voids with circular cross-section but very different sizes (i.e., polydisperse distributions). This allows us to reach extremely large porosities in the range of 90%. The converged unit cells may be readily 3D-printed [1] and tested experimentally.

In the present study, the RSA algorithm [2] is modified accordingly in the two-dimensional case allowing to generate random distributions of mono and polydisperse non-overlapping elliptical inclusions/voids with arbitrary shape, size, and orientation. The center and orientation of the ellipses are set randomly with a uniform probability distribution. The final in-plane (i.e. surface fraction) porosity, denoted here with f, is controlled exactly in the context of monodisperse voids and up to a small tolerance in the context of polydisperse ones. In the latter case, that tolerance is defined by the smallest void radius used in the RSA process. Subsequently, the numerical computation of the effective elastic and nonlinear elastic-viscoelastic properties is carried out using the FE method together with periodic boundary conditions. The number and size ratio of the largest to smallest voids are gradually increased to have a converged response. The following results focus on voids with a circular cross-section, whereas a study of voids with elliptical cross-section is left for the future.

LINEAR ELASTICITY: FINITE ELEMENT VERSUS HASHIN-SHTRIKMAN BOUNDS

The elastic properties of the matrix phase are assumed to be isotropic with Young's modulus $E = 1$GPa and Poisson's ratio $\nu = 0.3$. We first analyze the effect of the different number of families, i.e. different void sizes: 1, 3, 5, etc. One family of inclusions refers to the monodisperse size of voids whereas more than two induces a polydisperse void distribution. Since the voids have a circular shape, the polydispersity is only in size and not shape but the general algorithm can deal with the latter case too but increases the parameters of the study substantially and is not pursued here. It follows from the numerical calculations that in the context of monodisperse voids, the increase of the porosity makes the addition of new voids progressively more challenging. In contrast, in the case of polydisperse voids, by allowing gradually smaller void sizes, one can easily reach a substantially higher porosity even up to 90%, as shown in figure 1.



(a) f=20% (b) f=40% (c) f=60% (d) f=80% (e) f=90%

Figure 1: Realizations of microstructures at different porosities with (a)-(b):Monodisperse and (c)-(e):Polydisperse distribution

The final porosity that may be reached depends on the different parameters such as the number of families, offsets, properties of each phase, and more importantly the mesh size required to analyze the final unit cell or the minimum void size that is attainable by the 3D-printing process. In the case of monodisperse distributions with 200 voids, this numerically saturating value corresponds to $f_{sat} = 55\%$. To be able to reach higher porosities even up to $f = 90\%$, the addition of different void sizes is added to the RSA algorithm via an auto-generated rule. This allows for the automatic reduction of the void size by a prescribed percentage (e.g. 1%) once a large number of attempts (e.g. 1000) to introduce a given void size is done and fails. Figure 1 shows such representative microstructures in the case of monodisperse and polydisperse distributions.

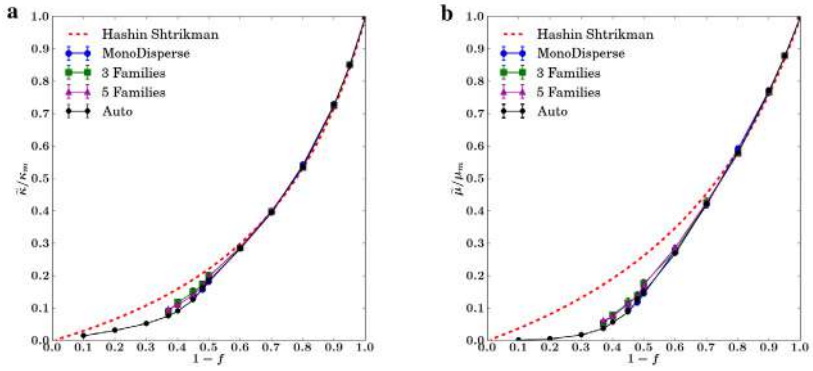

Figure 2: Numerical FE versus HS bounds for monodisperse and polydisperse distributions with 3 and 5 families as well as auto-generated distributions. (a) bulk modulus $\widetilde{\kappa}/\kappa_m$ and (b) shear modulus $\widetilde{\mu}/\mu_m$, where subscript m denotes the matrix phase.

Figure 2 shows comparisons between the numerical FE estimates and the analytical HS bounds for monodisperse and polydisperse voids (with a different number of families) for the effective bulk and shear moduli. The FE results remain very close to the HS estimates for porosities up to 50% for the bulk and 30% for the shear modulus. In turn, they start quickly diverging from those optimal bounds at larger porosities. The differences are much more pronounced for the shear modulus than for the bulk modulus. An attempt to further improve the FE estimates with respect to the HS bounds is made by manually designing the family choices and maximum to minimum void radii but is not shown here due to lack of space.

EFFECTIVE NONLINEAR ELASTIC-VISCOELASTIC RESPONSE

The elastomers exhibit more often than not a nonlinear elastic-viscoelastic response, particularly those resulting from 3D-printing. We present here briefly numerical FE estimates of the nonlinear elastic-viscoelastic behavior of porous polymers for different porosities and strain rates. For simplicity, we use the constitutive laws and parameters proposed in [3]. Figures 3(a) and 3(b) display plots of the stress-stretch response of the Nitrile rubber at constant stretch rate of 0.025 s^{-1} and for different strain rates at constant porosity $f = 20\%$, respectively. Interestingly, we see in figure 3(a) that the porosity leads to a reduction of the overall stress in the unit-cell but does not alter the final stretch after unloading and before relaxation. For completeness, in figure 3(c) we show the effect of porosity upon the overall volume change in the material as measured by the determinant average deformation gradient $\overline{J}$ at constant stretch rate 0.025 s^{-1}.

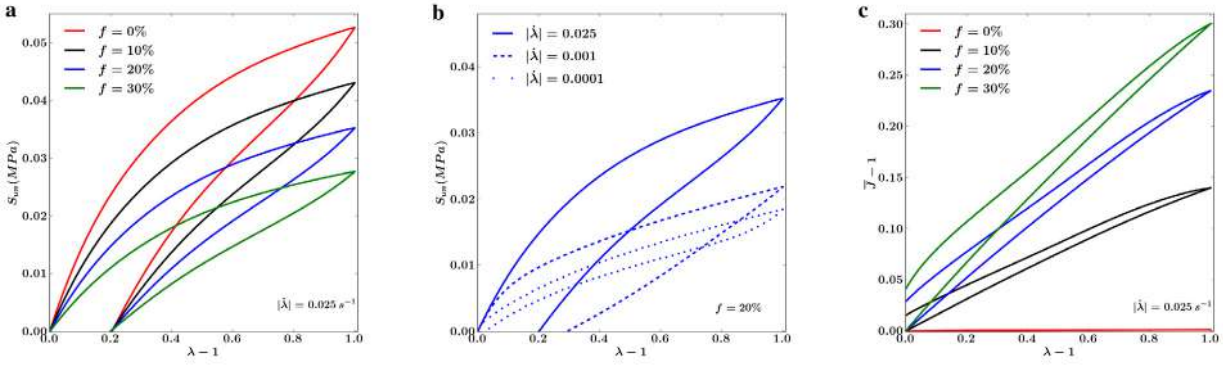

Figure 3: Stress-stretch effective response of porous Nitrile rubber at (a) different porosities and constant stretch rate 0.025 s^{-1} and (b) different stretch rates and porosity $f = 20\%$. (c) Determinant of the average deformation gradient $\overline{J}$ in terms of stretch at different porosities and constant stretch rate of 0.025 s^{-1}.

A NEW METHOD TO MODEL DISLOCATION SELF-CLIMB DOMINATED BY CORE DIFFUSION

Fengxian Liu[1], Alan C.F. Cocks*[2], and Edmund Tarleton[2,1]
[1]Department of Materials, University of Oxford, Parks Road, Oxford OX1 3PH, UK
[2]Department of Engineering Science, University of Oxford, Parks Road, Oxford OX1 3PJ, UK

Summary Fast atomic transport along a dislocation core allows the dislocation to climb (referred to as dislocation self-climb) and is of particular importance in low-temperature creep and post-irradiation annealing. A variational principle is presented for problems in which this is the dominant mechanism of material redistribution. Studies of emergent dislocation behaviour involving both self-climb and glide are presented, in which the huge time scale separation between climb and glide is bridged by an adaptive time-stepping scheme. Loop coarsening of parallel prismatic loops is modelled. Excellent agreement is obtained with published experimental results. The formation of prismatic loops from the break-up of an edge dislocation dipole is also investigated. We demonstrate that edge dipoles sequentially pinch-off prismatic loops, rather than spontaneously breaking-up into a string of loops.

INTRODUCTION

The mobility of atoms in dislocation core regions is many orders of magnitude faster than in the surrounding lattice, resulting in a dislocation climb motion referred to as self-climb. In self-climb, atoms are rapidly rearranged in the dislocation core region to balance the difference of chemical potential along the dislocation line, which is more energetically favorable than mass exchange with the surrounding lattice (bulk diffusion), particularly at low temperatures where bulk diffusion is effectively frozen out. The rapid atomic diffusion along dislocations represents in itself an interesting physical phenomenon and plays a significant role in a wide variety of material behaviors, such as creep, loop or particle coarsening, precipitation and phase transformations, dynamic strain aging, and solute segregation. A systematic investigation of core diffusion and the corresponding self-climb process is therefore essential.

METHODOLOGY

The variational principle, as proposed by Needleman and Rice [1] and generalised by Cocks et al. [2] and Suo [3], has been widely used to solve mass diffusion or migration processes in which the rate of evolution of a system is given by the stationary value of the functional. That is,

$$\Pi = \Psi + \dot{G} \tag{1}$$

where Ψ is a rate potential, which contains contributions from all of the different kinetic and dissipative processes in the system and $\dot{G}$ is the rate of change of Gibbs free energy, which is the origin of the thermodynamic driving forces. It is the combination of thermodynamics and kinetics that determines the actual evolution path and the final state. Here, the

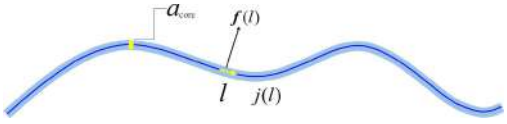

Figure 1: A system of an arbitrarily shaped dislocation line under $\mathbf{f}(\mathbf{l})$.

one-dimensional core diffusion-controlled self-climb process,as schematically shown in 1, is investigated. In which Ψ is caused by core diffusion, and $\dot{G}$ is the rate of change of Gibbs free energy during the self-climb motion. So that,

$$\Psi = \int_L \frac{j^2(l)}{2D(l)} dl, \qquad \dot{G} = -\int_L f_c(l) \mathrm{v}_c(l) dl \tag{2}$$

where $j(l) = -D\frac{\partial \mu}{\partial l}$ is the volumetric flux, which follows the Fick's law. $D(l) = \frac{D_{core}\Omega}{kT}$ is the effective diffusivity. f_c is the components of the Peach-Kohler force $\mathbf{f}$ in the climb direction. Additionally, during the self-climb process, mass conservation requires that the climb velocity is balanced by the variation of the flux,

$$\frac{dj(l)}{dl} + \mathrm{v}_c(l) b \sin\theta = 0 \tag{3}$$

The variational functional of the system can then be developed by subscribing Eq.2 into Eq.1. It can further be shown that, of all classes of assumed compatible flux and velocity fields, the actual motion renders Π stationary. So we can obtain the governing equations for the diffusion process from $\delta\Pi = 0$, which gives the climb velocities of the dislocations. We then implement the variational principle by discretizing the core diffusion formulation into the nodal based 3D-DDD framework to simulate the self-climb process.

VALIDATION AND APPLICATIONS

In this section, applications are presented to simulate dislocation evolution in engineering materials. The examples described in the following are chosen to illustrate the proposed method, and to demonstrate that it produces accurate results by comparison with available experimental observations. Addional examples are given in [6, 7] .

Loop coarsening during post-irradiation annealing: Dislocation self-climb has been proved to be the primary mechanism in the post-irradiation annealing process. The coarsening process of prismatic loops after irradiation by a glide and self-climb mechanism is then investigated based on the self-climb model. Two interstitial prismatic loops with $\mathbf{b} = \mathbf{a}/\mathbf{2}\langle\mathbf{111}\rangle$ and different radii, $R_1 = 12$ nm, $R_2 = 20$ nm, were introduced as the initial configuration. The results of a discrete dislocation simulation are shown in Fig.2 (a)-(d), experimental results for a similar coarsening process reported by [4] is reproduced in Fig.2 (e). The excellent consistency in both the dislocation configuration and time scale validates the new method and indicates the leading role played by self-climb during the post-irradiation annealing process.

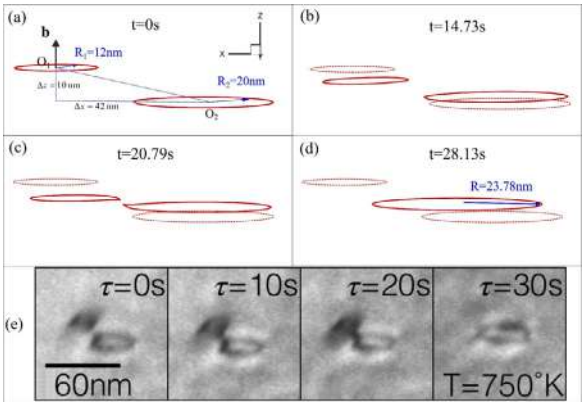

Figure 2: (a)-(d), DD simulation about loop coarsening over a time period, a movie is available in the supplementary S2, (e) Experimental results about the evolution of loop coarsening [4]

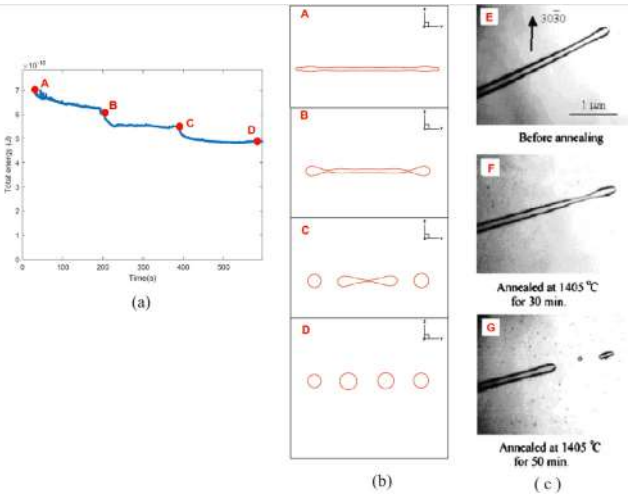

Figure 3: Prismatic loops forms from pinch-off of an edge dipole. (a) The energy evolution over time; (b) Dislocation profiles corresponding to the marked points A-D in (a); (c) Experimental observations from [5]

Formation of prismatic loops from pinch-off of a closed-end edge dipole : At high temperature or during annealing of deformed crystal, dislocation dipoles can annihilate and break up into prismatic loops by a conservative dislocation climb mechanism, which is primarily controlled by core diffusion along the dislocation line. An elongated edge dislocation dipole formed by jog dragging is introduced as the initial configuration, as shown in Fig. 3 (a). The results show that loops are pinched-off sequentially from the tip of the dipole rather than the dipole spontaneously breaking-up into a string of loops.

CONCLUSIONS

In the present work, a new methodology has been proposed for describing the core diffusion dominated dislocation self-climb process, which allows traditional DDD modeling to be extended to a new clan of physical problem. Applications in modeling the post-irradiation prismatic loop annealing and pinch-off of edge dislocation dipoles are conducted and compared with available experimental results.

PREDICTION OF THE EFFECT OF INDIVIDUAL TEXTURE COMPONENTS ON THE PLASTIC ANISOTROPY OF POLYCRYSTALLINE METALLIC SHEETS

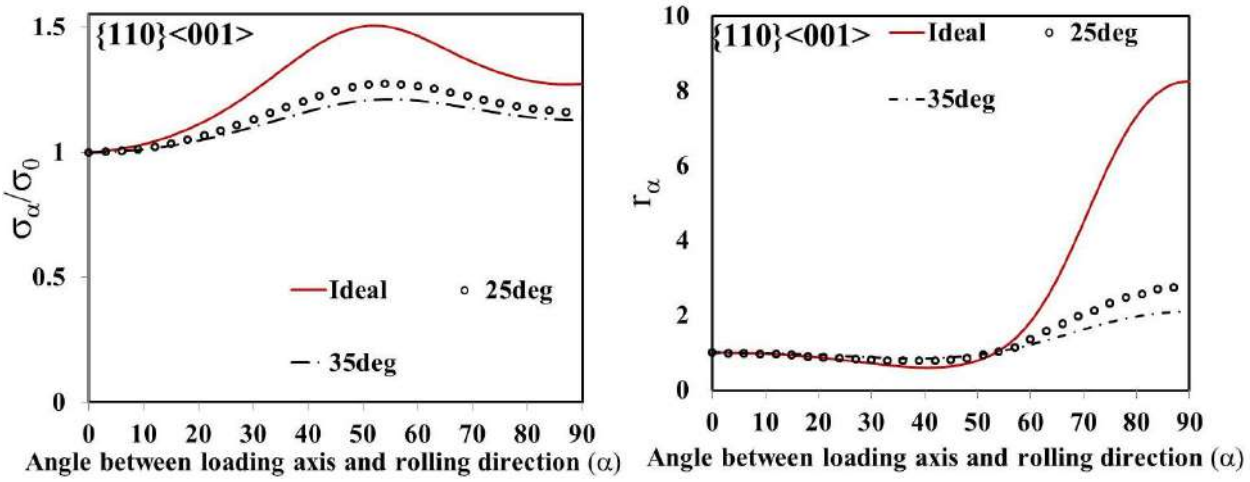
Oana Cazacu[1a)], Nitin Chandola[1], Benoit Revil-Baudard[1]
[1]Department of Mechanical &Aerospace Engineering, University of Florida/REEF, Shalimar, Fl, U.S.A

Summary In this study, the recent polycrystal model [1] is used to predict the influence of individual texture components on the macroscopic plastic properties of textured polycrystalline sheets. The constituent grain behaviour is described using the single-crystal yield criterion [2]. First, we present the predictions of plastic anisotropy in mechanical properties for metallic sheets containing a single texture component (e.g. Goss, cube, brass, copper) specified in terms of a Gaussian distribution of misorientations with scatter width ranging from 0º (i.e. ideal texture) up to 45º around the respective ideal texture component (i.e. close to random texture). Irrespective of the number of grains considered, the predicted Lankford coefficients have finite values for all loading orientations. When more than one ideal texture component exists in the material, it is shown that the polycrystal model captures the effect of each texture components on the overall plastic anisotropy of the polycrystal.

In this paper, using the yield criterion [2] for description of the plastic behaviour of single crystals, we study the effect of individual texture components on the plastic anisotropy of polycrystalline metallic sheets. Specifically, we predict the anisotropy in uniaxial yield stresses and Lankford coefficients (r-values) in metallic sheets containing the following texture components that are commonly observed experimentally: cube, Goss, Brass and Copper. First, results are presented for sheets having one texture component specified in terms of a Gaussian distribution of misorientations with scatter width ranging from 0º (i.e. ideal texture) up to 35º around the respective ideal texture component. It is shown that for ideal textures, using the single-crystal criterion [2] the directional dependence of the yield stress and Lankford coefficients can be obtained in closed-form. For the case of strongly textured sheets containing a spread about the ideal texture components, the polycrystalline response is calculated numerically using the polycrystal model [1]. It is shown that irrespective of the tensile loading direction the predicted r-values have finite values for all loading orientations. As an example, in Fig.2 are shown the predicted variations of macroscopic plastic properties with the loading orientation for a polycrystalline sheet for which the {111} pole figures are shown in Fig.1. Note the effect of the spread with respect to the ideal Goss texture on the directional dependence of the yield stresses and plastic strain ratios. For a spread of $\omega = 25º$ around the ideal Goss orientation, the numerical predictions of the yield stresses and r-values of the polycrystalline sheet are very close to those obtained for $\omega = 35º$. On the other hand, the anisotropy in $\sigma(\alpha)/\sigma(0)$ vs. α and $r(\alpha)$ vs. α variations are much less pronounced than the respective curves for the ideal Goss texture For example, for a spread $\omega = 35º$, the value of r(90º) is about five times smaller than the corresponding r-value of the ideal Goss texture. Nevertheless, the nature of the r-values variation is similar irrespective of the spread, with a point of inflection at around 55^0 from the reference direction (see Fig. 2).

(a) (b)

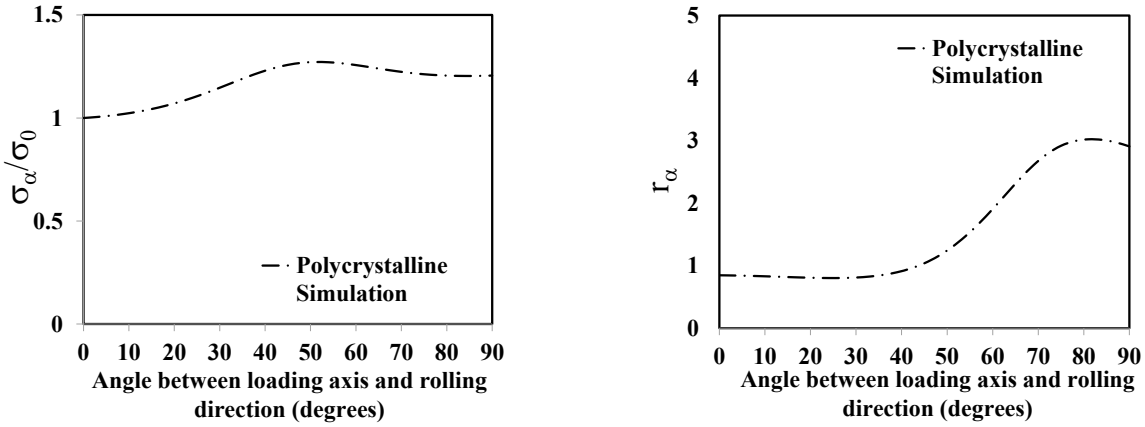
Figure 1: {111} pole figures for Goss texture corresponding to a series of Gaussian distributions of increasing scatter width : (a) $\omega=25^0$ and (b) $\omega=35^0$.



(a) (b)

Figure 2: Predictions obtained with the polycrystal model [1] of the directionality in: (a) yield stress ratio $\sigma(\alpha)/\sigma(0)$, and (b) plastic strain-rate ratio r(α) in the plane of the {110}<001> textured polycrystalline sheet. The textures for different scatter width are shown in Fig. 1. The results for ideal texture were obtained with analytical formulas in conjunction with the single-crystal model [2].

Next, an example is given for a polycrystalline sheet with dominant Goss texture component (70% volume fraction) and a minor $\{\bar{2}1\,\bar{1}\}<011>$ component (30% volume fraction). It is predicted that the $\{\bar{2}1\,\bar{1}\}<011>$ component contributes to a significant decrease in anisotropy of the material. Indeed, the predicted *r*-value in the transverse direction is significantly lower than that predicted for the ideal Goss component (compare results in Fig. 3(b) with the r-values variation shown in Fig. 2(b) for the ideal Goss component).



(a) (b)

Figure 3: Predictions of anisotropy in (a) yield stress ratio and (b) plastic strain-rate ratio in the plane of the polycrystalline sheet predicted with the polycrystal model [1] for a strongly textured polycrystal with components spread around the $\{\bar{2}1\bar{1}\}<011>$(30%) and ideal Goss (70%) orientation.

CONCLUSIONS

When more than one ideal texture component exists in the material, the polycrystalline simulations based on the new description of the plastic behavior of the constituent grains capture the influence of individual texture components on the overall plastic anisotropy of the polycrystal. The examples presented demonstrate the predictive capabilities of the model

RECIPROCAL RELATIONS IN DISLOCATION-MEDIATED PLASTICITY

Victor L. Berdichevsky
Department of Mechanical Engineering, Wayne State University, Detroit, USA

Summary Reciprocal relations are established for nonlinear driven dissipative systems. A consequence of these relations for dislocation-mediated viscoplasticity is the potentiality of constitutive equations in the limit of small and large stresses. Implications for double slip in single crystals are discussed.

Almost a century ago Onsager found a universal feature of all dissipative systems describing approach to thermodynamic equilibrium, the reciprocal relations. They hold for linear differential equations describing an evolution of macrovariables in vicinity of equilibrium states. The derivation assumed implicitly that underlying microdynamics is Hamiltonian and ergodic. There are many situations which are not covered by these assumptions. Such are the cases where macrovariables, which are the slow parameters of microdynamics, describe, in fact, the mesoscopic phenomena. Thus, an additional course graining is to be done to get the equations of macroscopic theory. In particular, this pertains to the problems of dislocation-mediated plasticity, where elimination of atomic degrees of freedom yields dislocation dynamics, and an additional averaging is needed to obtain the equations of macroscopic plasticity. This averaging problem is qualitatively different from the classical problems of nonequilibrium statistical thermodynamics because the equations to be averaged are not Hamiltonian, they are dissipative. However, the basic question remains the same: Are there universal relations which macroscopic equations must respect? In this talk, a positive answer to this question is given. Though the major focus of this work is on dislocation viscoplasticity, the results are formulated in quite general form. Let a mesoscopic process be described by a system of ODE with thermal noise,

$$B_{ij}\dot{x}_j = F_i - \frac{\partial H(x)}{\partial x_i} + \alpha_{ij}\dot{w}_j. \tag{1}$$

Here B_{ij} are drag coefficients, i,j run through the values $1,\dots,n$, summation over repeated indices is implied, F_i external force, $H(x)$ interaction energy which is either periodic or quasi-periodic function of x_i, $\dot{w}_i$ independent white noises, α_{ij} their intensities. The system coordinates x_i drift with some average velocities V_i which are functions of external forces F_i. The major result of this work is: In the limit of small and large forces, there exists a dissipative potential $D(F)$ such that

$$V_i(F) = \frac{\partial D(F)}{\partial F_i}. \tag{2}$$

Moreover, in the limit of small forces the dissipative potential is determined from the variational principle

$$D(F) = \frac{1}{\langle e^{-H/T}\rangle}\min\langle \frac{1}{2}B_{ij}^{-1}e^{-H/T}\left(F_i - \frac{\partial u}{\partial x_i}\right)\left(F_j - \frac{\partial u}{\partial x_j}\right)\rangle \tag{3}$$

where in periodic case $\langle\cdot\rangle$ is the cell average and minimum is sought over periodic functions $u(x)$, while in quasi-periodic case $\langle\cdot\rangle$ is the space average, and minimization is done over quasi-periodic functions $u(x)$; B_{ij}^{-1} is inverse tensor to B_{ij}, T temperature. In the limit of large forces, the dissipative potential is computed analytically for periodic structures,

$$D = \frac{1}{2B}F_iF_i - \frac{1}{B\epsilon^2}\sum_{k\in\mathbb{Z}_n'}|k|^2\,|H_k|^2\ln\left[|k|^2 + \left(\frac{\epsilon}{T}F\cdot k\right)^2\right].$$

Here the periodic cell is supposed to be an n −dimensional cube with the size ϵ, H_k are Fourier coefficients of energy $H(x/\epsilon)$, $\mathbb{Z}_n'$ is the orthogonal lattice in R_n with the size 2π and the excluded origin $k=0$, tensor B_{ij} is spherical $\left(B_{ij} = B\delta_{ij}\right)$, $F\cdot k$ is the scalar product of vectors F and k. The dissipative potential is a convex function of force F. The result formulated is based on homogenization theory of parabolic equations with minor terms developed by Jikov, Kozlov and Oleinik in their monograph [1].

For small forces, equations (2), (3) yield the relations which look similar to Onsager relations,

$$V_i = A_{ij}F_j, \quad D = \frac{1}{2}A_{ij}F_iF_j, \quad A_{ij} = A_{ji}. \tag{4}$$

However, the origin of the reciprocity relations (4) is quite different: they are caused by driven dissipative dynamics.

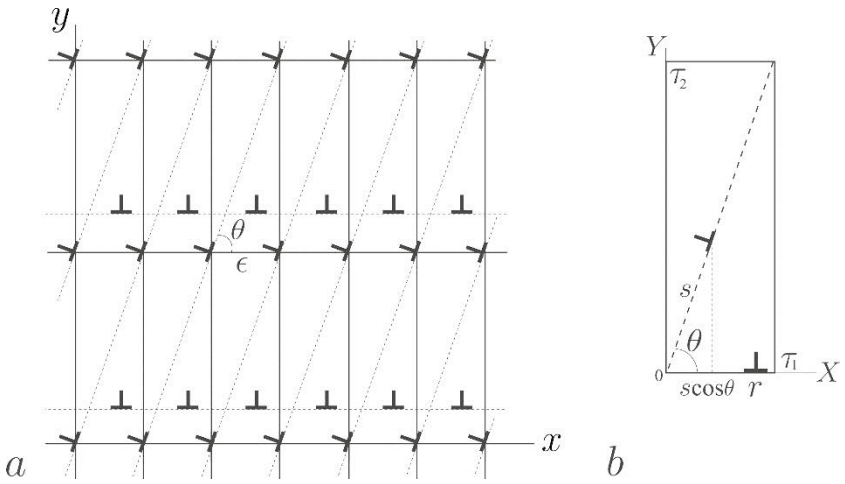

Fig. 1

As an application of (2), (3), we study the dislocation viscoplasticity in two interacting slip systems of a single crystal with cubic symmetry. Slip systems are in planes (111) and (-1-11). Dislocation microstructure is periodic (Fig. 1a), and dislocations in each slip systems move as a rigid body, so the flow has two degrees of freedom, *r* and *s* (Fig. 1b). Interaction energy for such dislocation systems was found in [2]. Typical values of dimensionless inverse temperature $\lambda = 5\mu b^3/(\pi(1-\upsilon)T)$ (μ, υ, b being shear modulus, Poisson's coefficient, and Burgers vector, respectively) are large. Therefore, we study asymptotics of variational problem (3) as *H/T* tends to infinity. General results for such type asymptotic problem were obtained by Kozlov [3, 4]. In the case under consideration the asymptotics is:

$$D = \frac{1}{2}A_{11}^2F_1^2 + A_{12}F_1\ F_2\ + \frac{1}{2}A_{22}F_2^2$$

$$A_{11} = 0.003\lambda e^{-0.001\lambda}B^{-1},\quad A_{22} = 0.16\lambda e^{-0.125\lambda}B^{-1}$$

$$A_{12} = 2A_{22}$$

These formulas reveal quite nontrivial interactions between two slip systems. If the slip systems were not interacting, then A_{11} and A_{22} would be equal to B^{-1}. In fact, A_{11} and A_{22} are exponentially smaller than B^{-1} due to interactions. Besides, A_{12} turns out to be equal $2A_{22}$. It is interesting and hard to foresee that A_{22} is much smaller than A_{11} (indices 1 and 2 mark horizontal and inclined slip systems, respectively). Physically, this means that dislocations of the second slip system are barely moving and rather play a role of a set of static obstacles for dislocations of the horizontal slip system. Apparently, this is caused by quite special non-symmetric geometry of the microstructure. In a special case of tension/compression by stress σ in the x-direction, F_1 vanishes, and both slip systems operate with extremely slow velocities, $V_1 = 2A_{22}F_2,\ V_2 = A_{22}F_2,\ F_2 = b\sigma\sin\theta\cos\theta$. Interestingly, V_1 is still larger than V_2, in fact, twice larger. All these intrinsic "reciprocities" are beyond of reciprocal relations (4) and came from the variational principle (3).

Dislocation dynamics equations can be cast in form (1) both in two-dimensional [2] and three-dimensional [5] cases. Thus, an immediate consequence of (2) and Orowan formula for dislocation-mediated viscoplasticity is the existence of a function of stresses σ_{ij}, $\mathbb{D}(\sigma_{ij})$, such that plastic strain rate $\dot{\varepsilon}_{ij}^{(p)}$ is linked to stresses by the constitutive equations,

$$\dot{\varepsilon}_{ij}^{(p)} = \frac{\partial\mathbb{D}(\sigma_{ij})}{\partial\sigma_{ij}}. \tag{5}$$

Equations (5) hold in the limit of small and large stresses. The validity of (5) in an intermediate range of stresses remains unclear.

CRYSTAL PLASTICITY LIKE THEORY OF DUCTILE FRACTURE

Amine Benzerga*[1] and R Vigneshwaran[1]
[1]Department of Aerospace Engineering, Texas A & M University, College Station, USA

Summary A constitutive framework is developed to describe damage accumulation to failure in ductile materials by void growth and coalescence. A multi-surface representation of effective yielding is adopted to represent the competition between a single mechanism of nominally homogeneous yielding and a finite number of systems for inhomogeneous yielding. Homogeneous yielding represents the usual void growth mechanism whereas inhomogeneous yielding aims to capture void coalesence under tension-dominated loading or mere void distorsion under shear-dominated loading. The theory bears some connections to continuum crystal theories of plasticity with some notable differences. Simple examples are provided for one or two localization systems to illustrate the potentially large scatter in ductility obtained when void distributions are clustered.

INTRODUCTION

Constitutive relations for porous plastic solids have historically been obtained by considering elementary cells subjected to *homogeneous* deformation, along with limit analysis theory [1, 2]. By definition, such boundary conditions preclude strain concentrations within the cell. This essential limitation of Gurson-like models can be relaxed by employing boundary conditions that allow for mesoscopically *inhomogeneous* deformation. This is precisely what has been achieved in e.g. [3, 4]. This new class of models represents the potentially inhomogeneous yielding of porous solids.

With that as basis, a general multisurface constitutive framework is outlined so as to accommodate homogeneous yielding as well as various mechanisms of inhomogeneous yielding. The latter rests on the notion of localization systems akin to slip systems in crystal plasticity.

THEORY

The constitutive framework is one for a material with distributed porosity. The porosity may have resulted from prior cavitation, say at second phases and brittle interfaces, or processing-induced. The plastic part of the rate of deformation is written as:

$$\mathbf{D}^p = \underbrace{\dot{\lambda}^{\mathrm{H}} \frac{\partial \Phi^{\mathrm{H}}}{\partial \boldsymbol{\sigma}}}_{\text{Hill–Mandel}} + \underbrace{\sum_{\alpha=1}^{N_{\mathrm{loc}}} \dot{\lambda}^{\alpha} \frac{\partial \phi^{\alpha}}{\partial \boldsymbol{\sigma}}}_{\text{localized}} \tag{1}$$

with Φ^{H} corresponding to homogeneous yielding. If yielding is inhomogeneous at some appropriate scale, then there may be various localization systems, each being associated with a threshold condition of the type $\phi^{\alpha} = 0$ in the rate-independent limit.

In general, the porosity may be described by the void volume fraction, f, the void axes, and parameters that describe the spatial distribution of voids. To illustrate the main ideas, let us focus on axially symmetric voids, say spheroidal or (finite-height) cylindrical. For homogeneous yielding, proper descriptors of the internal state are the porosity f, void aspect ratio and orientation, so that

$$\Phi^{\mathrm{H}}(\boldsymbol{\sigma}; f, w, \mathbf{n}^{(3)}) = 0 \tag{2}$$

An example of this type of yielding was developed in [5].

For inhomogeneous yielding, the spatial distribution of voids matters, here represented by scalar W^{α} and director $\mathbf{n}^{\alpha}$:

$$\phi^{\alpha}(\boldsymbol{\sigma}; f, w, W, \mathbf{n}^{(3)}, \mathbf{n}^{\alpha}) = 0 \tag{3}$$

Here, $\mathbf{n}^{\alpha}$ denotes the normal to the localization plane, or in some cases the direction of localization itself (column coalescence). Examples of this type of model may be found in [6, 4].

DISCUSSION AND RESULTS

Localization systems are for the proposed theory what slip systems represent for crystal plasticity. In particular, the theory does not predict localization systems. Instead, they are provided as input based on the assumed toplogy of the void aggregate. Voids, unlike atoms, are generally not orderly distributed. For periodic void distributions, localization systems may be defined on the basis of nearest-neighbour topology. However, for clustered void distributions, as expected in practice, it is postulated that there is a *finite* number of potential localization systems, Fig. 1a. In the limit of an inifinite number of such systems, the distribution is random, and a statistically isotropic behavior is retrieved.

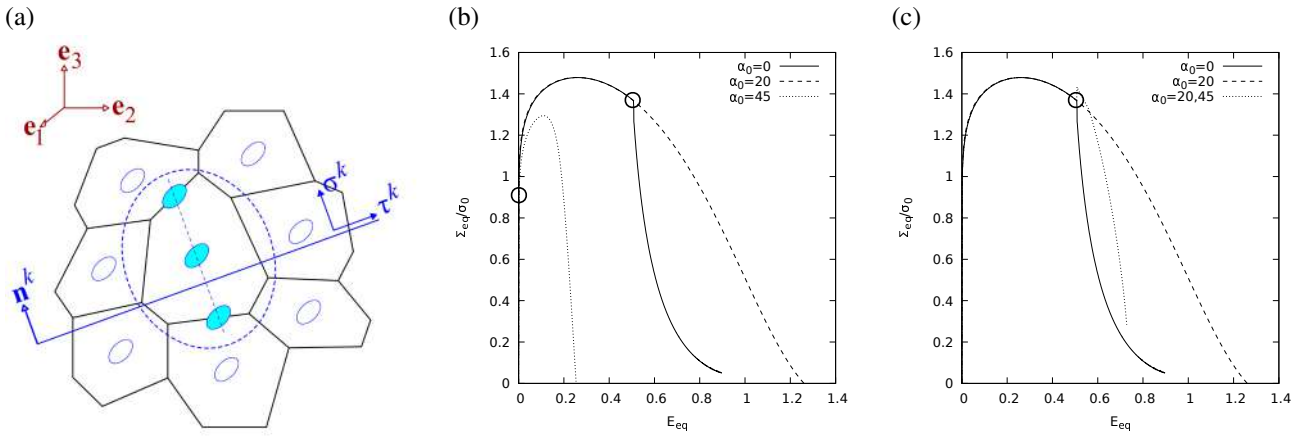

Figure 1: (a) Relative spacing in a void cluster. (b) Response and ductility for various orientations of a single localization system at fixed initial structure. (c) One versus two systems of localization.

For illustration, Fig. 1b shows a typical dependence of the response upon the orientation of the localization system. Here, plane strain was assumed with an imposed stress triaxiality $T = 1$. The variation of ductility between the various cases shown is indicative of the scatter in multiple realizations since various local void orientations may be encountered in a physical specimen.

Fig. 1b shows the effect of the number of localization systems on the response. A parallel with crystal plasticity is obvious, but with some key differences: (i) dependence upon the normal stress in addition to the shear stress (generalized normality holds); (ii) the constitutive relations are obtained through scale transition operations, thus involving no ad hoc parameters.

CONCLUSION

A crystal-plasticity like theory of ductile fracture is constructed on the basis of recent models of inhomogeneous yielding in porous plastic solids. The theory enables seemless transitions from void growth to void coalescence, tension-dominated to shear-dominated loadings and allows for scatter in ductility to be rationalized and quantified. In addition, the constitutive framework may be used in conjunction with the theory of strain localization (in the macroscopic sense) [7] in order to discriminate fracture by void impingement versus failure by instability.

CREEP BEHAVIOUR OF METALLIC GLASSES AND EVOLUTION OF MATERIAL INHOMOGENEITY

Xiaoding Wei*[1,2], Wenqing Zhu [1]
[1]State Key Laboratory for Turbulence and Complex System, Department of Mechanics and Engineering Science, College of Engineering, Peking University, Beijing 100871, China
[2]Beijing Innovation Center for Engineering Science and Advanced Technology, Peking University, Beijing 100871, China

Summary In this work, a chemo-mechanical continuum theory based on a thermodynamically consistent framework is proposed to describe the creep behaviour of metallic glasses. In our theory, the inherent material inhomogeneity in metallic glasses at the nano- and micro-scale is taken into account. Visco-plastic deformation is described as the outcome of the atomic diffusion driven by the chemical potential gradient. Scenarios of microstructural evolutions under both stable and unstable creep are reproduced by finite element simulations. Different scaling of the steady-state creep strain rate and stress for the regimes below and above a critical stress are captured and consistent with the former studies.

Lack of dislocations and grain boundaries, metallic glasses (MGs) also known as amorphous metals, have distinct mechanical properties than their crystalline counterparts. Creep tests have been carried out on MGs at a variety of stress, temperature and sample size to study their unique plastic deformation mechanisms [1-3]. Particularly, when subjected to a high stress, the creep becomes unstable and the strain localization with shear band instability takes place [4, 5]. So far, theoretical studies on the creep of MGs have been studied mostly at the nanoscale (<100nm) using molecular dynamic simulations [6]. To overcome the limitations of system sizes and time scales in molecular simulations, a continuum theory that reflects the microscopic mechanisms of creep deformation in metallic glasses MGs is necessary to study the creep behaviors on large scale and at low temperature. In this study, we develop a chemo-mechanical continuum theory within a thermodynamically consistent framework that established earlier by Gurtin [7], and later developed by Anand [8] and Miehe et al. [9]. In this theory, the atomic diffusion is correlated with the inelastic deformation of MGs, as shown in Figure 1. Multiplicative decomposition of the deformation gradient assumes $\mathbf{F} = \mathbf{F}_e\mathbf{F}_p\mathbf{F}_c$ where $\mathbf{F}_e$ is the elastic deformation gradient, and $\mathbf{F}_p$ and $\mathbf{F}_c$ are two rate-dependent inelastic eigen deformation gradients. $\mathbf{F}_p$ is the plastic deformation gradient with $\det(\mathbf{F}_p)= 1$ due to the incompressibility of the plastic deformation. $\mathbf{F}_c = J_c^{1/3}\mathbf{I}$ is the dilatation deformation gradient where $J_c=\det(\mathbf{F}_c)$.

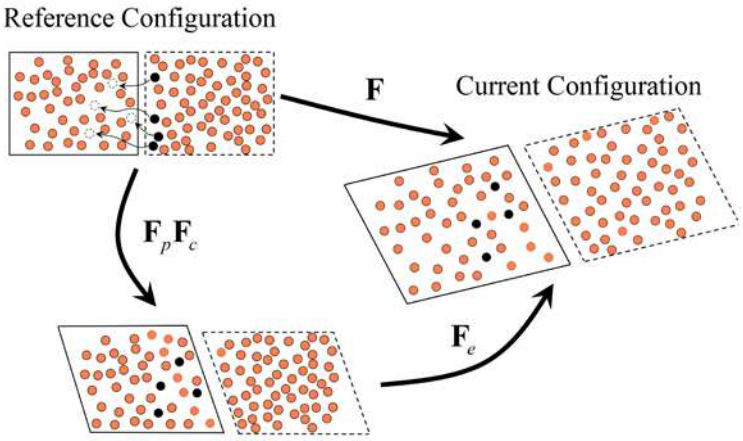

Figure 1. Illustration of decomposition of the total deformation.

The creep behavior of Cu-Zr MG is investigated at two stress levels ($\tilde{\sigma} = 1.93$ and 9.66), where the non-dimensional stress is $\tilde{\sigma} = \sigma\Omega^* / (k_B\theta)$. Note that Ω^* is the atomic volume, k_B is the Boltzmann constant, and θ is the temperature. The strain evolution trends under two stresses are summarized in **Figure 2**. Under the low stress ($\tilde{\sigma} = 1.93$), there is a steady-state creep stage (at a constant creep strain rate, manifested by the slope of 1) following a transient creep stage (decreasing creep strain rate). Under the high stress ($\tilde{\sigma} = 9.66$), however, a tertiary creep stage takes place following transient and steady-state creep, where the creep strain rate is rapidly increasing and the material fails eventually with mechanical instability.

*Corresponding author. E-mail: xdwei@pku.edu.cn

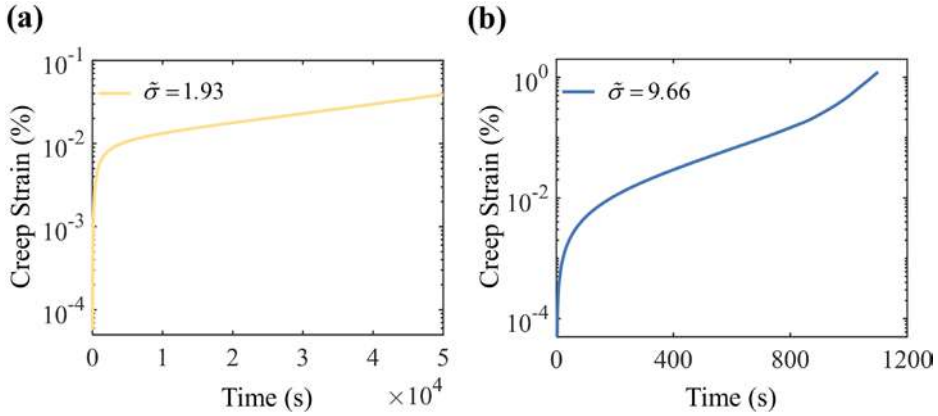

Figure 2. Creep history under (a) low ($\tilde{\sigma}=1.93$) and (b) high ($\tilde{\sigma}=9.66$) stresses.

Further, inspection of the free volume and von Mises stress evolutions under the low stress reveals that at transient creep stage interior atoms flow from low-free-volume regions to high-free-volume regions. As a result, the material becomes more homogeneous. Then, atoms on the free surfaces start to flow inside and thus free volume is accumulated on the free surfaces. The same phenomena in metallic glasses have been found in previous molecular dynamic simulations [10]. However, in the case of the high stress, we found that atoms flow from high-free-volume regions to low-free-volume regions so that the spatial heterogeneity becomes more prominent with the average free-volume gradient continuously increasing. With the time going, cavitation and voids nucleate and coalesce inside the material forming thin shear bands and leading to the strain localizations and mechanical instability. This finding is consistent with the void formation in shear bands recently observed through high-resolution electronic microscopy [11].

CONCLUSIONS

In summary, this work introduces a thermodynamically consistent chemo-mechanical theory to describe the atomic diffusion and resulting inelastic deformation in metallic glasses. The theory is implemented into a finite element code to simulate the creep responses varying imposed stress and temperature. Microscopic characteristics such as surface diffusion for stable creep and strain localization for unstable creep are successfully captured. An abrupt change of scaling at critical stress is found which is verified the existing experiments and molecular simulations.

NUMERICAL DESCRIPTION OF SCREW DISLOCATION IN DILUTE AND HIGHLY-CONCENRATED BCC ALLOYS

Summary Plastic deformation of BCC alloys is generally achieved by the fundamental motion of screw dislocations via kink process of dislocation. We evaluated solid solution softening/strengthening behavior of various solutes in dilute and highly-concentrated BCC alloys by the first-principles calculations in combination with classical theory of dislocations. We identified a clear trend in interactions between a solute and a screw dislocation and found that the change in the energy barrier to kink nucleation is related to the interaction energy. These two properties are the main effects contributing to solid solution softening/strengthening. We proposed new analytical models describing kink process of screw dislocations, in which the fundamental properties are evaluated by the electronic structure calculations. The model found to reproduce reasonably well the complex solid solution behavior as a function of temperature and solute concentration. This specific balance of the interactive and repulsive interactions is the origin of macroscopic solid solution behavior.

MANUSCRIPT PREPARATION

Dislocation have been regarded as the most important lattice defects in plastic deformation, especially in metallic materials. The fundamental properties of the dislocation core have a dominant influence on the intrinsic ductility or brittleness of materials. The interaction between dislocations and other crystal defects plays a critical role in determining the mechanical properties of metals. The classical strengthening mechanism was developed by this major premise, and the mechanical properties of metals have been developed by under-standing and controlling the dislocation behavior. While continuum theory expresses an excellently long-ranged elastic field of a dislocation, it breaks down owing to the singularity near the dislocation core. With improvements in computer technology, atomic scale simulations such as molecular dynamics have been implemented to explore the relation between the dynamic behavior of defects and the mechanical response. Recently, a dislocation core structure can be captured directly by first principles calculations.

Especially, plastic deformation in BCC metals is achieved by a fundamental motion of screw dislocations through a kink mechanism. The first-principles calculations have been widely applied to directly calculate the dislocation core of various metals. The fundamental glide motion and the core structure of a dislocation in pure BCC metals and the effects of solutes on core structure have been investigated by the first-principles calculations. We have aimed to achieve a comprehensive understanding of solid solution softening/strengthening in BCC metals. The effects of various solutes in BCC metals have also been comprehensively investigated by the first-principles calculations through a solid solution model. In the present study, we performed the first-principles calculations of the dislocation core and examined the interaction energy between a screw dislocation and solute and the change in energy barrier for dislocation motion, where a quadrupolar configuration was used to evaluate the effects of solute on dislocation motion. These energy factors were applied to non-empirical evaluation of a solid solution model to elucidate the fundamental nature of solid solution softening and strengthening, which can be generalized for various kinds of dilute BCC alloys.

ANARYSIS METHODS

We constructed the core structure using the following procedure. The introduction of dislocations within our periodic cell was accomplished through application of a continuum linear elastic theory solution for the periodic dislocation dipole array [1]. The distortion field caused by periodic distribution of dislocations is expressed as a Fourier series:

$$\underline{\underline{\Delta}}(\mathbf{r}) = \sum_{\mathbf{G}} \underline{\underline{\tilde{\Delta}}}(\mathbf{G}) \exp(i\mathbf{G}\cdot\mathbf{r}), \tag{1}$$

Where $\underline{\underline{\Delta}}(\mathbf{r})$ is the distortion tensor at point **r**, **G** are the reciprocal lattice vectors, and $\underline{\underline{\tilde{\Delta}}}(\mathbf{G})$ is the Fourier coefficient describing the distortion tensor. The elastic energy per unit length of the supercell can be expressed in terms of the $\underline{\underline{\tilde{\Delta}}}(\mathbf{G})$ s as

$$E_{elastic} = \frac{1}{2} A_c c_{ijkl} \sum_{\mathbf{G}} \tilde{\Delta}_{ij}(\mathbf{G}) \tilde{\Delta}^{*}_{kl}(\mathbf{G}), \tag{2}$$

where A_c is the area of the supercell containing the dislocation dipole and c_{ijlk} represents the elastic constants of the material. The distortion field was then selected to minimize the total elastic energy subject to the topological constraints imposed by the screw dislocations. The predicted displacement at the atomic positions was determined by applying a line integral starting from a reference coordinate.

The interaction energies between the various solutes and the screw dislocation dipole were then evaluated. In the calculations of the solute-dislocation interaction energy, we used the supercell containing two sets of dislocations defined

above and solute atoms. The interaction energy is defined as the energy difference between two states: the solutes are substituted close to and far from the dislocation. First-principles electronic structure calculations were performed within the DFT framework using the Vienna Ab-initio Simulation Package (VASP) [2,3] We ensured that the total energy converged to within 10−6 eV for all calculations. The relaxed configurations were obtained by the conjugate gradient method, and the search was terminated when the force on all atoms had reduced to 0.02 eV/Å.

RESULTS AND DISCUSSION

The most stable configuration, the so-called easy-core, of a screw dislocation core was calculated by the first-principles calculations. A straight dislocation can move on two-dimensional configuration space perpendicular to direction. We evaluated the Peierls potential surface. Figure 1 shows the examples of energy barrier for the motion of strain screw dislocation along <112> direction. The core structures of easy-core saddle point configuration are given, where the core structure of the screw dislocation was visualized using a differential displacement (DD) vector [4]. Subsequently, we evaluated the effect of solute atoms on the solid solution behavior. The interaction energy between a solute and a screw dislocation is one of the main properties for solid solution softening/strengthening behavior through the pinning effect during the kink migration process. In our previous study, we investigated the interaction energy between the 5d solutes and the screw dislocation with the solutes being substituted around the dislocation core and found that trends the type of solute existed, which depended on the solute element. In the present study, we explored the interaction energy between wider range of solutes, including all 3d to 5d elements and a dislocation, to enable a more universal discussion of these findings. The interaction energies after full atomic relaxation are shown in Figure 2 for typical and transition metal elements, respectively. Finally, we applied these fundamental features of dislocation around solutes to the analytical model [5]. The solid solution model can reproduce the macroscopic softening/strengthening behavior. In the present study, the new model based on three-dimensional line tension model is also developed to reproduce the temperature-dependent kink process for dilute and highly-concentrated alloys.

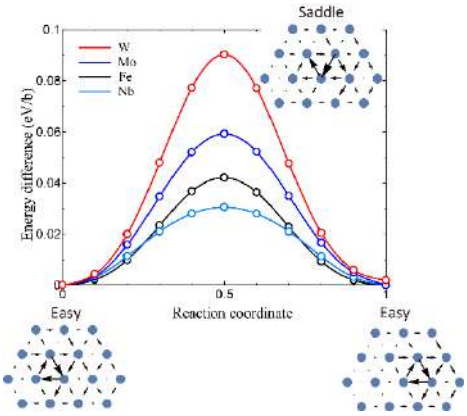

Figure 1. Energy barrier for dislocation motion.

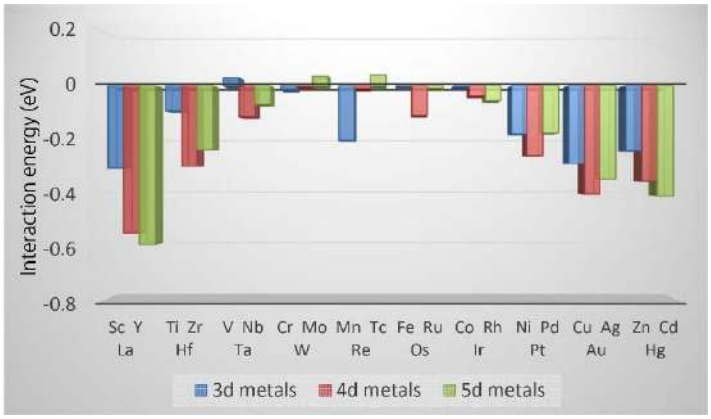

Figure 2. Interaction energies between 3d-5d solutes and a screw dislocation.

CONCLUSIONS

We evaluated softening/strengthening behavior of dilute and highly-concentrated BCC alloys by the first-principles calculations. We identified a clear trend in interactions between a solute and a screw dislocation and found that the change in the energy barrier to kink nucleation is related to the interaction energy. These two properties are the main effects contributing to solid solution behavior. The fundamental properties are efficiently applied to the analytical model such as solid solution model and line-tension model, reproducing macroscopic solid solution softening/strengthening depending on the temperature.

EFFECT OF RATE OF LOADING AND CREEP CHARACTERISTICS OF EPOXY POLYAMIDE BLENDS

Chethana P Rao*1, Utkarsh Srivastava, Ramakrishna P A and H Murthy
Department of Aerospace Engineering, Indian Institute of Technology of Madras, Chennai, India

Summary Epoxy resins have been extensively used in composite industries due to their high strength, less shrinkage post curing and strong adhesion between fibres and matrix. However, their brittle nature has limited their usage in many industrial applications and thus are modified to increase plastic strain. Conventional additives increase the stiffness as well as brittleness in the material. Thereby, an alternative method is to change the curing agent. Polyamides is one such curing agent which naturally increases the toughness in epoxy. The current study focuses on acquiring material properties of epoxy and polyamide blends at different loading rate and its creep characteristics, for extending the material usage germane to sustain high impact load.

INTRODUCTION

Epoxy resins are toughened with additives to overcome their inherent brittle nature so that they can be used in industrial applications. However, rigid additives enhance stiffness and decrease the flexibility. Applications pertaining to sustenance of high impact loads require material with higher toughness. High toughness in epoxy resin can be achieved by curing it with polyamide resin [1, 2]. The present study aims on investigating the effect of rate of loading and creep behaviour at various stress levels for epoxy polyamide blends.

EXPERIMENT DETAILS

The material used for the study is epoxy (CY 230-1) with modified polyamide (XY 54) as hardener. The samples were prepared as per ASTM D 638 for uniaxial tensile test and ASTM D2990 for creep test and the tests were conducted on 0.5kN Universal Testing Machine. The uniaxial tensile tests were conducted at three different displacement rates of 5, 10 and 50 mm/min. The Creep tests were conducted at 50% and 35% of failure stress of the material. Strain for both the cases was obtained from digital image correlation (DIC) technique.

RESULTS AND DISCUSSION

Uniaxial test results: For each of the three displacement rates, three samples were tested. The typical stress strain curves are shown in Fig 1.

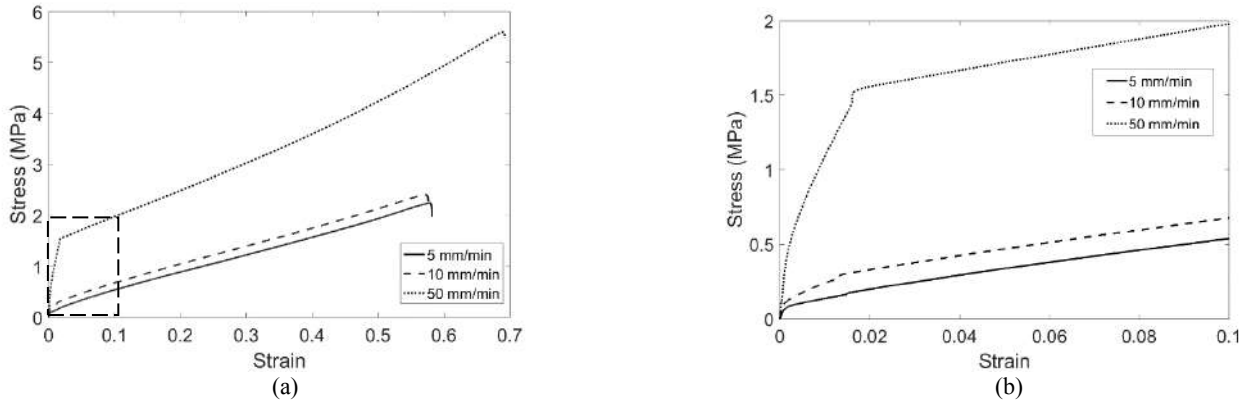

Figure 1 (a) Stress strain curves at different strain rate and (b) Magnified view of the region boxed in (a).

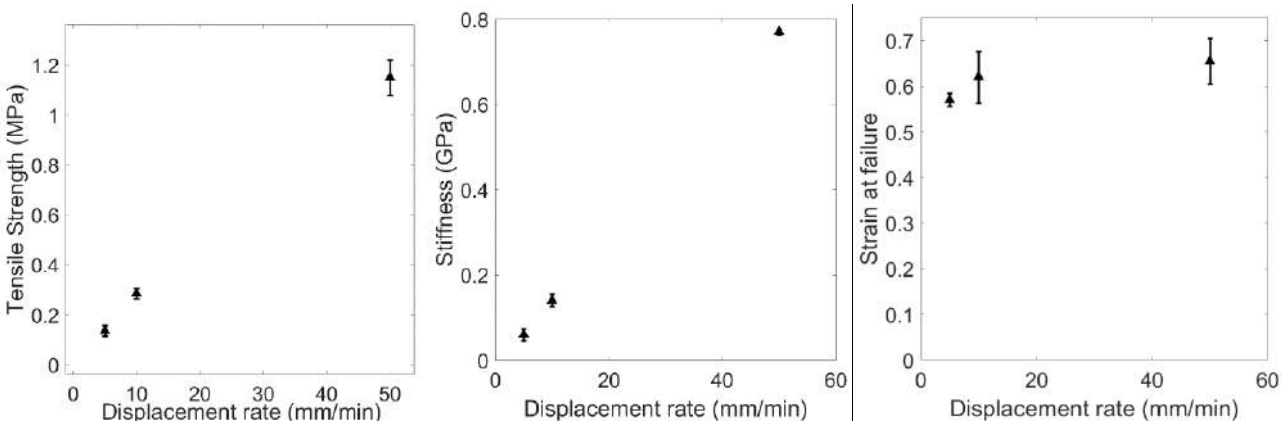
Fig.1 depicts that with increase in rate of loading, the tensile strength, the elastic modulus and the strain at failure increase. The material response from these stress strain curves consists of two major parts: the initial linear region followed by strain hardening. With the increase in rate of loading, the linear region becomes predominant and is distinct. The increased rate of loading decreases the strain hardening region. From these curves, it can be inferred that toughness of the material is very high even with an increase in rate of loading.

Fig 2 illustrates that tensile strength, stiffness and strain at failure increase with the rate of loading. The Tensile strength and the slope of initial linear region increased by seven and twelve times respectively in case of 50mm/min as

*Corresponding author. E-mail: ae13d209@smail.iitm.ac.in

compared to that of 5mm/min displacement rate. The strain at failure did not significantly change for higher rates. Results for the tensile test are summarised in Table. 1.



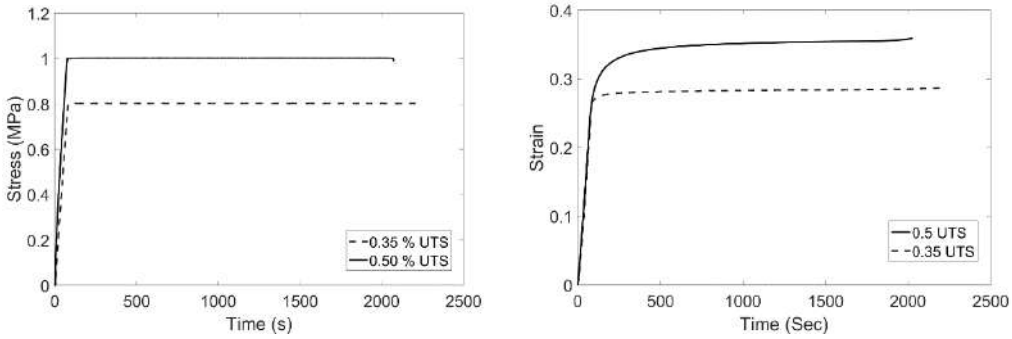
(a) (b) (c)

Figure 2 Effect of rate of loading on material properties

Table 1. Uniaxial tensile test results

Sl. No	Displacement rate (mm/min)	Tensile Strength (MPa)	Elastic modulus (GPa)	Strain at failure
1	05	0.14 ± 0.01	0.06 ± 0.01	0.57 ± 0.01
2	10	0.29 ± 0.02	0.14 ± 0.04	0.62 ± 0.06
3	50	1.15 ± 0.10	0.77 ± 0.01	0.66 ± 0.05

Creep test results: The creep tests were conducted at 50% and 35% of failure strength of the material at a loading rate of 10mm/min. The test was initially planned for two hours under constant stress and one hour of relaxation. However, the material failed within an hour of testing. The creep tests failed prematurely as the stress levels were out of the linear region. It can be observed that the material fails relatively quickly at even 35% of its failure stress. This shows that the creep fracture loads are very low for epoxy/polyamide blends.



(a) (b)

Figure 3 Creep tests conducted at 35% and 50% stress levels

CONCLUSION

The study revealed that the material is highly deformable and nonlinear. With the increase in rate of loading, the tensile strength, modulus of elasticity and strain at failure increased. It is observed from these tests that polyamide blends performed better than tertiary blends in terms of fracture toughness and the strain at failure was seven times larger. Complete comparative study of all these tests with tertiary amines will be presented in the conference.

USING THRUST LINES TO CALCULATE BOTH STATIC AND KINEMATIC COLLAPSE MULTIPLIERS OF MASONRY ARCH BRIDGES

Giuseppe Stagnitto*[1] Massimiliano Ghioni [2]
[1]Department of Civil Engineering and Architecture, University of Pavia, Pavia, Italy
[2]Anastasi & Partners S.A., Locarno, Switzerland

Summary This paper presents an exhaustive exposition of the collapse multiplier calculation methods for arch bridges based on two recent limit analysis theorems. Starting with Jacques Heyman's ideas, originally expressed in terms of bending moments, the application has been extended to the bending and compression structures in no-tension material. Mechanical interpretations of static and kinematic collapse multiplier are derived using thrust lines. In the applicative field, the two multipliers' numerical correspondence can be made precise to the required degree.

SINGLE-SPAN BRIDGES

In limit analysis domain, the structural safety of a masonry arch bridge is usually assessed using the so-called kinematic approach. In the present paper, the adoption of the dual static method it is proved to be more convenient, since a recent theorem - Minimum Equilibrated Compression (M.E.C.) theorem [1] - makes its application straightforward for any kind of arch, including the case of multi-span bridges. The theorem identifies the collapse configuration in the equilibrated solution associated with the minimum compressive stress under the assumption of uniform stress distribution. The theorem starts from a key idea by Jacques Heyman [2], which was originally expressed in terms of bending moments and was then transposed to the stress field due to axial and flexural forces. The theorem has the following mechanical interpretation: "the collapse thrust line is the geometric axis of the inner arch with minimum uniform compression".

Computations are checked via kinematic method, by locating the plastic hinges (as many as needed to form a collapse mechanism) in the sections with maximum compression stress. Thanks to the Consecutive Plastic Hinges theorem (C.P.H.) [3], the kinematic multiplier may then be evaluated, using familiar moments of forces, without computing the virtual displacements due to the vertical and horizontal loads acting on the arch.

The theorem allows to calculate the virtual work as the sum of the products of the moments of the forces, that "precede" the plastic hinges, times the virtual rotations of hinges themselves. The name of the theorem is due the fact that the virtual displacement field associated with the single-degree-of-freedom mechanism, in which all the hinges rotate at the same time, can alternatively be obtained by allowing subsequent rotations of one hinge at a time (once the constraints are neglected). Even the consecutive plastic hinges theorem extends to the bending and compression case an original idea by J. Heyman [4], i.e. the possibility of expressing the virtual work of the external forces applied to a bending structure in form of the virtual work generated by "any system of bending moments", which equilibrates such forces.

Similarly, the Consecutive Plastic Hinges (C.P.H) theorem can use "any thrust line", balancing the forces themselves, in order to obtain virtual work through the moments of applied force resultant with respect to the plastic hinges, without computing the virtual displacements [5]. If the thrust line runs through three of the four plastic hinges of the arch, the virtual work of all the vertical and horizontal forces can be written as a simple single product.

Assuming infinite compressive strength, the further simplification of zero virtual internal work is obtained. Hence, if the resistance is infinite, the kinematic collapse multiplier has been obtained not only without calculating any displacement, but even without calculating any rotation.

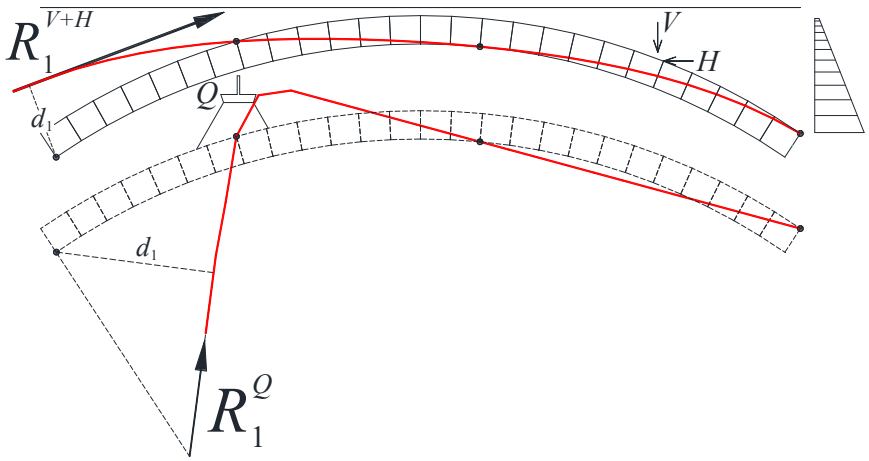

Figure 1. Virtual works using thrust lines.

*Corresponding author. E-mail: giuseppe.stagnitto@unipv.it

The paper focuses on masonry arch bridges (see Fig.1) and the thrust lines are obtained – separately for dead loads (V+H) and for live load Q – through three of the four plastic hinges. The kinematic collapse multiplier is given by the ratio between the moments of the resulting thrust force R_1 , due to permanent loads V+H, and the one due to live loads Q, with respect to the remaining hinge (hinge 1 in the Fig.1):

$$\lambda_Q = -\frac{(L_V + L_H)}{L_Q} = -\frac{(R_1 \cdot d_1)^{V+H}}{(R_1 \cdot d_1)^{Q}}$$

MULTI-SPAN BRIDGES

Even in the case of a collapse mechanism involving successive arches, the C.P.H. theorem allows one to calculate the kinematic multiplier without determining any virtual displacements. At first, the Minimum Equilibrated Compression theorem is used to obtain the static collapse multiplier for any compressive strength value [6] (even, at the asymptote, for infinite strength). This multiplier is checked via the kinematic method by drawing thrust lines (separately for the dead and live forces) through all the plastic hinges except the first one (see Fig.2).

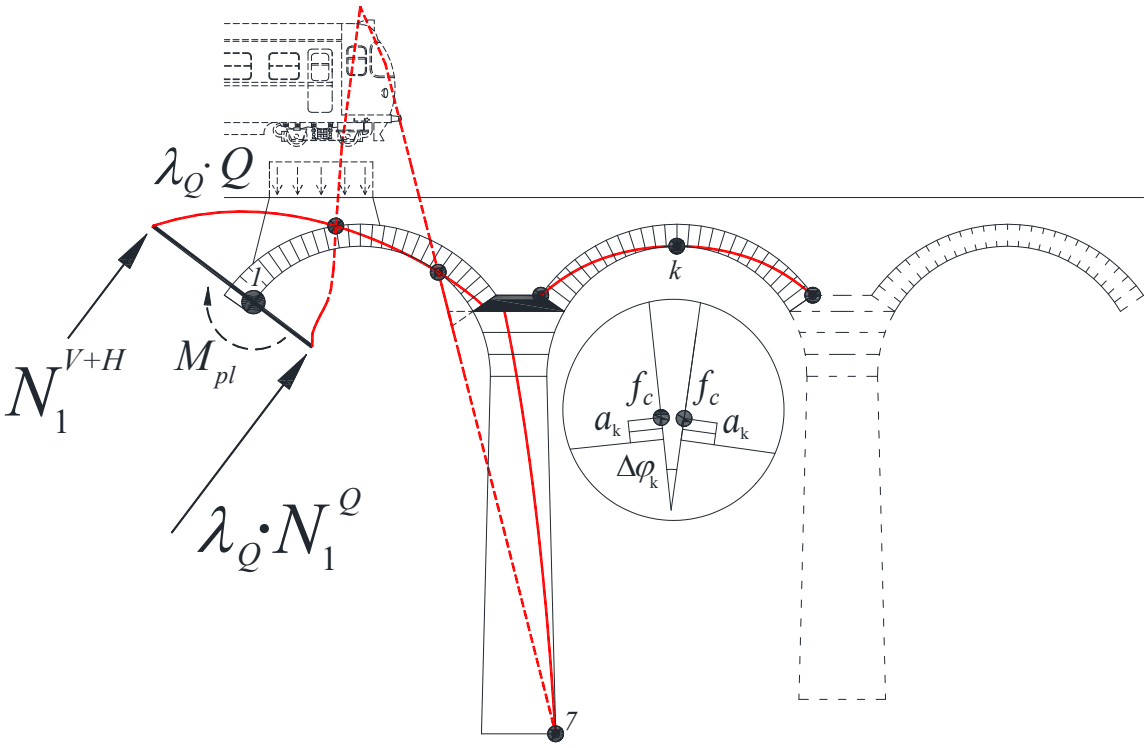

Figure 2. Mechanical interpretation of the kinematic multiplier

To automate the process, it is easier to calculate the moment using the axial action. The kinematic multiplier is simply "the multiplicative coefficient that must be applied to the axial force of the live forces to have the moment balance around the hinge 1".
If the compressive strength is not infinite, the balance equation should also account for the moment M_{pl} that is responsible for the effect of the rotations of all plastic hinges.

Summary In order to investigate ductile fracture behavior and validate damage models, computational experiments on unit cells have been widely used. Such experiments, consisting in simulating the response of a plastic matrix embedding a single void, oversimplify the interaction between defects. In order to better analyze the influence of this interaction on ductile fracture, this work proposes to simulate the response of microstructures containing randomly distributed voids. The dependence of the failure behavior on the stress state and the dispersion of results are quantified. The simulations on random microstructures are then used to calibrate an effective model of ductile behavior, taking into account the effects of the stress state and of the random distribution of voids. This model should be able to represent both extension (coalescence) and shear failure modes.

INTRODUCTION AND GOALS

Accurately predicting ductile fracture is still an open problem due to the diversity of phenomena taking place at a small scale and their dependency on the stress state. In order to represent these local phenomena and explicitly take into account local small scale plasticity, two main approaches have been undertaken. Analytic models such as Gurson's [1] have been and continue to be developed. They require to hypothesize plastic flows but they can easily be applied for engineering applications. On the other hand, computational methods which simulate the response of a matrix containing voids to some loading conditions, can provide insight on failure phenomena but they are numerically too expensive for applications.

Moreover, most numerical studies focus on unit cells, in which the matrix contains a single void. Even with periodic boundary conditions, using unit cells oversimplifies the interaction between voids, which behave as if they were arranged on a lattice. Some studies did however consider microstructures with a random distribution of defects. The response of such microstructures was simulated up to yield [2] and even coalescence [3]. The authors of these studies were able to fit a Gurson-Tvergaard-Needlemann-type model [4]. However both these studies only considered simple axisymmetric loading, and are therefore not able to represent all stress states.

We propose here to extend their method to general stress states, characterized by stress triaxiality T and Lode parameter L. We investigate the dependency of failure behavior on stress state and the dispersion due to the randomness of the microstructures. Moreover we use these results to calibrate an effective plasticity and ductile fracture model of materials with a random population of voids.

FINITE ELEMENT SIMULATIONS OF RANDOM MICROSTRUCTURES UP TO COALESCENCE

With a Poisson point process, a random distribution of identical non-overlapping spherical defects is inserted in a cubic matrix. A random microstructure is thus obtained and meshed (example in figure 1a). For the matrix, two material behavior models are compared: a perfect von Mises elastoplastic model, and a more realistic one, with hardening and damaging (represented by a GTN-type model). A corotational formulation is used to accommodate large strains. Periodic boundary conditions are applied on the faces of the microstructure. Finally a special macroscopic element is used to control five components of the macroscopic Cauchy stress tensor and an axial deformation component, so that the macroscopic stress triaxiality and the Lode parameter remain constant throughout the simulation. The random microstructure can then be proportionally loaded in a FEM simulation using Z-set software [5].

RESULTS AND DEVELOPMENT OF AN EFFECTIVE MODEL

Typical results for a perfectly plastic model are shown in figure 1. A sudden stress drop is present on the stress strain curves and can be interpreted as the failure of the cell. The cumulative plastic strain field after this failure shows the complex path of the strain localization band. Such a simulation can be repeated with various loading conditions (figure 1d shows for instance the dependence of failure strain on stress triaxiality). Contrary to unit cells, the randomly distributed voids entail a dispersion of results.

A response surface of the porosity at coalescence depending on the triaxiality and Lode parameter can be obtained with enough simulations. In order to decrease the computational cost, a kriging method is used to combine results from unit cells and random microstructures to compute the critical porosity response surface: numerous unit cell computations allow to recover the general form of the response surface, whereas the statistical distributions of failure quantities can be deduced

*Corresponding author. E-mail: samuel.forest@mines-paristech.fr

from simulations on random microstructures. Moreover the beginning of each simulation defines the yielding behavior of the random microstructure, following the method from [2, 3].

Combining the yielding behavior and the critical porosity response surface allows us to build and calibrate effective models, representing yield and possible failure modes, and accounting for the effect of T and L. Dispersion can also be taken into account in the response surface by specifying a risk threshold. Several forms of effective models are investigated: a GTN-type one whose critical porosity is given by the failure porosity response surface obtained from the simulations, and a more realistic multimechanism model representing growth and coalescence under tension and shear. These effective models are finally validated in more complex loading conditions.

LOCALIZATION IN PSUEDOELASTIC NITI TUBES UNDER BIAXIAL STRESSES

Karlos Kazinakis[1] and Stelios Kyriakides [*1]
[1]Research Center for Mechanics of Solids, Structures & Materials, University of Texas at Austin, Austin, Texas, USA

Summary NiTi can undergo solid-state phase transformation at room temperature, which is responsible for the unique ability of the material to fully recover from strains of about 8%. Transformation under uniaxial tension leads to inhomogeneous deformation with transformed and untransformed material coexisting, and forming distinctive deformation patterns in the structure. NiTi tubes tested under combined tension and internal pressure have been shown to develop localized helical bands with helix angles that depend on the stress biaxiality. However, stress states close to equibiaxial tension do not induce localization. This complex interaction between the transformation induced material instability and the structure is reproduced by implementing a new constitutive model in a finite element analysis of tubes loaded proportionately under different biaxialities of internal pressure and tension.

INTRODUCTION

Under tension pseudoelastic NiTi traces a closed hysteresis with stress plateaus associated with the solid-state reversible transformation between the austenitic and martensitic phases. In the case of thin-walled tubes, the transformations take the form of multi-helical localization patterns of higher/lower strain that propagate while the two stress plateaus develop [1]. When the tubes are loaded under radial stress paths in the axial-hoop stress space [2], transformation again leads to localized helical deformation bands but with helix angles that change with the stress ratio. In addition, the transformation stresses trace a biaxial stress surface that is elongated along the equibiaxial direction, and stress plateau extents exhibit significant anisotropy between axial and hoop dominant stress paths. Furthermore, stress paths close to equibiaxial exhibit material hardening and homogeneous deformations. The present work uses finite element analysis coupled with the constitutive model of pseudoelastic behavior in [3], suitably extended to account for the strain anisotropy, to simulate this phenomena-rich biaxial behavior of NiTi tubes.

SIMULATION OF INHOMOGENEOUS BEHAVIOR OF NiTi TUBES UNDER BIAXIAL STRESS STATES

The tubes are discretized with solid incompatible elements and loaded under combined axial load and internal pressure. The radial stress paths are simulated in the manner followed in the experiments: prescribing for example the change in the volume of the incompressible fluid, monitoring the pressure and relating it to the prescribed axial force. The constitutive model of pseudoelastic behavior of NiTi in [3] capable of capturing the inhomogeneous evolution of phase transformation in tension, the nearly homogeneous behavior exhibited in compression, and reproducing the strong tension/compression asymmetry, is adopted. Figure 1 shows the measured and adopted stress-strain responses in compression and tension. Key feature of the latter is the softening branches that span the measured upper and lower stress plateaus. The model is extended in order to also address the recorded strain anisotropy. Here we outline the results of the simulations of three radial stress paths.

Figure 2 shows the measured and calculated nominal stress-"mean" strain responses in the hoop and axial directions for the stress ratio σ_x/σ_θ = 0.375 (strains are volumetric averages over the 8-diameter length of the tube). The specimen is deformed to a hoop strain of just under 6% and is unloaded. The closed hystereses involve upper stress plateaus during which the austenitic phase yields to the martensitic one, and lower plateaus when reverse transformation takes place. The calculated responses reproduce these plateaus as well as their extents. In the model, transformation is initiated from a small thickness depression close to the right end of the tube resulting in the stress peak and valley at the beginning of each stress plateau. In the experiment these were masked by the stress concentrations at the ends caused by the clamping of the tubes. The evolution of resultant localized deformation is illustrated by the accompanying nine tube deformed images with color contours of hoop strain superimposed. With the first load drop two bands of higher strain oriented at $\pm$ 34° to the axis of the tube nucleate from the depression. They first broaden uniformly as shown in image 1, but by image 2 the propagating front develops a second pair of symmetric bands, and subsequently additional ones as illustrated in images 3 and 4. With the completion of "transformation," deformation becomes uniform, and remains uniform during elastic unloading (image 5). The stress valley indicates the onset of reverse transformation that results in the nucleation of a single right-handed band (image 6). The band broadens as illustrated in images 7 and 8, but as the left end is approached it switches to a multi-pronged front as observed in 9.

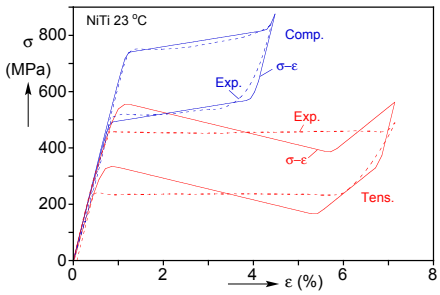

Figure 1. Measured and adopted tensile and compressive stress-strain responses.

Figure 3 shows results from an axial stress dominant case of σ_x/σ_θ = 2, where the axial strain exceeds 7%. The stress-mean strain responses of the experiments are reproduced quite well except that the lower stress plateaus are somewhat under-predicted. Two angled bands initiate again from the local imperfection (image 1) but now the angles are $\pm$ 57°.

*Corresponding author. E-mail: skk@mail.utexas.edu

The bands evolve into a symmetrical multi-pronged front (images 2 and 3), which closer to the left end yields to a left-handed spiral seen in image 4. Reverse transformation now initiates as a left handed single band, which first broadens and then switches to a left handed multipronged front seen in images 8 and 9.

Figure 4 shows the stress-mean strain responses for the equibiaxial stress path of $\sigma_x = \sigma_\theta$. The model captures the exhibited hardening as well as the strain asymmetry. Most importantly, the model tube deforms homogeneously as indeed was the case in the experiment. In summary, similar agreement between experiment and analysis will be reported for several other radial paths. The band angles in all cases agree with those of the experiments. The evolution of the localized deformation exhibit similar features as the experiments but one-to-one comparison is not appropriate as the model uses idealized boundary conditions.

TUNABLE BUCKLING STRENGTH OF MAGNETICALLY ACTIVE ELASTIC SHELLS

Dong Yan*[1], Matteo Pezzulla [1], Lilian Cruveiller [2], and Pedro M. Reis [1]
[1]Flexible Structures Laboratory,Institute of Mechanical Engineering,Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland
[2]Ecole Polytechnique,Palaiseau,France

Summary It is well-known that shell buckling is highly sensitive to material or geometric imperfections, causing critical loads to be significantly lower than classic predictions. The associated knockdown factor (ratio between the experimentally measured critical load and the classic theoretical prediction) is typically regarded as an intrinsic structural property; the imperfections are encoded into the shell during fabrication. Here, we demonstrate the ability to tune the knockdown factor of pressurized spherical shells actively using magnetic actuation. We fabricate our shells with a magneto-rheological elastomer by coating. The shells are first magnetized and then loaded by pressure under a uniform magnetic field. We find that, by adjusting the flux density and polarity of the field, the knockdown factor of our shells can be increased or decreased, on-demand, by up to 30%.

FABRICATION OF MAGNETICALLY ACTIVE SHELLS

Thin spherical shell specimens containing a precisely engineered imperfection were fabricated using a coating technique [1, 2] (see schematic in Fig. 1). These shells are made out of a magneto-rheological elastomer (MRE) mixture of vinylpolysiloxane (VPS 22) and NdPrFeB magnetic particles. This mixture was poured into a negative spherical mold (radius $R = 25.4\,\mathrm{mm}$), 100 s after the preparation. The elastic mold contains a circular soft spot with reduced thickness at the north pole, which, upon external pressurization during fabrication, deformed to produce a dimple-like geometric defect in the shell. After curing, we magnetized the specimens (along the z-direction) permanently using a strong applied magnetic field $B \approx 4.4\,\mathrm{T}$ to saturate the particles in the MRE. The effective residual flux density of our MRE is $B_\mathrm{r} = 63\,\mathrm{mT}$, which is set by the residual flux density of the saturated individual particles and the volume concentration (7%) of the mixture. We characterized the defect geometry using an optical profilometer, finding that its 2D profile can be described by $w = -\delta(1-\beta^2/\beta_0^2)^2$ (Fig. 2b) set by the deflection of the soft spot in the mold during fabrication under uniform pressure (zenith angle $\beta \le \beta_0$, assuming it is flat and clamped at the boundary). The defect amplitude, δ, and angular width, β_0, were determined through fitting. This fabrication technique allows us to engineer a precise geometric defect in the shell with an amplitude that can be systematically set during manufacturing.

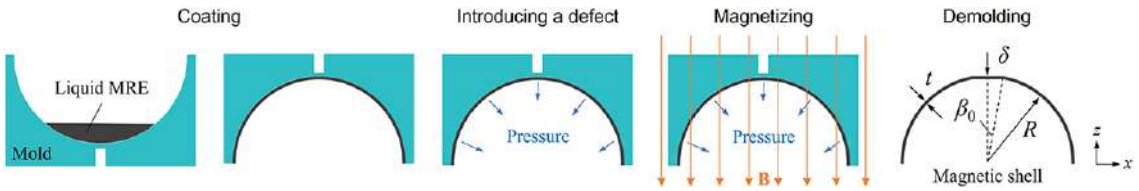

Figure 1: Schematic diagram of the experimental protocol used to fabricate a magnetic spherical shell containing a geometric defect.

TUNABLE CRITICAL BUCKLING PRESSURE

We investigate the onset of buckling of our magnetic shells under pressure loading. In the experiments, the shell was positioned in between Helmholtz coils, which generate a steady and uniform magnetic field (flux density B_e); see inset of Fig. 2a. Under this external magnetic field, the shell was then pressurized with an imposed volume change. We first focus on a shell containing a defect of amplitude $\delta/t = 0.38$ and width $\lambda_\beta = [12(1-\nu^2)]^{1/4}(R/t)^{1/2}\beta_0 = 3.16$. In Fig. 2a, we present curves of pressure versus volume change for this one shell at different levels of magnetic loading. In this plot, the pressure has been normalized by the classic critical pressure as $\overline{p} = p/p_\mathrm{c} = p/[2E(t/R)^2/\sqrt{3(1-\nu^2)}]$ [3] and the imposed volume change, $\Delta\overline{V}_\mathrm{i} = \Delta V_\mathrm{i}/\Delta V_\mathrm{c} = \Delta V_\mathrm{i}/[2\pi(1-\nu)R^2t/\sqrt{3(1-\nu^2)}]$, has been normalized by the corresponding critical volume change [4]. Without a magnetic field ($B_\mathrm{e} = 0\,\mathrm{mT}$), $\overline{p}$ increases linearly with $\Delta\overline{V}_\mathrm{i}$ during prebuckling. Buckling occurs accompanied by an abrupt pressure drop, and the normalized peak pressure is the knockdown factor, $\kappa_\mathrm{d} = 0.44$ for this particular curve. When a magnetic field is applied, the shell is active as long as the deformation breaks the alignment of its magnetization with the external field. As a result, distributed torques are applied to the shell, thereby affecting the buckling conditions. As shown in Fig. 2a, under a positive field (the field lines are parallel to the shell magnetization in the initial configuration), the knockdown factor is increased from 0.44 to 0.56 at $B_\mathrm{e} = 33\,\mathrm{mT}$, and to 0.68 at $B_\mathrm{e} = 66\,\mathrm{mT}$. The buckling also becomes less catastrophic with a smaller pressure drop. In contrast, the knockdown factor is decreased to 0.33 and 0.23 at $B_\mathrm{e} = -33\,\mathrm{mT}$ and $B_\mathrm{e} = -66\,\mathrm{mT}$, respectively, when the polarity of the magnetic field is flipped.

*Corresponding author. E-mail: dong.yan@epfl.ch.

Following the protocol detailed above, we fabricated different shells with a variety of defect amplitudes (Fig. 2b) and measured their knockdown factors as a function of the external flux density (see Fig. 2c). We find that, for the same shell, its buckling strength can be tuned actively by varying the applied external magnetic field. Within the range of flux density accessible in our experiments, κ_{d} can be increased or decreased up to a maximum change of $\approx 30\%$. In parallel to the experiments, we have developed an axisymmetric shell (1D) model within the framework of small strains and large displacements/rotations by minimizing the Helmholtz free energy [5] of the system (including both elastic and magnetic effects). Excellent agreement is found between this theory and the experiments (Fig. 2c).

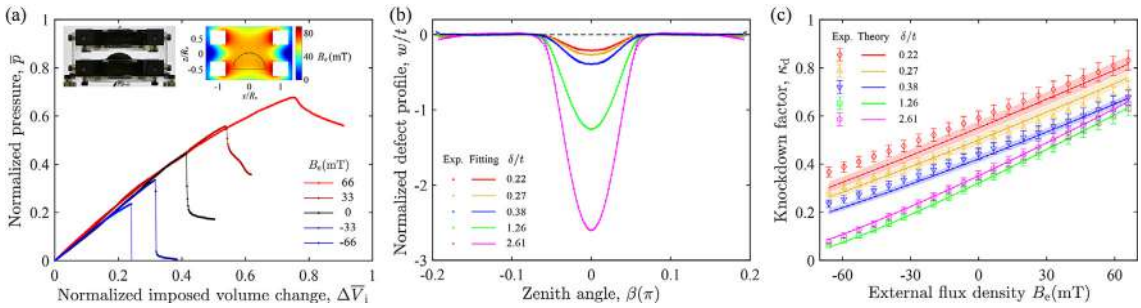

Figure 2: Tunable knockdown factor of magnetic shells. (a) Loading curves, $\overline{p}(\Delta\overline{V}_{\mathrm{i}})$, at different levels of external flux density, B_{e}, for the shell containing a defect of amplitude $\delta/t = 0.38$ and width $\lambda_\beta = 3.16$. Inset: Photograph of the shell positioned in between Helmholtz coils and the generated magnetic field calculated by COMSOL. (b) Defect profiles with different amplitude. (c) Knockdown factor, κ_{d}, versus the external flux density, B_{e}, for shells containing the defects shown in (b).

IMPERFECTION SENSITIVITY

We proceed to investigate the imperfection sensitivity of our magnetic shells by quantifying the relationship between the knockdown factor, κ_{d}, and the defect geometry. In the experiments, we varied the defect amplitude systematically and obtained the corresponding κ_{d} at different levels of external flux density. The latter is considered in the parameter $\lambda_{\mathrm{m}}R/t$, where $\lambda_{\mathrm{m}} = B_{\mathrm{e}}B_{\mathrm{r}}/\mu_0 E$ with μ_0 as the permeability of air and E as the Young's modulus of the MRE. In Fig. 3a, the same trend is observed for different cases of $\lambda_{\mathrm{m}}R/t$: κ_{d} is sensitive to small defects, but reaches a plateau for large δ/t. The onset of this plateau is shifted towards smaller or larger δ/t for a positive or negative field, respectively. In Fig. 3b, we plot the change of knockdown factor, $\Delta\kappa_{\mathrm{d}}$, as a function of defect amplitude at different levels of external flux density. We find that $\Delta\kappa_{\mathrm{d}}$ is significantly less sensitive to small defects and approximately constant when δ/t increases above a threshold. Although the buckling of magnetic shells is still sensitive to imperfections, the tuning of the knockdown factor is robust. We also find that the experimental data and theoretical curves for the knockdown factors of shells made with VPS 22 or VPS 32 collapse when they have the same value of $\lambda_{\mathrm{m}}R/t$. Therefore, $\lambda_{\mathrm{m}}R/t$ is a governing parameter of this problem, and the presented results are independent of the properties of MRE, shell radius to thickness ratio, and external flux density.

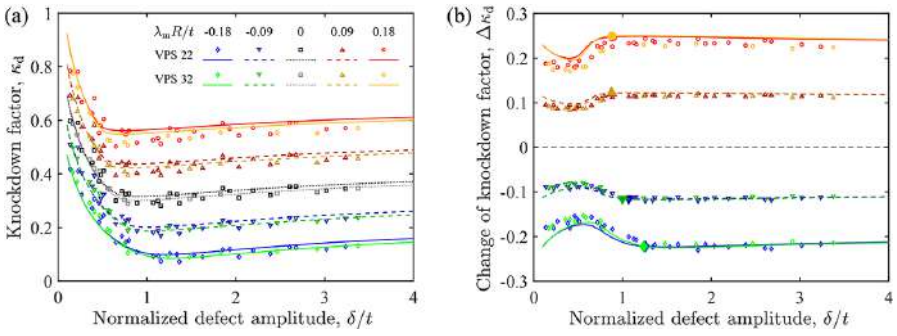

Figure 3: Imperfection sensitivity of magnetic shells. (a) Knockdown factor, κ_{d}, and (b) the change of knockdown factor, $\Delta\kappa_{\mathrm{d}}$, as a function of defect amplitude, δ/t. The parameter $\lambda_{\mathrm{m}}R/t$ is varied in the range {-0.18, -0.09, 0, 0.09, 0.18}. Defect width $\lambda_\beta = 3.16$ for shells made with VPS 22 and $\lambda_\beta = 3.35$ for shells made with VPS 32.

CURVATURE TUNES WRINKLES IN TENSILE HYPERELASTIC SHELLS

Fan Xu*, Yifan Yang, and Ting Wang
Institute of Mechanics and Computational Engineering, Department of Aeronautics and Astronautics, Fudan University, Shanghai, China

Summary Transverse wrinkles usually occur in a uniaxially tensile elastic membrane and will be smoothed upon excess stretching. This instability-restabilization response (isola-center bifurcation) can originate from the nonlinear competition between stretching energy and bending energy. Here, we find a crucial factor, the curvature, which can control effectively and precisely the wrinkling and smoothing regimes. When the sheet is bent with curvature, the regime of wrinkling amplitude versus membrane elongation is narrowed, with local wrinkling instability coupled with global bending. There exists a critical curvature, where no wrinkles appear when the value is beyond this threshold. The curvature effects on wrinkling-smoothing behavior have been quantitatively explored by our theories, computations and experiments. The models developed in this work can describe large in-plane strains of soft shells to effectively capture this transition behavior, which build on general differential geometry and thus can be extended to arbitrary smooth surfaces with varying curvature such as torus. Our findings may shed light on designs of wrinkle-tunable membrane surfaces and structures.

INTRODUCTION

Recent studies revealed that curvature in conforming materials to rigid substrates has proven a versatile tool to guide the self-assembly of defects such as pleats [1] and crack paths [2]. Spontaneous curvature can induce rotational symmetry-breaking buckling and snapping instability in bilayered thin shells [3]. Understanding the mechanism of curvature effects on morphological evolution and pattern formation is, in fact, crucial for the effective use of wrinkling as a tool for realizing multifunctional surfaces. Do tensional wrinkles in thin films depend on geometric curvature? How does curvature affect pattern formation and pattern evolution? Whether curvature triggers or delays stretch-induced wrinkling behavior? These questions remain uncovered in prior works and will be addressed here.

This study quantitatively explores curvature effects on wrinkling-smoothing behavior of highly stretched soft shells by theories, computations and experiments. We design an experiment of stretching soft cylindrical shells, incorporated with 3D surface imaging technology to acquire spatial data from 2D images of structured-light projection, in order to examine the curvature effect on the wrinkling and smoothing regimes. Differential-geometry based shell models for mostly used hyperelastic materials are derived, which can be extended to arbitrarily curved surfaces. Numerical implementation [5] through coupling Chebyshev spectral collocation method for spatial discretization and *Asymptotic Numerical Method* (ANM) for nonlinear resolution is adopted to trace the nonlinear morphological evolution of wrinkles. Curvature effect on wrinkling-smoothing behavior of highly stretched cylindrical shells is carefully explored and a 3D phase diagram on stability boundaries is provided.

ARBITRARILY CURVED FINITE STRAIN SHELL MODELS

How to quantitatively predict the curvature effect on wrinkle-smooth evolution remains a theoretical challenge. Classical thin shell theories, *e.g.,* Donnell-Mushtari-Vlassov (DMV) model and Sanders-Koiter model, normally treat cases when the parametrization of the surface is prescribed and describe moderate rotation and deflection, yet small membrane strains with linear Hooke's law. Soft shells under overstretching, however, generally experience large deformations, and the existing small strain shell models become inadequate and fail in predicting isola-center bifurcation behavior considered here. For this purpose we derive more generalized shell models for commonly used hyperelastic materials, which build on general differential geometry and thus can be extended to arbitrarily curved surfaces. After some manipulations, the membrane strain tensor for cylindrical surface with finite curvatures reads

$$E_{\alpha\beta} = \frac{1}{2}(u_{\alpha,\beta} + u_{\beta,\alpha} + 2wb_{\alpha\beta}) + \frac{1}{2}(u_{\gamma,\alpha}u_{\gamma,\beta} + u_{\gamma,\beta}wb_{\gamma\alpha} + u_{\gamma,\alpha}wb_{\gamma\beta} + wb_{\gamma\alpha}wb_{\gamma\beta}) + \frac{1}{2}w_{,\alpha}w_{,\beta}, \tag{1}$$

where $b_{\alpha\beta}$ is the curvature tensor, Greek indices α, β,... take values in $\{1, 2\}$, u_α denotes the in-plane displacements, while w is the out-of-plane deflection. The linearized bending strain tensor for cylindrical surface with finite curvatures reads

$$K_{\alpha\beta} = -w_{,\alpha\beta} + \frac{1}{2}\left(u_{\gamma,\alpha}b^\gamma_\beta + u_{\gamma,\beta}b^\gamma_\alpha\right) + wb_{\gamma\alpha}b^\gamma_\beta. \tag{2}$$

Based on the well-known Euler-Lagrange equation, equilibrium governing equations can be obtained straightforwardly and the model is capable of accounting for various hyperelastic constitutive laws such as Saint-Venant Kirchhoff, neo-Hookean and Mooney-Rivlin, and even material anisotropy [4]. Furthermore, our finite strain shell model can be flexibly extended to soft shells with varying curvatures, *e.g.,* S-shape and C-shape surfaces.

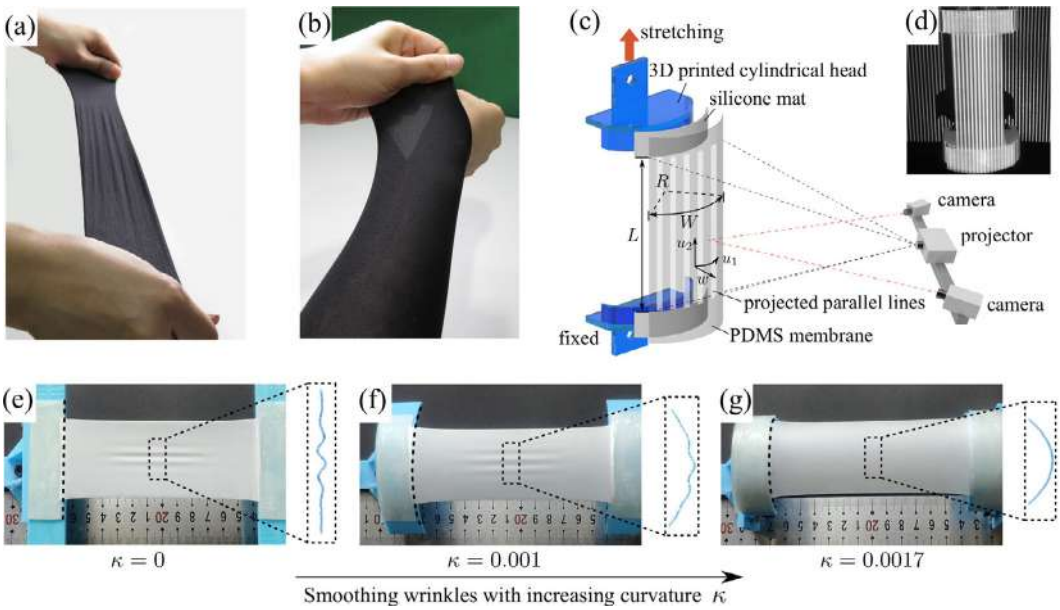

Figure 1: Transverse wrinkles appear in a stretched flat sleeve (a), while no wrinkles occur in a stretched cylindrical sleeve (b). (c) Sketch of the experimental setup and geometry of an open cylindrical shell. (d) Zebra lines (parallel and straight lines) are projected on the surface of tested sample. Wrinkles are smoothed with increasing curvatures $\kappa = h/R$ at the same stretching strain $\varepsilon = 0.1$: (e) $\kappa = 0$, wrinkling, (f) $\kappa = 0.001$, a coupling behavior of wrinkling and bending, (g) $\kappa = 0.0017$, global bending with smooth surface. In three cases, $L = 10$ cm, $W = 5$ cm and $h = 50$ μm.

RESULTS

We experimentally find that the curvature can smooth wrinkles and determine the wrinkling and smoothing responses (see Fig. 1(e)-(g)). Notably, with an increasing curvature, the wrinkling amplitude declines accordingly, showing a coupling behavior of global bending and local wrinkling instability (see Fig. 1(f)). However, there exists a curvature threshold κ_{cr} (depending on aspect ratios L/W and W/h), above which the wrinkling is avoided, with monotonic global bending deformation instead (see Fig. 1(g)). In theoretical computations, for a planar sheet, wrinkles occur first, then decrease, and finally disappear with continuous stretching, with demonstrating the entire path of morphological evolution namely isola-center bifurcation [5, 6]. However, for a curved surface, we find a novel nonlinear behavior coupling global bending and local wrinkling upon stretching, confirmed by experimental observations in Fig. 1(f). The regime of wrinkling amplitude *vs.* membrane elongation is narrowed with increasing curvature, and vanishes at a critical curvature. At the critical curvature and beyond, bending deformation dominates, with maintaining smooth surface. By varying the curvature, we can effectively tune and control the wrinkling and smoothing regimes, which would provide insights into fabricating topology-related functional membranes.

CONCLUSIONS

We have uncovered the curvature-tunable smooth-wrinkle-smooth transitions and postbuckling evolutions of a soft shell upon highly stretching, which can be quantitatively predicted by our general shell models that are developed for hyperelastic curved surfaces under large deformations, agreeing with carefully designed experiments. A remarkable finding lies in the motion and change of the curvature-determined wrinkling regime, the area of which can dramatically shrink with increasing curvature. Notably, no wrinkling happens above a critical curvature, yet demonstrating monotonic global bending deformation with smooth surfaces. Moreover, a 3D phase diagram of stability boundaries, based on our theoretical calculations and experimental data, was first provided. Understanding morphological evolution and in particular the dependence of wrinkling behavior on curvature (*e.g.*, 3D phase diagram of stability boundaries) is, in fact, crucial for the effective use of wrinkling as a tool for realizing multifunctional surfaces.

Summary We are motivated by the celebrated Biot problem ([1]) of surface instability in a hyperelastic half-space under axial compression and in particular the evolution, from an initially unstable bifurcated short wavelength, periodic deformation path to a stable solution involving a localized deformation. This feature is shared by other classical problems in mechanics, such as the problem of a beam on an elastic foundation which is used in modeling important technological problems including sun-kinking of railroads and failure in pipelines. A common feature in all these problems is their high initial symmetry (translational invariance) leading to a complex bifurcation pattern. Understanding the evolution of bifurcated solutions from a periodic pattern (wrinkling) to a highly localized one (crease) is the goal of this work. With an eye on relative simplicity, due to the complex structure of these nonlinear problems, we study here the behavior of an inextensible infinite Euler-Bernoulli beam that is subjected to a compressive axial force and connected to a nonlinear (polynomial) elastic foundation. We use group-theory methods to follow all bifurcated equilibrium paths in a systematic way and explore the emergence of stable localized solutions.

INTRODUCTION AND MOTIVATION

Surface instabilities in soft elastic materials under compression, leading to highly localized deformation regions known as creases, have been reported in the recent experiments by [2], thus providing renewed interest within the Mechanics community for the Biot problem (see [3]). Biot's original work applies the conventional method of bifurcation theory to the problem of an anisotropic, hyperelastic half space subjected to uniaxial far-field compressive stresses. Biot's results show that (a) the onset of instability occurs at an axial stretch of $\lambda = 0.544$ (for a Neo-Hookean solid) where a bifurcation occurs; (b) the associated bifurcation modes correspond to sinusoidal surface waves (wrinkles) whose amplitude decays with distance below the surface of the half space; and (c) wrinkles of all wavelengths become unstable at the critical stretch. Since creases, consisting of spatially localized finite-strain deformations typically involving self-contact, are often observed well before the Biot critical value, a portion of the Mechanics community has come to the conclusion that creases are a distinct *"nonconventional"* bifurcation phenomena, to be contrasted with *"conventional"* bifurcation phenomena. Numerical computations have been proposed to search for the creased solutions by introducing an *a priori* imperfection which biases the system to a desired configuration. This *ad-hoc* numerical search method does not fully explain the emergence of stable localized deformation solutions from the initially periodic ones, thus motivating the present investigation.

To avoid complicated numerical calculations in the reference continuum mechanics problem and gain insight, we revisit here the classic stability problem of the buckling of an inextensible, axially compressed beam on a nonlinear elastic foundation. This analytically tractable problem allows us to understand how localized deformation solutions emerge in Biot's problem and also in many other similar applications in mechanics problems with high initial symmetry. Instead of a numerical search for localized solutions using arbitrary imperfections – impossible due to the high initial symmetry of the problem and the multitude of closely spaced bifurcation points – we propose a systematic search using path-following bifurcation techniques and group-theoretic methods to find all the bifurcated solution orbits (primary, secondary etc.) of the system and examine their stability to establish their observability.

THEORY AND METHODOLOGY

The model adopted here is that of an inextensible, linear elastic beam resting on a nonlinear elastic foundation (with a cubic-quintic nonlinearity). A dimensionless version is hereby used. In order to make the problem manageable – and deal with compact symmetry groups – we will consider the L-periodic solutions of an infinite beam and then choose $L \gg 1$. The beam has bending stiffness $EI = 1$ and its undeformed centerline coincides with x-axis. The beam is subjected to an axially compressive load λ and has the lateral deformation $w(x)$. The total potential energy of the system is given by

$$\mathcal{E}(w(x);\lambda) = \frac{1}{L}\int_{-L/2}^{L/2}\left[\frac{1}{2}\left(\frac{d^2w}{dx^2}\right)^2 - \frac{1}{2}\lambda\left(\frac{dw}{dx}\right)^2 + \frac{1}{2}w^2 + \frac{\alpha}{4}w^4 + \frac{\gamma}{6}w^6\right]dx\ . \tag{1}$$

*Corresponding author. E-mail: nicolas.triantafyllidis@polytechnique.edu

The foundation force per unit length opposing a displacement w is $f = -(w + \alpha w^3 + \gamma w^5)$. Two different nonlinear foundation types will be considered: a "*softening foundation*" with $\alpha = -1$ and a "*hardening foundation*" with $\alpha = +1$. From the first category ($\alpha = -1$) we distinguish three different variations: the "*no re-hardening*" foundation where $\gamma = 0$, the "*mild re-hardening*" foundation where $\gamma = 0.25$ and the "*strong re-hardening*" foundation where $\gamma = 0.50$, resulting in a monotonically increasing foundation force-displacement response. We propose a systematic search using path-following bifurcation techniques and group-theoretic methods to find all the bifurcated solution orbits (primary, secondary etc.) of the system and examine their stability and hence their observability. Unlike previously proposed methods for the problem at hand that use multi-scale perturbative techniques near the critical load (see [4]), we show that to obtain a localized deformation equilibrium path for the perfect structure, one has to follow the secondary bifurcation with the longest wavelength far away from the critical load. The use of group-theory methods for this problem illustrates the general methodology for a systematic search in nonlinear problems in mechanics with a high degree of symmetry where localized deformation solutions do appear.

RESULTS AND CONCLUSION

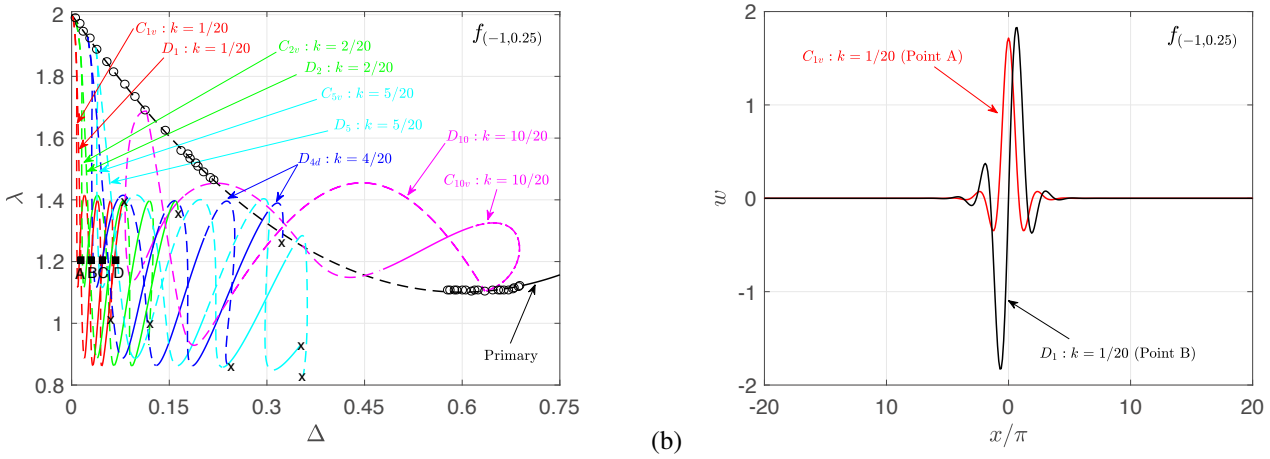

Figure 1: In (a) the load λ vs the work-conjugate dispacement Δ of a periodic beam of length $L = 40\pi$ (period of primary bifurcation is 2π) on a softening foundation with mild re-hardening ($\alpha = -1, \gamma = 0.25$) showing the primary and some of the secondary bifurcation orbits (labelled by their symmetry group), illustrating the problem's complex structure and multitude of equilibrium paths. In (b) stable localized solutions at points A and B of the secondary bifurcated orbits with the longest wavelength, i.e. the ones (marked in red) emerging from the primary orbit nearest the critical load $\lambda_c = 2$. NOTE: Stable segments of orbits are marked by a continuous line, while unstable ones by a dashed line.

The nonlinear beam model problem analyzed here, although it looks deceptively simple, has a very rich and complex set of solutions due to the high degree of its initial symmetry. We show that to obtain a stable localized deformation for the perfect structure, one has to follow the secondary bifurcating equlibrium path with the longest wavelength far away from the critical load. Although it is also necessary to have an initially softening foundation, a monotonically softening foundation precludes stable and hence observable localized deformation solutions, which require re-hardening of the nonlinear foundation. For monotonically stiffening foundations, no localized deformation modes can be found on the bifurcating solution branches. In addition to explaining how to find stable, localized deformation solutions in the problem at hand, the use of group-theory methods for this problem illustrates the general methodology for tackling nonlinear problems in mechanics with a high degree of symmetry for which the standard imperfection method is not a reliable option.

AN ANALYTICAL METHOD FOR REPAIRED STEEL PLATE AFTER BUCKLING

Takuro Tomioka[1], Yasuhito Beppu [1]and Takumi Ito[1],
[1]Department of Architecture, Faculty of Engineering, Tokyo University of Science, Tokyo, Japan

Summary Recently, a digital fabrication method combined with 3D modelling, image analysis, and robotics is attracting, and which can realize the automation and sophistication under construction site. It is expected to support the quick restoration of damaged building after severe disasters. In this study, to investigate the feasibility of DF-method, the fundamental study is conducted on steel elementally member with local buckling. The simple and optimized shape of repair member is suggested which is assumed to be made of 3D-printting. Furthermore, the analysis method is suggested, and it can estimate the test result well.

INTRODUCTION

In recent years, there have been many reports of damaged buildings due to large earthquakes. In the stricken area, it is worried to keep the safety of investigators who conduct surveys and diagnoses, and to take a lot of time for recovery work of damaged buildings due to the shortage of materials and personnel. There is a need to resolve these issues and establish technical systems for the rapid restoration and reconstruction of seismic damaged cities.

Recently, to realize the automation and sophistication of construction procedure (new construction and renovation, etc.), ICT technology has been introduced. In addition, to speed up the construction and reduce the workers under the disaster-stricken buildings, an innovated system such as digital fabrication method has been discussed which combine the manufacturing technology using 3D printing and robots, and image analysis method for estimation of damage status of buildings.[1)]

Therefore, in this study, the optimal shape of repair member by 3D printing (Fig. 1) for the plastic deformation and buckling of the damaged steel member is examined. In addition, to estimate the recovered strength of repaired member, the analytical method is suggested. Also, the applicability is investigated here.

OUTLINE OF THE EXPERIMENT

In the case of damaged H-section steel members of earthquake-resisting steel frame, a repair method of linear lamination is assumed for local buckling of flanges. Therefore, an elemental test of a steel plate simulating a flange repair is performed using steel bar and steel plate, imitating the shapes of lines and plates that can be formed by 3D printing (Fig. 2).

Fig. 3 shows the dimensions of the test piece and Fig. 4 shows the setup diagram.

First, compression loading is performed on the base material (75×6×600mm, SM490B) (initial loading). Out-of-plane deformation was considered as parameters of the degree of damage. Three types of out-of-plane deformation, large (27mm), medium (17mm), and small (5mm) were assumed, which is based on the past test results of buckling waveform during the horizontal loading test of H-shaped steel members[2)].

Next, the damaged specimen is restored by welding a steel bar (SDG3K / SWRM8) or steel plate (SS400) as shown in Fig.5. Three types of repair positions were considered: on the load axis, outside and inside.

After that, compression loading is performed (secondary loading), and the repair effect is examined.

RESULT OF THE EXPERIMENT

Fig.6 shows the state of the specimen during the secondary loading. Four types of collapse modes were observed. Table 1 shows the ratio of the maximum proof stress, the rate of increase in strength, the ratio of the rigidity and the collapse mode of each specimen. It can be seen that when plate repair was performed on a specimen with a small degree

*Corresponding author. E-mail: **t.tkr28424@gmail.com**

of damage, both the maximum proof stress and rigidity were restored to the same level as the original state. In the case of bar repair, when Φ9mm was used rather than Φ6mm, both proof stress and rigidity were increased, and the repair effect was obtained. In the comparison of collapse modes, in modes A and B, high strength and rigidity were obtained after repair.

ANALYTICAL STUDY FOR RECOVED STRENGTH OF REPAIRED STEEL MEMBER

A mechanical model is assumed based on the experimental results, and the proof stress is evaluated.

From Fig.6, it was observed that in Mode B, plastic hinges were generated near the upper and lower welded portions and in the center of the repair plate and they proceeded together with the hinges generated during the initial loading. Therefore, a dynamic model shown in Fig.7 is assumed. The full plastic moment of the base material is M_1, the hinge rotation angle is θ_1, the full plastic moment of the repair material is M_2, the hinge rotation angle is θ_2, and the hinge rotation angle of the initial load is θ_i.

$$P\delta=4M_1\theta_1+4M_2\theta_2 \quad \text{--- (1)}$$

Here,

$$(l/2)\cos\theta_i\,(1-\cos\theta_2)=\delta/2 \quad \text{--- (2)}$$

$$(l/2)\cos(\theta_1+\theta_i)=(l/2)\cos\theta_i\cos\theta_2 \quad \text{--- (3)}$$

From this equation, the relationship between P and δ is shown in Fig.8. This figure shows that the maximum proof stress of the analysis values is close to the experimental values. It seemed that the behaviour after buckling is almost the same.

Mode A Mode B Mode C Mode D

Figure 6. Specimen during second loading

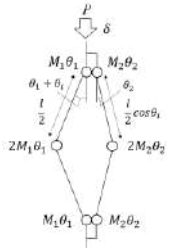

Figure 7. Dynamic model

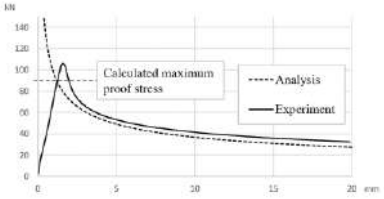

Figure 8. Relationship between P and δ

CONCLUSIONS

We proposed a plate-shaped and bar-shaped repair method for buckled steel plates, and the experimental results confirmed the repair effect of strength and rigidity. In particular, a high effect was obtained by repairing outside the buckling waveform. In the specimen with small damage, both the maximum proof stress and rigidity recovered to the same level as the original state. From the results of Mode B, the possibility of controlling the formation position of the plastic hinge after repair was shown. Based on the experimental results, a strength evaluation method using dynamic model was proposed and the possibility of evaluating the strength of the repaired part of H-shaped steel members was shown.

TENSILE BUCKLING OF REPETITIVE RIGID RODS SYSTEMS WITH OVERLAPPING

Pedro Dias Simão[1,2] and Vítor Dias da Silva[1,2]
[1]INESC-Coimbra, Coimbra, Portugal
[2]Department of Civil Engineering, University of Coimbra, Coimbra, Portugal

Summary Overlapping is used to create innovative repetitive structural systems that buckle under tension, in the present case a one-dimensional frame made up by the sequential repetition of a module composed by a set of lined up rigid rods connected by rotational joints. Each module is composed by two main bars and two smaller bars overlapping the main ones. When tensioned, the global frame buckles, and it is observed that the tensile critical load shows little change when new modules are added to the system, in clear contrast with the compressive case. In addition, a global variation is imposed to a module's mechanical properties at each repetition step. Although smooth and kept within small values, this variation provokes significant changes in the tensile buckling behaviour of the global frame, here illustrated by a sequential buckling case. The findings pave the way to the future development of 2D or 3D innovative repetitive frames, deployable structures, cellular materials, polymer chains and origamis showing original buckling properties under tension, owing to overlapping.

THE STRUCTURAL SYSTEM WITH OVERLAPPING AND ITS MATHEMATICAL MODEL

In structural mechanics, buckling is usually associated with compressive stress and/or shortening deformation states, so that, for a frame under tension, buckling is not a concern. On the other hand, it is often considered that overlapping is a mere waste of material. In the present paper we prove this is not so. In fact, some original mechanical properties can be observed in frames showing secondary parts overlapping the main ones, such as tensile buckling. Pure tensile buckling was originally observed in members with transverse sliders [1], and in [2] we linked this phenomenon to alternative frames showing overlapping and rotational joints only. Besides, repetitive frames are widely used in nature and in engineering, owing to their strength and ease of erection. Within this context, we analyse a repetitive frame made up by the sequential repetition in series of the module presented in Fig. 1, for which the secondary bars [AB] and [CD] overlap the main ones [BC] and [DE], implying that $\overline{\mathrm{AB}}+\overline{\mathrm{CD}}$ must be always smaller than $\overline{\mathrm{BC}}$ or $\overline{\mathrm{DE}}$. By numbering sequentially all nodes of the frame, starting by denoting node A of the first module as node 0, and by relating each bar to the number index of its end node, the kinematic description of a frame made up by the repetition of n_M modules for node k is:

$$\begin{cases} u_k = 0+\sum_{i=1}^{k}(-1)^i L_i\left(\cos\theta_i-1\right) \\ w_k = 0+\sum_{i=1}^{k}(-1)^i L_i \sin\theta_i \end{cases} \tag{1}$$

to which corresponds the total potential energy of the system ($n_N = 4n_M$ is the index of the last node of the sequence, for bar i L_i is its length and θ_i its rotation, K_i is the stiffness coefficient of joint i, λ is a Lagrange multiplier associated with a restriction that forces the last node of the system to remain along the xx axis and P is the axial load, positive for tension):

$$V = \underbrace{\frac{K_0}{2}\theta_1^2+\sum_{i=2}^{n_N}\frac{K_{i-1}}{2}\left(\theta_i-\theta_{i-1}\right)^2+\frac{K_{n_N}}{2}\theta_{n_N}^2}_{V} \underbrace{-P\cdot\sum_{i=1}^{n_N}(-1)^i L_i\left(\cos\theta_i-1\right)}_{\Pi}+\underbrace{\lambda\sum_{i=1}^{n_N}(-1)^i L_i\sin\theta_i}_{G(\theta_i)} \tag{2}$$

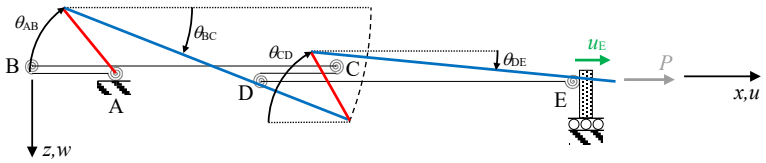

Figure 1. The rods module with overlapping bars.

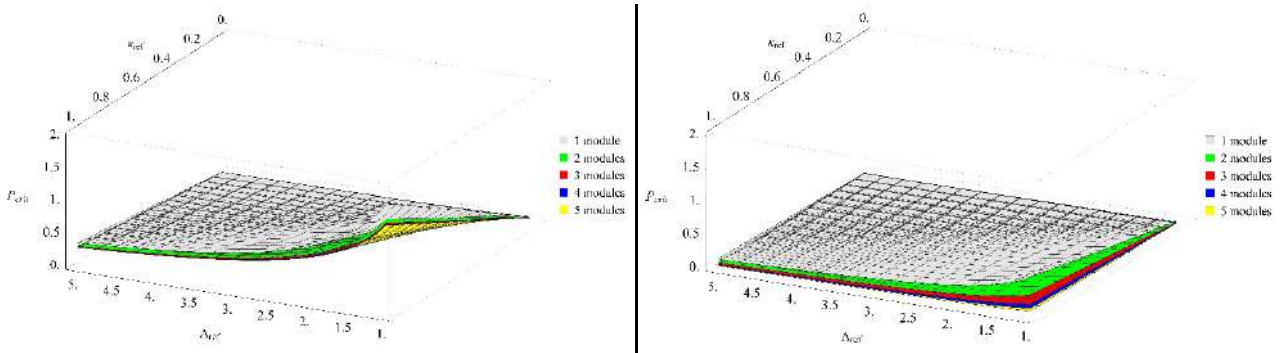
BUCKLING BEHAVIOUR UNDER A TENSILE AXIAL LOAD

Application of the stability procedures [3] to expression (2) yields the stability behaviour of the structural system. Henceforth, all examples are kept dimensionless in order to allow any consistent set of units at macro or micro scales, and overlapping is mathematically modelled by factor $(-1)^i$ in expressions (1) and (2). Focusing now on the buckling behaviour of the system, Fig. 2 compares the tensile and compressive critical loads against the adopted number of modules associated in series considering, for all modules, all K_i equal to $1\times\kappa_{ref}$, lengths $\overline{\mathrm{AB}}$ and $\overline{\mathrm{CD}}$ equal to $1\times\Lambda_{ref}$ and lengths $\overline{\mathrm{BC}}$ or $\overline{\mathrm{DE}}$ equal to $3\times\Lambda_{ref}$. A relevant property is noticed immediately: the compressive buckling, arising from the lowest negative eigenvalue of the stability problem [3], is always smaller than the lowest tensile critical load, and it is much more sensitive to the number of adopted modules than the tensile critical load, which depends mainly on the ratio overlapping length/main length, constant as the number of modules increase.

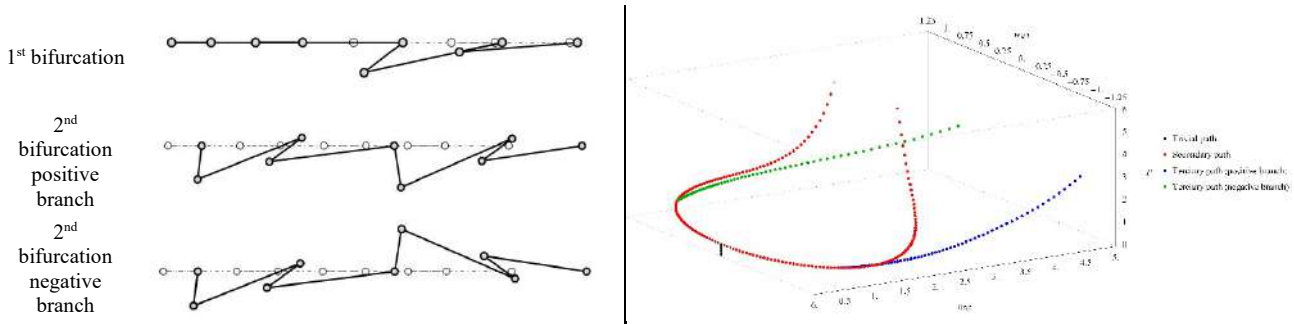


a) critical tensile loads b) critical compressive loads

Figure 2. Influence of the number of modules on the tensile and compressive buckling loads.

TENSILE POST-BUCKLING BEHAVIOUR AND THE INFLUENCE OF SMOOTH CHANGES OF THE MECHANICAL PROPERTIES ALONG THE FRAME

The repetitive frame just analysed considers a perfect repetition of the modes, in the sense that any new module added to the sequence is precisely equal to the previous one. It doesn't have to be always like that and, in nature or in engineering applications, we find often repetitive structures or cellular materials that, at each repetition step, show small changes in some module's mechanical properties, in order to better the performance of the whole system. By doing this, repetitive frames with original mechanical behaviours can be created [2] and so, in order to exemplify the effect of such variations on the tensile buckling behaviour of the frame made up by the sequential repetition of the module depicted in Fig. 1, we consider a structural systems composed by two modules, whose lengths are initially equal those of the previously analysed problem for $\Lambda_{ref}=1$. Then, the i^{th} rod's length is multiplied by $1+0.25\sin\left(\dfrac{i-1}{n_N-1}\pi\right)$, $i=1,\ldots,n_N$ (for the case with 2 modules $n_N=8$). The springs stiffness coefficients remain unchanged throughout the repetition process and, for each module, we consider $K_{\text{A}}=K_{\text{E}}=0$ and $K_{\text{B}}=K_{\text{C}}=K_{\text{D}}=1$. Fig 3 depicts the post-buckling behaviour, which constitutes a case of sequential tensile buckling. In fact, after the occurrence of a first critical load with value $P_{crit,1}=0.529$ along the trivial path, a second critical state occurs along the secondary path, for both branches, at $P_{crit,2}=0.684$. Fig. 3-a) depicts the deformed shape of the frame for $P=1.1\,P_{crit,1}$ and $P=2\,P_{crit,1}$ for the secondary and terciary paths respectively.



a) Post-buckling deformed shape (positive bifurcation only) b) Displacement (u,w) against P of point B of the second module

Figure 3. Post-buckling behaviour for a two modules structural system.

CONCLUSIONS

The tensile buckling behaviour for a repetitive frame with overlapping was analysed, showing some original properties. Bearing in mind that, nowadays, buckling is no longer seen as a mere route to collapse but also as a new way of creating structures and materials with original constitutive behaviours [4], we showed that this strategy can also be extended to frames under tension by means of overlapping. The findings pave the way to the development of innovative 2D and 3D repetitive frames, deployable structures, origamis or polymer chains showing original behaviours under tension.

PHASE TRANSITION AND LOCALIZATION IN INFLATED ARCHITECTURED ELASTIC PLATES (BAROMOPHS)

Emmanuel Siéfert[1],José Bico[1],Etienne Reyssat[1],and Benoît Roman*[1]
[1]PMMH, CNRS, ESPCI Paris, Universit PSL, Sorbonne Universit, Universit de Paris, F-75005, Paris, France

Summary In some systems, two very different equilibrium states exist for the same loading condition, and it is then often observed that an extended homogeneous system spontaneously divides spatially into coexisting regions in different states (or phase). These "propagating instabilities" [1]) (also denoted "localization") are in fact the equivalent in mechanics of phases transitions. Here we will show a new example of this type of instability in an architected elastomer plate including an internal network of airways ("baromorph" [2]) : although these systems are in this case designed to undergo homogeneous in-plane expansion, we find that they sometimes present very unusual three-dimensional shapes, that we interpret as buckling induced by phase-separation.

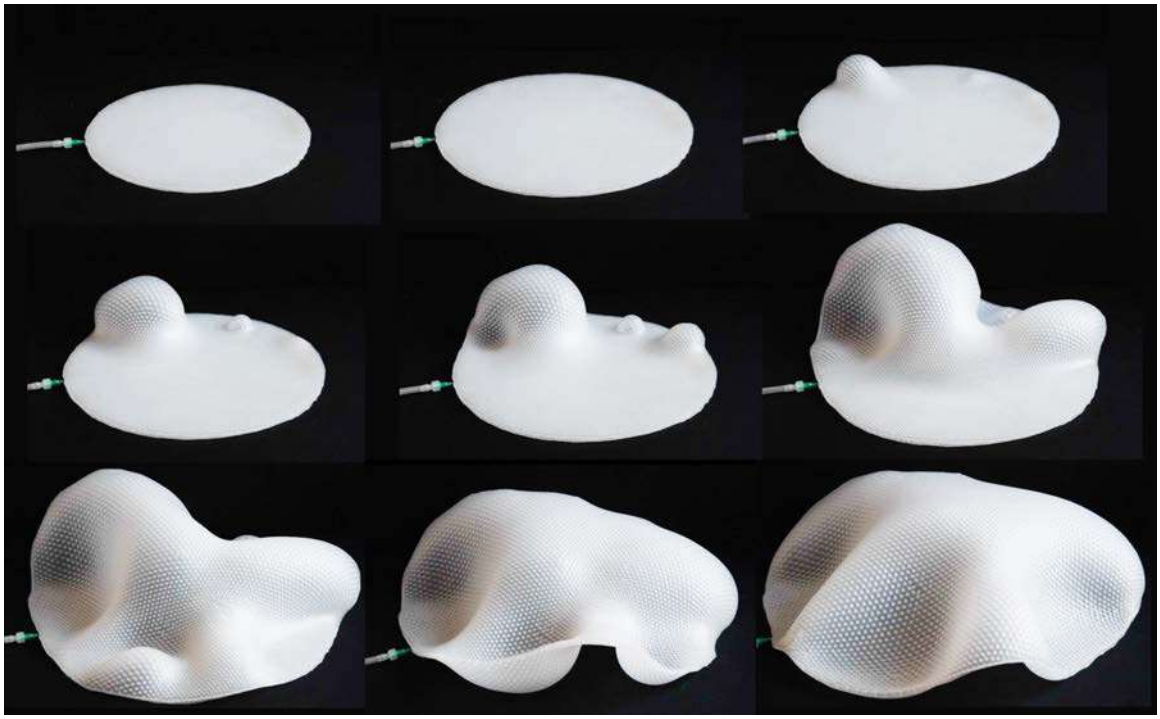

Figure 1: Series of pictures of a large plate embedding a regular hexagonal lattice of pillars upon inflation. Bulges appear in the plate and then propagate through the whole structure, at a nearly constant pressure.

We consider an architected elastomeric plate, with the following internal structure: a triangular network of cylindrical pillars connecting a top and bottom layer (thickness e), as in Fig. 2. When a pressure p is imposed in this internal chamber,

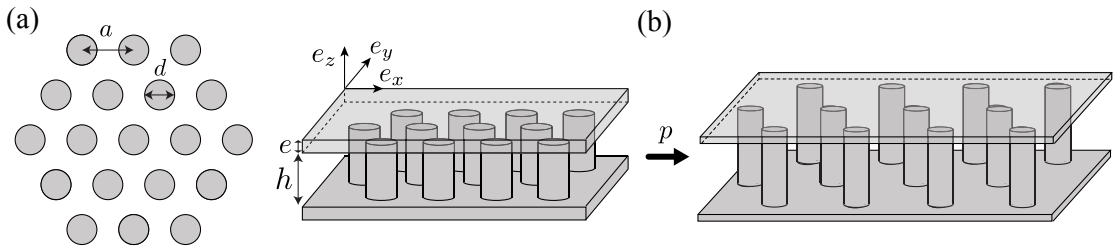

Figure 2: (a) (left) Schematic top view of the regular pillar lattice of pitch a, the diameter of the pillars being d. (right) Schematic 3D representation of a portion of the structure, e being the thickness of the top and bottom membranes, and h the height of the pillars. (b) Upon inflation, the structure deforms with a large in-plane expansion.

which has a internal structure everywhere identical, we would expect a uniform response of the material, so that the plate should simply expand everywhere by the same factor. But very surprising shape changes are observed at one critical pressure (pressure is approximately constant in all pictures except the first one on Fig. 1), where the structure locally

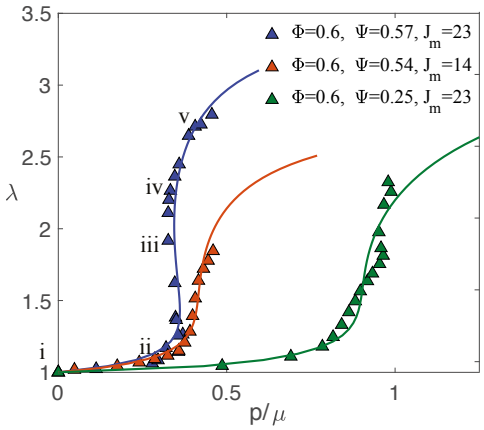

Figure 3: Deformation response of the plate as a function of the dimensionless applied pressure p/μ for various geometries of the inner architecture $\Psi = h/(h+2e)$ the relative height of the pillars compared to the total thickness of the plate, Φ the in-plane density of pillars, and J_m the maximum material stretching invariant in Gent's model [3] . Triangles correspond to experimental measurements, solid lines to the theoretical response

buckles out of plane in several areas, whereas the rest remains flat. As the air volume inside the plate is increased, the shape evolves, with the bumps progressively merge though a complex series of shapes in a very homogeneous structure.

In this presentation we wish to elucidate this instability. When computing the mechanical deformation of the inflated plate (assumed to be homogeneous), and we find that depending on the geometry and the material properties (see figure 3) several states may be attained for the same imposed internal pressure (a family of equilibrium states have a negative stiffness). A localization instability is therefore expected [4,5], with the coexistence of the two phases (in strongly different stretch state, which are thus geometrically incompatible). We interpret the complex shapes observed in Figure 1 as the result of out-of-plane buckling induced by such incompatible in-plane strains.

MAGNETICALLY CONTROLLED SURFACE PATTERNS OFBIAXIALLY PRE-STRAINED MULTI-LAYERED MAGNETO-ELASTICSTRUCTURES

Matthias Rambausek*[1] and Konstantinos Danas[2]
[1]Institute for Analysis and Scientific Computing, TU Wien, Wiedner Hauptstr. 8-10, 1040 Wien, Austria
[2]LMS,CNRS,École Polytechnique,Institut Polytechnique de Paris,Palaiseau,91128,France

Summary The research presented is concerned with instabilities in composites featuring layers of magnetorheological elastomers (MREs). It is already known that a thin magnetic film on an soft non-magnetic substrate exhibits complex surface patters in the post-bifurcation regime not only due to mechanical but also due to magneto-mechanical and purely magnetic loading. However, present literature mainly covers 1d surface patterns enforced by uniaxial mechanical pre-strain. In our current work we aim for full 2d surface patters as they appear in 3d structures under general conditions. Moreover, we generalize the basic thin-film-on-substrate-type structure to layers of MREs and non-magnetic elastomers and study their instabilities and post-bifurcation behavior. For this purpose we employ Fourier schemes for structures of infinite lateral extent combined with finite elements.

INTRODUCTION

Buckling and more complex instabilities such as folds and creases of slender or thin structures are a prominent field of study (not only) in mechanics and an important source of innovation. With the advent of finite-strain magneto-mechanics and the study of corresponding soft magneto-elastic composites it was only natural to explore instability phenomena also in the area of coupled magneto-mechanics [4]. One class of structures investigated for instabilities are thin films attached to soft substrates. In the purely mechanical case, such a structure exhibits instabilities resulting in one-dimensional or two-dimensional surface patterns, depending on the lateral loads [6, 5]. In case of magnetic films it has been shown that similar patterns can be initiated with applied magnetic fields in out-of-plane direction. Moreover, the critical magnitude of the magnetic field can be controlled via sub-critical mechanical pre-loads, ie. pre-stress or pre-strain. Uniaxial pre-strains have been shown to yield one-dimensional patterns such as wrinkling and more complex modes such as crinkling have been observed when going deeper in the post-bifurcation regime [1, 2]. As summarized in Figure 1, our current work is concerned with the effect of *biaxial* mechanical pre-loads on *magneto-mechanical* surface patterning which has not been investigated up to know. The idea behind is that biaxial pre-strains may be used to control the surface pattern obtained by increasing the magnetic load beyond the critical value. As a second generalization of prior work we study multi-layered magneto-elastic structures, ie. structures featuring more than one magnetic and non-magnetic layer.

For the exploration of critical loads we consider planar structures of infinite lateral extent. These results then serve as an important guide for real-world scenarios with structures of finite lateral extents treated with finite elements.

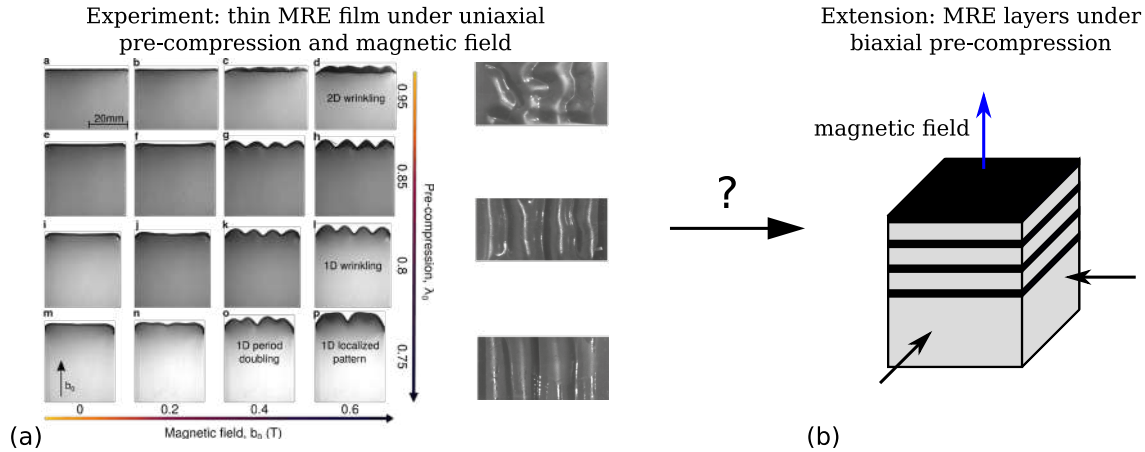

Figure 1: Prior experimental observations of a thin MRE film on a compliant substrate [1] (a) and scope of our current work (b): multiple layers of MREs under biaxial pre-compression and magnetic field.

THEORY

The study is within the scope of magneto-elasticity at finite strains and quasi-static conditions. We employ mechanical displacements $\boldsymbol{u}$ and the (referential) magnetic vector-potential $\boldsymbol{A}$ as primary fields. The corresponding governing variational principle can be found in, e.g., [3]. The body of interest is of infinite extent in the X_1-X_2-plane, where we may prescribe strains in either direction. As magnetic loading we prescribe $\boldsymbol{b}^\infty = (0, 0, b^\infty)$ in X_3 direction. Under such conditions, the principal solution of the problem yields states $\boldsymbol{F}$ (deformation gradient) and $\boldsymbol{B}$ (referential magnetic

*Corresponding author. E-mail: matthias.rambausek@tuwien.ac.at

field) that are uniform in the X_1-X_2-plane and piecewise constant in X_3. For our stability investigations we employ a Fourier-based discretization in X_1 and X_2 and finite elements (second-order Lagrange elements) in X_3. Accordingly, one *possible* Ansatz for an Eigen-mode is given as

$$\boldsymbol{u}(X_1, X_2, X_3) = \hat{\boldsymbol{u}}^c(X_3)\cos(\Omega_1 X_1 + \Omega_2 X_2) + \hat{\boldsymbol{u}}^s(X_3)\sin(\Omega_1 X_1 + \Omega_2 X_2) \tag{1}$$

$$\boldsymbol{A}(X_1, X_2, X_3) = \hat{\boldsymbol{A}}^c(X_3)\cos(\Omega_1 X_1 + \Omega_2 X_2) + \hat{\boldsymbol{A}}^s(X_3)\sin(\Omega_1 X_1 + \Omega_2 X_2), \tag{2}$$

where the amplitudes $\hat{\boldsymbol{u}}^c(X_3)$, $\hat{\boldsymbol{u}}^s(X_3)$, $\hat{\boldsymbol{A}}^c(X_3)$ and $\hat{\boldsymbol{A}}^s(X_3)$ have a standard finite element representation.

For given loading parameters $(b^\infty, \lambda_1, \lambda_2)$ we find the pair (ω_1, ω_2) which yields the smallest Eigenvalue of the system matrix. Then, the magnetic load is adjusted such that the smallest Eigenvalue is (numerically) zero, which marks the loss of stability.

A REPRESENTATIVE RESULT

We perform the procedure described above for a range of material parameters and combinations of material layers. In Figure 2 we show the critical magnetic load $b^{\infty,c}$ and the critical $(\omega_1^c = \Omega^c/\lambda_1, \omega_2^c = \Omega_2/\lambda_2)$ for a variety of pre-strains (λ_1, λ_2).

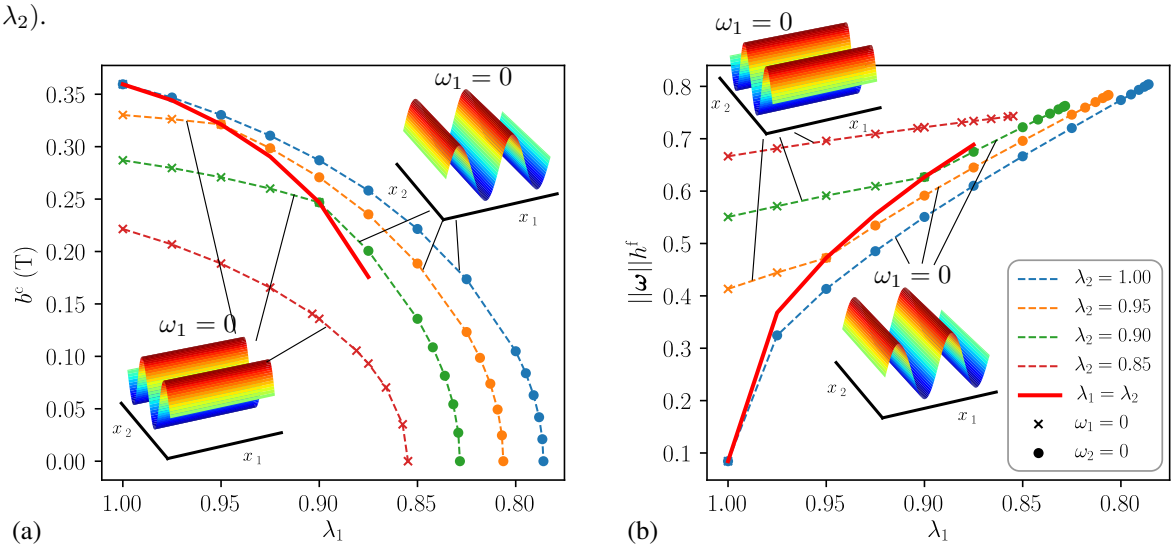

Figure 2: Critical applied magnetic field $b^{\infty,c}$ (a) and norm of critical Eulerian wave vector $||(\omega_1^c, \omega_2^c)||$ (b) for a set of pre-stretches in x_1 and x_2 direction, λ_1 and λ_2, respectively. The latter is plotted because the critical wave-numbers are not unique for the equi-biaxial case [5]. For non-equi-biaxial pre-stretches, the wave number in the direction of the larger pre-stretch is observed to be zero. Results for magnetic substrates and various topologies can be found in [7].

CONCLUSIONS

In our contribution we investigate the stability of multi-layered magneto-elastic structures of infinite lateral extent. Thereby, our research interest is two-fold: the first question is the magnetic loading required for loss of stability for a variety of pre-strains and combinations of layers. Second, we aim for a characterization of the stability of surface patters in the post-buckling regime. The results shown are intended to serve as a guideline for future studies in the nonlinear post-buckling regime and practical applications.

INVESTIGATION OF INSTABILITY-INDUCED PATTERN TRANSFORMATIONS IN PERIODIC HYDROGELS BASED ON AN INCREMENTAL MINIMIZATION PRINCIPLE

Elten Polukhov[1] and Marc-André Keip*[1]
[1]Institute of Applied Mechanics, University of Stuttgart, Stuttgart, Germany

Summary The present contribution deals with swelling-induced pattern transformations of periodic hydrogels due to diffusion of solvent molecules. The deformation-diffusion processes are modeled by a rate-type variational formulation in terms of the deformation map and the solvent-volume flux as independent fields. This setting yields a minimization principle that is readily suitable for stability analysis. A conforming discretization requires edge-based finite elements for the flux degrees of freedom, which will be realized by Raviart–Thomas-type finite elements. Within the discussed framework, we investigate pattern transformations in periodic hydrogels using Bloch–Floquet wave analysis.

INTRODUCTION

Hydrogels are soft polymeric materials that have promising application areas in engineering, medicine and agriculture. Their advantageous properties, such as high porosity and biocompatilibity, and their characteristic swelling due to diffusion of solvents make them also attractive for developments in soft electronics as well as next-generation actuators and sensors. As could be shown in experiments, periodic porous hydrogel structures undergo swelling-induced instabilities that result in complex deformations in the form of pattern transformations [1, 2]. In hydrogel thin films such transformations do not only occur in the plane of periodicity, but also develop out of plane. As a result, related materials show complex three-dimensional patterns [3]. So far, associated studies of three-dimensional swelling-induced instabilities often rely on simplifying assumptions. Thus, the aim of the present contribution is twofold: We will (i) develop a versatile framework for the structural stability analysis of hydrogels within a variational minimization principle and (ii) exploit the variational framework for the investigation of pattern transformations of soft periodic hydrogels in two and three spatial dimensions.

VARIATIONAL FORMULATION OF DEFORMATION-DIFFUSION PROCESSES

We model the deformation-diffusion processes using a two-field variational minimization principle. This principle relies on the deformation map $\boldsymbol{\varphi} : \mathcal{B}_0 \times \mathcal{T} \to \mathcal{B}_t \subset \mathcal{R}^3$ and the solvent-volume flux $\mathbb{H} : \mathcal{B}_0 \times \mathcal{T} \to \mathcal{R}^3$ as independent fields. $\mathcal{B}_0$ and $\mathcal{B}_t$ denote the reference and current configuration of a hydrogel body, respectively [4]. To describe swelling phenomena, we introduce the concentration of the solvent volume $s : \mathcal{B}_0 \times \mathcal{T} \to \mathcal{R}$ which is related to the solvent flux via the conservation of the solvent-volume concentration via $\dot{s} = -\mathrm{Div}\mathbb{H}$. Due to the dissipative nature of deformation-diffusion processes, we model them using two constitutive functions given by the energy-storage function $\hat{\psi}(\boldsymbol{F}, s)$ and the dissipation-potential function $\hat{\phi}(\mathbb{H}; \boldsymbol{F}, s)$. The energy-storage function is assumed to depend on the deformation gradient $\boldsymbol{F}$ and the solvent-volume concentration s and, furthermore, is considered to have an additive form as $\hat{\psi}(\boldsymbol{F}, s) = \hat{\psi}_{mech}(\boldsymbol{F}) + \hat{\psi}_{chem}(s) + \hat{\psi}_{coup}(J, s)$. Here, $\hat{\psi}_{mech}$, $\hat{\psi}_{chem}$ and $\hat{\psi}_{coup}$ are the mechanical, chemical and coupling terms, respectively. Having introduced constitutive state variables and functions, we can determine the evolution of the deformation map and the solvent-volume flux from the rate-type variational formulation

$$\{\dot{\boldsymbol{\varphi}}, \mathbb{H}\} = \mathrm{Arg}\Big\{ \inf_{\boldsymbol{\varphi} \in H^1(\mathcal{B}_0)} \inf_{\mathbb{H} \in H(\mathrm{Div}, \mathcal{B}_0)} \int_{\mathcal{B}_0} \frac{\mathrm{d}}{\mathrm{d}t}\hat{\psi}(\boldsymbol{F}, s) + \hat{\phi}(\mathbb{H})\, \mathrm{d}V - \int_{\partial\mathcal{B}_0^t} \bar{\boldsymbol{t}} \cdot \dot{\boldsymbol{\varphi}}\, \mathrm{d}A - \int_{\partial\mathcal{B}_0^\mu} \bar{\mu}\mathbb{H} \cdot \boldsymbol{N}\, \mathrm{d}A \Big\}. \tag{1}$$

Above, $\bar{\boldsymbol{t}}$ and $\bar{\mu}$ denote the prescribed traction and chemical potential on $\partial\mathcal{B}_0^t$ and on $\partial\mathcal{B}_0^\mu$, respectively. In order to solve the above problem, we consider a space-time discretization of the variational principle using implicit Euler time integration and a Raviart–Thomas-type finite element formulation for the spatial discretization [4].

SWELLING-INDUCED STRUCTURAL STABILITY ANALYSIS OF PERIODIC HYDROGELS

We investigate the structural stability of periodic hydrogels by using Bloch–Floquet wave analysis [5, 6]. This allows us to determine possible pattern transformations that go beyond the periodicity of a typical periodic unit cell of the microstructure. In the finite-element setting, the structural stability of the hydrogel can be described by the condition

$$\Lambda = \min_{k_i \in [0,\pi]} \min_{\mathbf{d}} \left\{ \delta\mathbf{d}^T \left[\Pi^\tau(\mathbf{d})_{,\mathbf{dd}} \right] \delta\mathbf{d} / \|\delta\mathbf{d}\|^2 \right\} \begin{cases} > 0 & \text{for a stable solution state } \mathbf{d}^\star \\ \leq 0 & \text{for an unstable solution state } \mathbf{d}^\star \end{cases} \tag{2}$$

where $\mathbf{d}$ denotes the degrees of the freedom of the unit cell and k_i, $i = 1, 3$ are the components of the Bloch vector, see [6, 7] for implementations. The periodic degrees of freedom are subjected to the Bloch–Floquet-type boundary conditions $\delta\mathbf{d}(\boldsymbol{X}^+) = \delta\mathbf{d}(\boldsymbol{X}^-) \exp[\mathrm{i}\boldsymbol{k} \cdot (\boldsymbol{X}^+ - \boldsymbol{X}^-)]$ on the boundary of the unit cell.

Figure 1: Periodic hydrogel with voids. **a)** Experimentally motivated boundary conditions on a unit cell of a hydrogel microstructure. **b)** Swelling-induced pattern transformation.

NUMERICAL EXAMPLE

We present a numerical example to demonstrate a typical pattern transformation in a porous planar hydrogel. We assume that the considered hydrogel has a periodic microstructure as described in Fig. 1a. Periodic boundary conditions $[\![\boldsymbol{\varphi}]\!] = \overline{\boldsymbol{F}}[\![\boldsymbol{X}]\!]$, $[\![\mathbb{H}]\!] = \boldsymbol{0}$ on the external boundary of the unit cell $\partial\mathcal{B}_0$ are considered. Motivated by experiments [2] the hydrogel is exposed to solvent molecules through the internal boundary, i.e., $\mathbb{H} \cdot \boldsymbol{N} = H_D$ on $\partial\mathcal{H}_0$. The energy function is assumed to be of Flory–Rehner-type

$$\hat{\psi}(\boldsymbol{F}, s) = \tfrac{\gamma}{2}\big[\boldsymbol{F} : \boldsymbol{F} - 3 - 2\ln(\det \boldsymbol{F})\big] + \alpha\left[s\ln\big(\frac{s}{1+s}\big) + \frac{\chi s}{1+s}\right] + \frac{\epsilon}{2}\big(\det \boldsymbol{F} - 1 - s\big)^2 \tag{3}$$

and the dissipation-potential function is given in time-discrete form as $\hat{\phi}(\mathbb{H}; \boldsymbol{C}_n, s_n) = 1/(2Ms_n)\boldsymbol{C}_n : (\mathbb{H} \otimes \mathbb{H})$ [4].

In Fig. 1b, we present a detected buckling mode of the hydrogel. We observe that at a certain critical fluid content the circular voids deform to elliptic shapes with alternating orientations of their major axes. This particular pattern is referred to as diamond-plate pattern and has been experimentally shown in [1, 2].

OUTLOOK

Future work will be directed towards the three-dimensional extension of the stability analysis. This will allow us to detect complex three-dimensional instability patterns that usually occur in composite hydrogels composed of phases with different swelling properties. We refer to [3] for experimental studies on high-swelling hydrogels with embedded non-swelling discs. There, it could be shown that two-dimensional hydrogel thin films buckle out of plane to form convex-concave patterns, therewith minimizing the overall energy of the system.

INCREMENTAL CONSTITUTIVE TENSORS AND STRAIN LOCALIZATION FOR PRESTRESSED ELASTIC LATTICES

Giovanni Bordiga[1], Luigi Cabras[2], Andrea Piccolroaz*[1], and Davide Bigoni[1]
[1]Department of Civil, Environmental and Mechanical Engineering, University of Trento, Trento, Italy
[2]Department of Civil, Environmental, Architectural Engineering, University of Brescia, Brescia, Italy

Summary A lattice of elastic rods organized in a parallelepiped geometry can be axially loaded up to an arbitrary amount without distortion and then be subject to incremental displacements. Using both quasi-static and dynamic homogenization theories, this lattice can be made equivalent to a prestressed elastic solid subject to incremental deformation, in such a way to obtain extremely localized mechanical responses. Features such as for instance shear bands inclination, or emergence of a single shear band, or competition between micro (occurring in the lattice but not in the equivalent solid) and macro (present in both the lattice and the equivalent continuum) instabilities are analysed. The analysis of localizations is performed using a Green's function perturbative approach to highlight the correspondence between micromechanics of the composite and homogenized response of the equivalent solid.

INCREMENTAL RESPONSE OF LATTICES OF AXIALLY PRELOADED ELASTIC RODS

A two-dimensional periodic lattice of elastic rods, deformable in the plane both axially and flexurally, is considered, in which all structural members are axially prestressed from an unloaded reference configuration $\mathcal{B}_0$. The axial prestress $\boldsymbol{p} = \{p_1, p_2\}$ is assumed to be produced by dead loading acting at infinity, while body forces in the lattice are excluded for simplicity. It is assumed that the preload not only satisfies equilibrium, but also preserves periodicity and leaves the structure free of flexure.

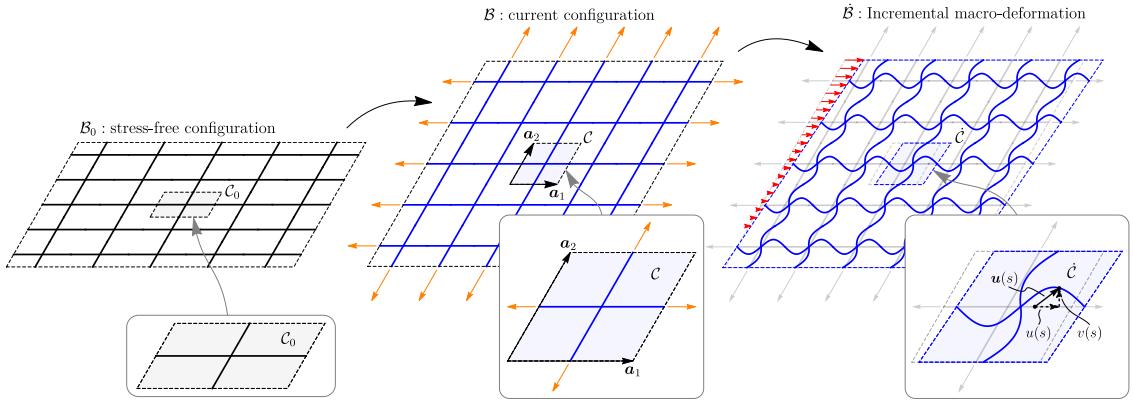

Figure 1: A periodic two-dimensional lattice of (axially and flexurally deformable) elastic rods is considered prestressed from the stress-free configuration $\mathcal{B}_0$ (left) by means of a purely axial loading state. The prestressed configuration $\mathcal{B}$ (center) can be represented as the tessellation of a single unit cell along the vectors of the direct basis $\{\boldsymbol{a}_1, \boldsymbol{a}_2\}$. Upon the current prestressed configuration, the incremental response (right) is defined by the incremental displacement field of each rod $\boldsymbol{u}(s)$, here decomposed in an axial and transverse component, $u(s)$ and $v(s)$.

QUASI-STATIC RESPONSE

A comparison is presented between the response of the lattice loaded with a concentrated force dipole and a dipole Green's function of the effective solid, in terms of maps of incremental displacements. The results are presented as contour plots in Fig. 2, where the color scale has been conveniently normalized according to the norm of the computed displacement field. In the upper part of the figure, results pertaining to the discrete lattice structure are presented, while, in the lower part, results are relative to the equivalent continuum, obtained via homogenization. The figures from left to right correspond to the application of increasing preloads, which approach the strong ellipticity boundary in the equivalent solid in situations where failure of ellipticity corresponds also to the occurrence of a macro bifurcation of infinite wavelength. The part (d) of the figure ($\boldsymbol{p} = 0.99\boldsymbol{p}_{\mathrm{E}}$) also illustrates a magnification of the lattice response in the neighborhood of the loading zone, thus disclosing the microscopic deformation pattern associated to the extreme mechanical response of the material when close to elliptic boundary.

*Corresponding author. E-mail: roaz@ing.unitn.it

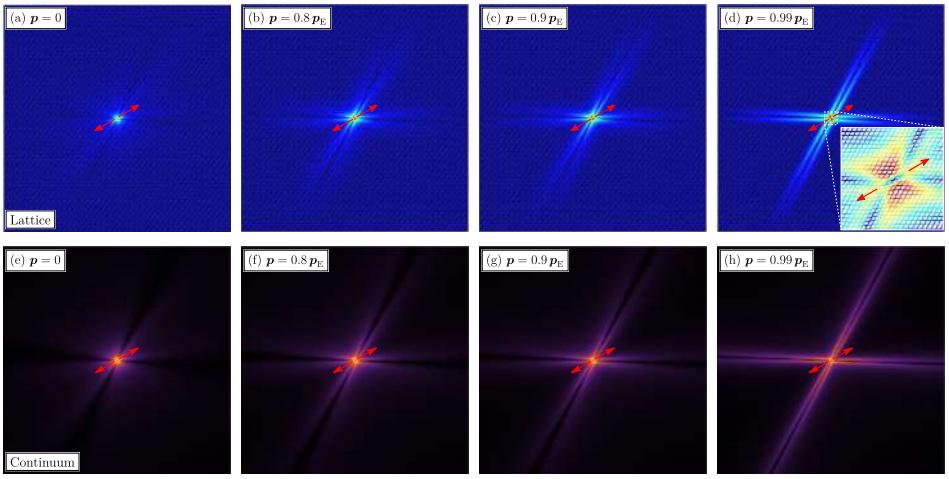

Figure 2: Progressive emergence at increasing load of two orthogonal shear bands visible in the displacement field generated by a diagonal force dipole applied to an orthotropic rhombic lattice (upper part, a–d, simulated via f.e.m.) compared to the response of the homogenized continuum (lower part e–h). From left to right the load increases towards failure of strong ellipticity $\boldsymbol{p}_E$. Shear bands are aligned parallel to the directions predicted at failure of ellipticity ($\theta_{cr} = 88.2°, 151.8°$).

INCREMENTAL DYNAMICS

By considering for instance a rhombic anisotropic grid, the deviation between the responses of the lattice (reported in blue in Fig. 3) and its equivalent continuum (reported in red in Fig. 3) can be visualized in terms of slowness contours computed at the frequency $\Omega = 0.01$. By comparing the contours for the four preload states, it can be appreciated that these are superimposed up $0.9\,\boldsymbol{p}_E$, so that the nonlinear dispersion of the lattice becomes non-negligible only when the material is very close to the elliptic boundary, namely, at a preload $0.99\,\boldsymbol{p}_E$, and only for waves close to the direction of ellipticity loss.

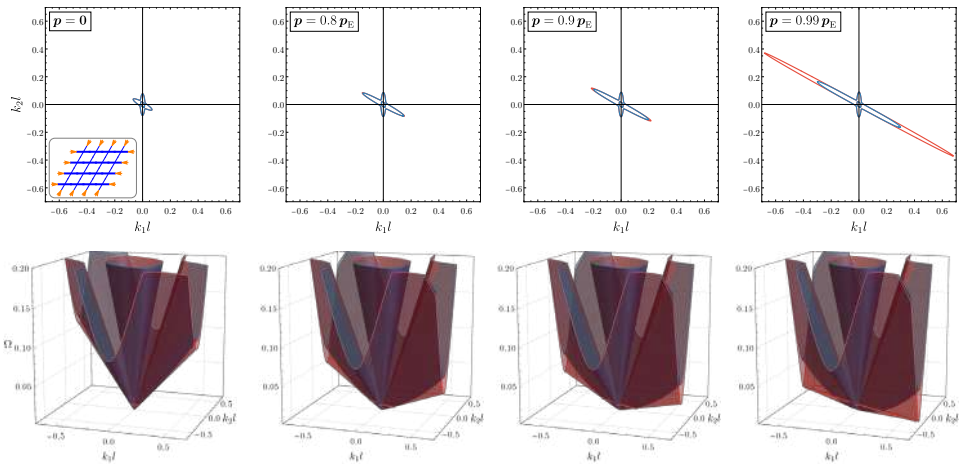

Figure 3: Slowness contours and dispersion surfaces for a rhombic anisotropic lattice (in blue) and for the effective Cauchy continuum (in red) at frequency $\Omega = 0.01$. The evolution of the contours and dispersion surfaces induced by a compressive preload of equal components $p_1 = p_2$ along two inclined directions demonstrates that the nonlinear dispersion of the lattice is negligible, except when the material is very close to the elliptic boundary, namely, for a prestress above $0.9\,\boldsymbol{p}_E$. The comparison between the behaviours of the lattice and its equivalent continuum shows a great agreement.

CONCLUSIONS

Homogenization of the incremental response of a lattice of elastic rods, axially pre-loaded to an arbitrary amount, has been shown to provide a superb tool for the design of cellular elastic materials of tunable properties and capable of extreme localized deformations.

EFFECT OF FINITE THICKNESS ON WRINKLING OF ELASTIC BILAYERS

Takuya Morimoto*[1]
[1]Department of Mechanical, Electrical and Electronic Engineering, Shimane University, Shimane, Japan

Summary Surface instabilities in bilayer systems composed of a thin film bonded to a thick substrate have been studied extensively. Most of the previous papers have focused on the elastic bilayer with an infinite substrate to simplify the analysis by removing the lower boundary effect. Here this paper explores the effect of finite thickness on the wrinkling of elastic bilayers under film-only growth and elucidates the role of the boundary condition at the bottom through the incremental analysis. The standard incremental analysis reveals that the critical growth ratio and wavenumber have a large discrepancy between the displacement-free and traction-free boundaries as the ratio of the substrate thickness to the film thickness becomes small. The results show the possibility to control the wavenumber by tuning the thickness ratio in a combination of the boundary condition at the bottom surface.

INTRODUCTION

The incremental analysis of elastic bilayer applies to the problems of surface instability and can determine the stretches and wavenumbers at the critical thresholds. Most of the previous papers have analyzed on the bilayer with an infinite substrate to simplify the analysis by removing the lower boundary effect, except for Ref. [6] where the bilayer undergoes a whole compression. In this case, the boundary condition at the bottom surface does not affect the wrinkling pattern. However, if the film thickness is comparative to the substrate thickness, the difference of the boundary condition may affect and modifies it. Specifically, the case for the bilayer under film-only growth may enhance the finite thickness effect since the film growth makes its thickness thicker.

This paper explores the effect of finite thickness on the wrinkling of elastic bilayers under film-only growth and elucidates the role of the boundary condition at the bottom surface by the incremental analysis [1, 2]. The analysis reveals that the critical growth and wavenumber have a large discrepancy between the displacement-free and traction-free boundaries as the ratio of the substrate thickness to the film thickness becomes small as expected. The results show the possibility to control the wavenumber by tuning the thickness ratio in a combination of the B.C. at the bottom surface.

WRINKLING ANALYSIS

The incremental analysis is performed for wrinkling superimposed on a homogeneous film-only growth as shown in Fig. 1. Each layer is assumed to be incompressible neo-Hookean material with the strain energy density function $W_\alpha = \frac{\mu_\alpha}{2}(\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3)$ where μ_α is shear modulus of layer $\alpha = (\mathrm{f}, \mathrm{s})$ where $\lambda_1 = 1/g_1 = 1/\gamma$, $\lambda_2 = g_1 g_3 = \gamma$ and $\lambda_3 = 1/g_3 = 1$ for growth in the $\mathbf{e}_1$-direction, and p is a Lagrange multiplier for imposing the incompressible constraint. The incremental equations composed of the equilibrium and constraint equations are given as $\mathrm{div}\,\boldsymbol{\Sigma} = \mathbf{0}$ and $\mathrm{tr}\,\boldsymbol{\Gamma} = \mathrm{div}\,\boldsymbol{u} = 0$ where $\boldsymbol{\Sigma} = \mathcal{A}_0\boldsymbol{\Gamma} + p\boldsymbol{\Gamma} - \dot{p}\mathbf{I}$, $\dot{p}$ is incremental Lagrange multiplier, the incremental displacement gradient $\boldsymbol{\Gamma} = \dot{\boldsymbol{F}}\boldsymbol{F}^{-1}$, and the incremental displacement $\boldsymbol{u}$. The elastic moduli $\mathcal{A}_0$ of the neo-Hooke material in Cartesian coordinates are given by $\mathcal{A}_{0ijkl} = \mu_\alpha \delta_{il} F_{jA} F_{kA}$ [1] with the Kronecker delta δ_{ij}. The boundary conditions are stress-free at the free surface and continuity at the interface between the film and the substrate. Here two types of boundary condition at the bottom surface are considered: (a) traction-free [6] or (b) displacement-free along the surface [3]. When the substrate is sufficiently thicker than the film, the boundary condition at the bottom surface should not affect the wrinkling pattern. On the other hand, if the film thickness is comparative to the substrate thickness, the difference of

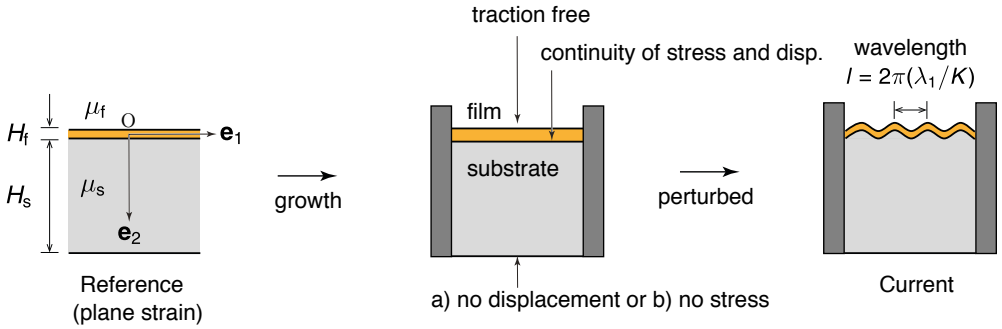

Figure 1: Elastic bilayer under film-only growth.

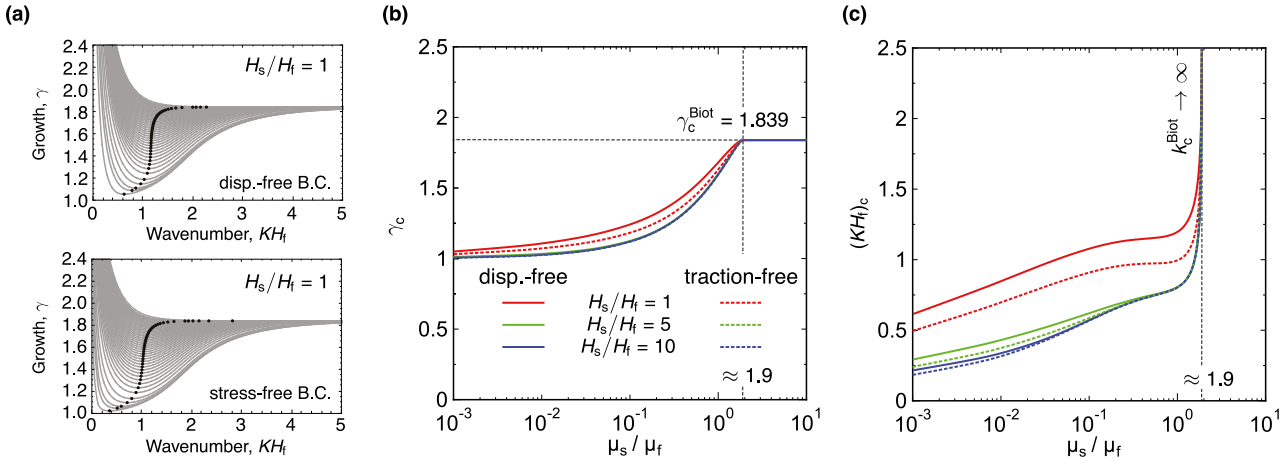

Figure 2: Critical conditions at the threshold of wrinkling for film-only growth. (a) Dispersion curves for a range of μ_s/μ_f values with $H_s/H_f = 1$. There is a slight difference between displacement-free B.C. (top) and stress-free B.C. (bottom) to the accuracy of visual inspection. The critical growth γ_c (b) and critical wavenumber (c) have a large discrepancy between displacement-free B.C and traction-free B.C. as H_s/H_f becomes small.

the boundary condition may affect and modifies it. This effect of finite thickness on the wrinkling of elastic bilayers is explored systematically.

The wrinkle mode may be expresses as the separation of variables $u_1 = f_1(x_2)\sin kx_1$, $u_2 = f_2(x_2)\cos kx_1$, $\dot{p} = f_3 x_2 \cos kx_1$ where $f_a(x_2)$ $(a = 1, 2, 3)$ is unknown functions and k is the wavenumber of wrinkle in a current configuration and relates to wavenumber in a reference configuration via $k = K/\lambda_1$. Substituting these $u_1, u_2, \dot{p}$ into the incremental equations, and then applying it to the boundary conditions [(i) or (ii)], we obtain eight equations for the constants $\mathbf{K}$ that can be written in a compact form as $\mathbf{MK} = \mathbf{0}$ where the matrix $\mathbf{M}$ is omitted for the brevity. The bifurcation condition $\mathbf{f}(\mu_s/\mu_f, H_s/H_f, KH_f, g_1) \equiv \det \mathbf{M} = 0$ determines the critical growth γ_c.

RESULTS AND DISCUSSION

Figure 2 shows the critical solutions value of growth and wavenumber as a function of μ_s/μ_f. The dispersion curves for a range of μ_s/μ_f values with $H_s/H_f = 1$. The growth rate γ increases from 1 and emerges the wrinkling solution at the minimum value of each dispersion curve which is marked point in the figure. There is a slight difference between displacement-free B.C. (top) and stress-free B.C. (bottom) to the accuracy of visual inspection, so that the minimum values are plotted as a function of μ_s/μ_f in Figs. 2(b) and (c). The critical growth ratio γ_c and wavenumber $(KH_f)_c$ decreases with increasing the substrate thickness. This tendency agrees with the theory [6] and experimental data [7] for a whole-domain compression. It is also confirmed that the solutions for $H_s/H_f \to \infty$ reduce to the same values in [4, 5]. As μ_s/μ_f increases, γ_c approaches $\gamma_c^{\mathrm{Biot}} = 1.839$ and the wavenumber first diverges at $(KH_f)_c \approx 1.9$ [4, 5], which are not dependence of the thickness ratio H_s/H_f. The critical growth γ_c [Fig. 2(b)] and critical wavenumber [Fig. 2(c)] have a large discrepancy between displacement-free B.C and traction-free B.C. as H_s/H_f becomes small as expected. The wrinkling pattern can be controlled by tuning the thickness ratio H_s/H_f in a combination of the B.C. at the bottom surface.

OPTIMISATION OF CONTINUOUS TOW-SHEARED CYLINDERS UNDER UNCERTAINTY

Reece Lincoln*[1], Paul Weaver[1,2], Alberto Pirrera[1], and Rainer Groh[1]
[1]Bristol Composites Institute (ACCIS), Department of Aerospace Engineering, University of Bristol, Bristol, BS8 1TR, UK
[2]Bernal Institute, School of Engineering, University of Limerick, Castletroy, V94 T9PX, Ireland

Summary The sensitivity to geometric imperfections limits the performance of thin-walled cylinders in compression buckling. The present work focuses on reducing the imperfection sensitivity of cylinders by using a novel manufacturing technique for composite materials known as Continuous Tow Shearing (CTS). CTS allows curvilinear steering of carbon fibre tows by shearing the carbon fibre tape, a 50 mm-wide strip of carbon fibre, that is placed via a robot arm. Steering of the carbon fibre tapes by shearing induces a smooth increase in the thickness of the tape and these localised thickness build-ups are used as a symmetry-breaking device to limit the impact of imperfections. The localised thickness build-ups are used to create embedded-stringers and -hoops that tailor the load path within the CTS cylinder. To maximise the effectiveness of the CTS cylinders, an optimisation framework that accounts for uncertainty is used. The results of the optimisation are corroborated with a Monte-Carlo analysis. The first optimisation goal is to maximise the thickness-normalised, mass-normalised buckling load of a CTS cylinder. The second optimisation goal is to minimise mass of a CTS cylinder under a specific load.

INTRODUCTION

The fuel and oxidizer cylindrical tanks of heavy launch vehicles are a large percentage of their total dry mass (60–70%). Using composite materials instead of current generation Li-Al fuel tanks is estimated to save up to 30% in mass and 25% in recurring manufacturing costs [1]. Several research programs have aimed to use composite materials to capitalise on these savings [2, 3] but have used blade-stiffened shells or foam/honeycomb sandwich structures. Few programmes have considered novel monocoque shell architectures due in part to their well-documented geometric imperfection sensitivity when loaded in compression—the design load case of heavy launch vehicles. Typically, the imperfection sensitivity is captured in the design phase using knockdown factors (KDFs), that are applied to the theoretical critical buckling load derived from a linear eigenvalue analysis. The classical KDFs of the NASA SP-8007 [4] guideline are still industry-standard but have been acknowledged to be too conservative for modern materials and manufacturing tolerances. Contemporary knockdown factors have been created that are less conservative [2, 5], but still show the imperfection sensitivity of cylindrical shells.

This paper looks at designing monocoque cylinders that are imperfection *insensitive* by tailoring load paths by using a novel variable-angle composite manufacturing technique, Continuous Tow Shearing (CTS) [6]. Preliminary work has found that CTS cylinders are less imperfection sensitive than straight-fibre cylinders [7, 8, 9]. It has also been shown that the imperfection sensitivity of composite cylinders can be decreased with Automated Fibre Placement (AFP) [10]. However, CTS has several benefits over AFP as a result of shearing the tows instead of bending the tows, *e.g.,* no in-plane bending; no fibre buckling or wrinkling; perfect tessellation of tows; smaller steering radii. In addition to these benefits, the shearing process couples the fibre angle change to the local thickness of the tow, enabling the formation of embedded stringers and hoops perpendicular to the fibre steering direction. Fibre paths are described using the notation $\phi\langle T_0|T_1\rangle^n$, where ϕ is the clockwise angle from the global x-axis that defines the refence axis for shearing; T_0 is the initial angle of shearing relative to ϕ; T_1 is shearing angle in the middle of the 'period' relative to ϕ; and n is the periodicity—the frequency of a $T_0 \rightarrow T_1 \rightarrow T_0$ cycle. For the sake of illustration, Figure 1 shows how a $0\langle 20|70\rangle^3$ layer and a $90\langle 0|30\rangle^2$ layer is defined.

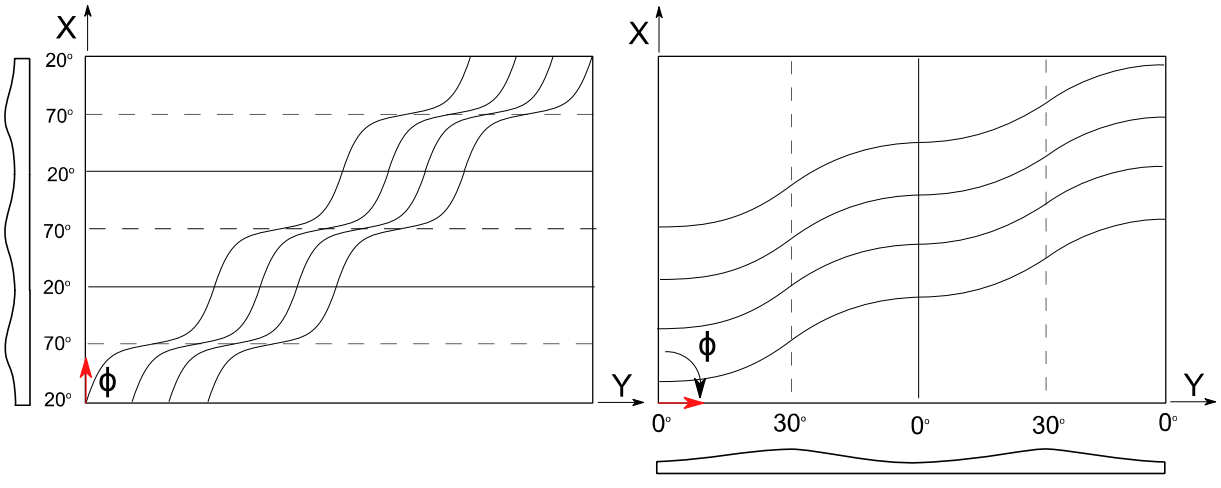

Figure 1 CTS lamina sheared where left is $0\langle 20|70\rangle^3$ and right figure is a $90\langle 0|30\rangle^2$ lamina.

FUTURE WORK

Two optimisations and a Monte-Carlo analysis will be carried out. The first optimisation will be to maximise the thickness-normalised and mass-normalised buckling load of a CTS cylinder. A by-product of the CTS process (where the local thickness of the tow is increased due to the shearing process) is that the average thickness of a CTS cylinder with shearing is greater than a straight-fibre cylinder. As the buckling load of a cylinder is proportional to t^2 and the mass of a cylinder proportional to t, the mass-normalised specific buckling load of a cylinder is proportional to t. Therefore, to ensure a fair comparison between CTS cylinders and straight-fibre cylinders, a thickness-normalised, mass-normalised buckling load is appropriate if the maximum load carrying capability of a structure is essential. The optimisation will use a reliability-based definition of buckling load. A forward-difference First-Order Second-Moment (FOSM) analysis will be used to calculate a conservative estimate of the buckling load. A realistic data bank of imperfections [11] will be spectrally decomposed into a five principal components that describe the data set. From the principal components, six FEA analyses of the CTS cylinder with different imperfections can approximate a distribution of buckling loads. A buckling load approximately equal to the mean buckling load minus three standard deviations will constitute P_{FOSM}, the buckling load calculated from the FOSM methodology. A Genetic Algorithm (GA) will be the framework in which the FOSM methodology is used to optimise towards maximising the thickness-normalised, mass-normalised P_{FOSM}. To test the robustness of the final result and the assumed distribution, a Monte-Carlo analysis of the converged value will be performed to ensure the assumptions are valid and the result is statistically significant.

As a secondary optimisation, the mass of a CTS cylinder will be optimised. The target function will be to minimise the mass of a CTS cylinder given certain loading criteria. A GA will be used as the optimisation framework. The buckling load will be calculated from the FOSM methodology previously described.

BUCKLING INSTABILITY AND MATERIAL DAMAGE: TOWARDS A UNIFYING GENERAL THEORY

Anton Köllner*[1] and M. Ahmer Wadee[1]
[1]Department of Civil and Environmental Engineering, Imperial College London, London SW7 2AZ, United Kingdom

Summary An extension of the general elastic stability theory to systems undergoing inelastic deformation is discussed. The underlying idea is to derive an extended total potential energy, which is the governing functional during inelastic deformation but only depends on the configuration of the system. Thus, relationships are derived which describe the state of damage within the system by explicit functions of the configuration and applied loading. Such relationships are determined by investigating the change of elastic and inelastic energies with respect to a change in the damage state. With the aid of the proposed extension of the elastic stability theory, the effect of material damage and its propagation on the stability behaviour of structures can be analysed. This is demonstrated with the aid of the problem of delamination buckling in composite panels.

INTRODUCTION

The loss of structural stability in a mechanical system often constitutes a catastrophic failure scenario, where the system more or less abruptly loses its load carrying capability. This type of failure is strongly related with slender structures, which can be found in a vast variety of applications mainly in the transportation and construction industries. Over the last few decades, these slender structures have been made increasingly from composite materials, e.g. multi-layered carbon fibre reinforced polymer laminates that are also prone to various damage mechanisms, e.g. matrix damage growth and delamination growth, which may influence the global structural stability. This is visualized in Figure 1 (left), illustrating the compressive response of delaminated composite panels (with all boundaries being supported); an application example with special relevance for the aircraft/aerospace industry. As can be seen in Figure 1 (left), the onset of delamination growth and the initial propagation may be barely visible causing unexpected catastrophic failure whenever unstable delamination propagation occurs.

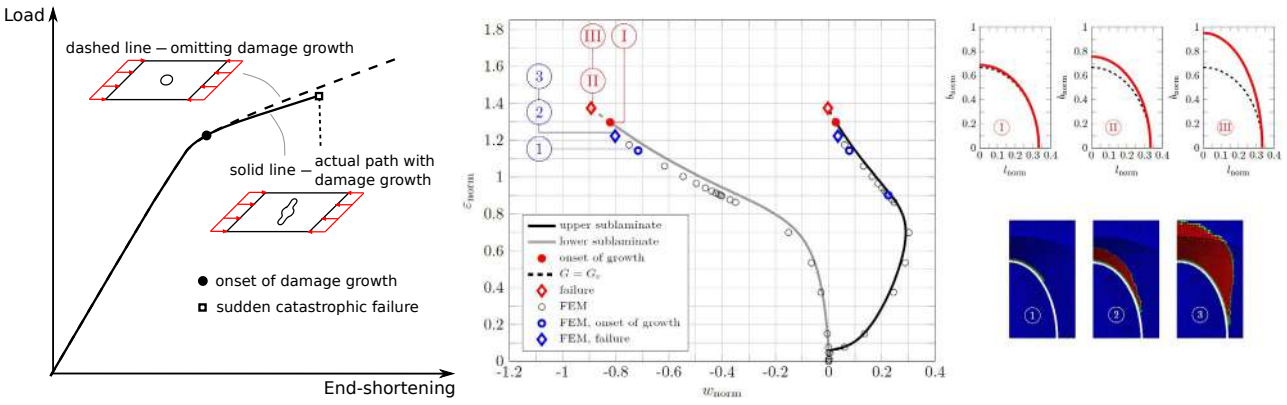

Figure 1: (left) Illustration of a characteristic compressive response of a delaminated composite panel; (middle) result in the form of applied compressive strain against midpoint deflection for an entire loading path up to failure with comparison against finite element (FE) simulations; (right) comparisons between model and FE simulation of delamination growth shapes associated with the deformation states shown in the middle graph.

Since the consideration of such damage mechanisms has had only limited relevance when using more traditional construction materials (e.g. structural steel), general theories of structural stability have hitherto tended only to consider elastic systems [1]. The current work aims at bridging the aforementioned gap in structural stability analysis techniques.

CONCEPT

A discrete coordinate approach is considered. Thus, all mechanical systems of interest are assumed to be fully defined by a set of generalized coordinates q_i, loading parameters λ_m and damage parameters ξ_k (i.e. internal state parameters) describing the configuration, applied loading and damage state respectively. During elastic deformation, i.e. whenever all damage parameters remain constant, the system is characterized by the total potential energy,

$$\Pi = \Pi(q_i, \lambda_m, \xi_k) \quad \text{with} \quad \xi_k = \text{const.} \tag{1}$$

and the well-known total potential energy principle $\delta\Pi(q_i) = 0$ yields the deformation path $q_i(\lambda_m)$. The damage parameters remain stationary so long as the thermodynamic forces f_k associated with the respective damage parameters ξ_k

*Corresponding author. E-mail: a.koellner@imperial.ac.uk

do not reach the thresholds required to cause damage growth which are denoted by g_k. The thermodynamic forces are determined by evaluating the change of the total potential energy with respect to the damage parameters, thus

$$f_k = -\frac{\partial \Pi}{\partial \xi_k}, \quad \text{whereas the thresholds are given by} \quad g_k = \frac{\partial W_\mathrm{d}}{\partial \xi_k}. \tag{2}$$

The later describes the change of the dissipative energy (W_d) with respect to the kth damage parameter. Whenever the thermodynamic forces f_k reach the respective thresholds required, i.e. $f_k \geq g_k$ damage growth is caused. As has been shown in [2, 3], equality between f_k and g_k holds during stable damage growth, such that the equality for these processes can be rewritten in terms of

$$f_k - g_k = D_k(q_i, \lambda_m, \xi_k) = 0. \tag{3}$$

From Eq. (3), the damage parameters are implicitly given as functions of the generalized coordinates and the loading parameters assuming that a unique solution exists, thus

$$D_k\Big[q_i, A_m, \xi_k(q_i, \lambda_m)\Big] \equiv 0. \tag{4}$$

The damage parameters are obtained in explicit form, $\xi_k = \xi_k(q_i, \lambda_m)$, by employing a TAYLOR series approximation around the deformation state causing damage growth (cf. [2]). With the damage parameters expressed in terms of the configuration and the applied loading, an extended total potential energy Π^* may be derived, i.e.

$$\Pi^* = \Pi^*\Big[q_i, \lambda_m, \xi_k(q_i, \lambda_m)\Big]. \tag{5}$$

The variational principle $\delta\Pi^*(q_i) = 0$ yields the deformation path $q_i(\lambda_m)$ considering damage growth starting from the deformation state at which growth is initiated. The behaviour of the damage parameters can then be determined by substituting the deformation path obtained into $\xi_k(q_i, \lambda_m)$.

DELAMINATION BUCKLING

The formalism is applied to study the compressive behaviour of delaminated composite panels, as illustrated in Figure 1 (left) [4]. A RAYLEIGH-RITZ formulation is employed approximating the displacement field. Loading in the form of in-plane compressive strain is applied and the delamination area is considered as an active damage parameter. Results presented in Figure 1 (middle and right) show that deformation paths for an entire loading process (until failure due to unstable delamination propagation, cf. red diamond symbols in Figure 1(middle)) can be determined with the aid of the extended total potential energy. The results obtained are verified by finite element (FE) simulations performed in Abaqus (cf. circle symbols in Figure 1(middle)). The delamination growth behaviour associated with the deformation path shown in Figure 1 (middle) is visualized in Figure 1 (right). Both deformation path and delamination growth characteristics are in good agreement with corresponding FE simulations.

CONCLUSIONS

A concept for extending the general elastic stability theory has been presented that enables the stability behaviour of structures undergoing inelastic deformation to be studied. The formalism has been successfully applied to model delamination buckling in multilayered composites. However, the interaction between multiple active damage parameters has not yet been addressed. Therefore, the respective variational inequalities are planned to be considered by introducing the well-known KUHN-TUCKER conditions. Upon a successful implementation, a generalized exposition for the stability analysis of structures undergoing inelastic deformation can be formulated.

EQUILIBRIUM AND STABILITY OF THE NONLINEARLY ELASTIC NONHOMOGENEOUS CYLINDER WITH INTERNAL STRESSES

Mikhail Karyakin*[1,2], Leonid Obrezkov [3]

Summary The problem of equilibrium of a nonhomogeneous cylinder subjected to simultaneous uniaxial tension/compression and inflation is considered within the framework of the three-dimensional nonlinear theory of elasticity. The effect of internal stresses caused by a linear defect such as a wedge disclination on the process of the buckling of the cylinder is investigated. For the analysis, the well-known models for describing compressible materials, Murnaghan model and Blatz & Ko model, were used. Two types of material inhomogeneity are considered. The stability analysis was carried out on the basis of a combination of the semi-inverse method of the nonlinear elasticity and bifurcation approach. The stability regions are presented as areas on the plane of loading parameters. The possibility of the bifurcation curves condensing was demonstrated.

Internal stresses caused by defects of crystal lattice draw an attention by the reason of a big impact to actual mechanical behaviour such as plasticity, creep, destruction and so on [1]. In the context of elasticity theory of finite strains much motivation for the research comes from soft tissue biomechanics, and for a recent discussion of internal stresses in artery walls [2]. In the present work some issues of effects of internal stresses on the equilibrium and stability of elastic cylinders were studied within the framework of nonlinear elasticity.

We present results on the one specific type of isolated defect, namely the wedge disclination (Fig.1). To describe the mechanical properties of a cylinder two constitutive models for compressible elastic solid were used: Murnaghan material and Blatz & Ko material [3]. The specific energy function W for these models has the following form (1) and (2) respectively:

$$W=\frac{1}{4}\left[W_1 I_1+W_2 I_1^2+W_3 I_2-mI_1 I_2+W_4 I_1^3+\frac{n}{2}(I_3-1)\right], \tag{1}$$

$$W=\frac{1}{2}\mu(1-\beta)\left[I_2 I_3^{-1}+\frac{1}{\alpha}\left(I_3^{\alpha}-1\right)-3\right]+\frac{1}{2}\mu\beta\left[I_1+\frac{1}{\alpha}\left(I_3^{-\alpha}-1\right)-3\right], \tag{2}$$

where

$$W_1=-3\lambda-2\mu+\frac{9}{2}l+\frac{n}{2},\ W_2=\frac{1}{2}(\lambda+2\mu-3l-2m),\ W_3=-2\mu+3m-\frac{n}{2},\ W_4=\frac{1}{6}(l+2m);$$

$\alpha,\beta,\lambda,\mu,l,m,n$ – material parameters, $I_k(k=1,2,3)$ – principal invariants of the right Cauchy–Green deformation tensor. The first model is usually used to account for geometrical nonlinearities while the second one describes physical nonlinearities also.

To model tension/compression as well as inflation of the hollow cylinder with wedge disclination at its axis we use following representation of the deformation:

$$r=f(R),\ \varphi=\kappa\Phi,\ z=\gamma Z \tag{3}$$

where R,Φ,Z and r,φ,z – cylindrical coordinates in the reference and actual configuration respectively, κ – parameter of the defect (proportional to the magnitude of the Frank vector of the disclination), γ – positive coefficient of the cylinder stretching or shortening. The function $f(R)$ in (3) describes radial (non-uniform, in general) displacement of the cylinder points.

The analysis of length changing of an unloaded cylinder due to the defect formation was performed. This changing is completely described by the dependence of γ on the disclination parameter κ at the absence of axial force. It was shown numerically that it is nonlinear effect and the elongation $(\gamma>1)$ or shortening $(\gamma<1)$ depends on material parameters of the mechanical models (1), (2). To verify the numerical results the asymptotic formula was obtained within the limits of the second-order effects theory [3]. To construct the solution of equilibrium equations in this case we replace $f(R)$ in (3) by a series in terms of powers of the parameter $\delta=\kappa-1$. Considering the sequence of tasks corresponding to different powers of δ we obtain the analytical relationship between length changing of the cylinder and material parameters. In particular, for the simplified version of Blatz & Ko model $(\alpha=0.5)$ the elongation–disclination relation has the form

$$\gamma-1=-\delta^2(0.121\beta-0.0605).$$

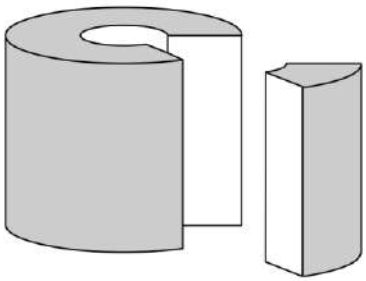

Figure 1. Scheme of the disclination formation in the hollow cylinder

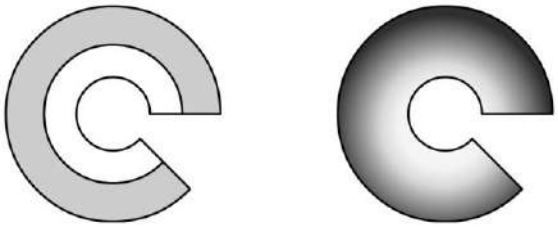

Figure 2. Two types of heterogeneity: composite cylinder and continuous inhomogeneity

To analyze the stability of a cylinder with isolated defect under tension and inflation the bifurcation approach was used based on linearization of the equilibrium equations in the neighborhood of the solutions obtained by means of the semi-inverse representation (3). Search of the bifurcation points is based on the analysis of the homogeneous linear boundary value problem of a six order, whose coefficients depend on radial displacement function $f(R)$ found in the first stage. The bifurcation point is treated as such value of the "loading" parameter – it can be the parameter of the defect, κ, or value of inflating pressure or axial force – for which the linearized problem has a nontrivial solution.

The semi-inverse approach based upon transformation (3) turns out to be applicable in some cases of an inhomogeneous cylinder. The most typical are two cases: a composite cylinder and a functional gradient material, in which the material parameters are continuous functions (Fig. 2).

In the first case, to determine the stress-strain state of the cylinder, that is, to find the function $f(R)$, it is required to solve a set of two second order ODE supplemented by the conditions of continuity of displacements and strains on the material dividing line. In the second case, coefficients of the equilibrium equation became variable and contain derivatives, $d\lambda/dR$, $d\mu/dR$ etc.

Numerical investigations of the problems under consideration showed, in particular, that the choice of the model had not a qualitative effect on the stress-strain state. If the parameters of the models were chosen so that in the linear approximation they corresponded to the same material, the difference in the distribution of normal stresses was no more than 10 percent. The effect of the choice of the model on the stability is much stronger. Special example of a variant of the Murnaghan material with a set of constants corresponding to plexiglass demonstrated the significance of the additional conditions of the Spector theorem in the analysis of the applicability of mathematical models of the behavior of elastic bodies in the region of large strains.

An important difference between thick and thin cylinders is the fact that the stability region is described by curves with different mode numbers. In addition, the condensing of bifurcation curves at one of the boundaries of the stability region was found for the case of the thick cylinder. Increasing the mode number n, starting from a certain value (about fifty), practically does not change the critical pressure. This fact agrees with the results obtained earlier in [1] for the harmonic material model. This, in particular, means that for such body it is impossible to predict the form of the stability loss based on the analysis of linearized equations. For a thinner cylinder, the $n=2$ mode is always preferred; the corresponding critical pressure is minimal. Another feature of thick cylinders is the existence of a zone where the loss of stability can occur only due to the presence of disclination without the application of external pressure. Such an area may be absent in the thinner cylinders.

Different types of the inhomogeneity of the cylinder material can also have noticeable influence upon the stability. In particular they can significantly change the region of stability of the unloaded cylinder having wedge disclination of the given strength. Although the shape of the stability region on the plane of loading parameters is generally preserved, it noticeably shifts depending on the parameters of the inhomogeneity. The direction of this bias, i.e., a positive or negative effect on stability, depends on both the type of heterogeneity and the disclination parameter.

Conclusions

The study of the equilibrium and stability of a hollow circular cylinder of compressible nonlinearly elastic material were carried out. Internal stresses in the cylinder are caused by the presence of a wedge disclination. A comparative analysis of the models used at various values of the parameters showed, in particular, that thick-walled cylinders are characterized by condensing of bifurcation curves, which can also occur in cases where there is no disclination, but its presence makes the condensation areas much more extensive. The presence of disclination can be both a stabilizing factor and vice versa – significantly reduce the value of the critical pressure. The type of inhomogeneity and its characteristics can also serve as a stability controlling factor.

TEMPERATURE-DEPENDENT DOMAIN PATTERN EVOLUTION IN FERROELECTRIC CERAMICS: A PHASE-FIELD INVESTIGATION

Roman Indergand[1] and Dennis M. Kochmann *[1]
[1]Department of Mechanical and Process Engineering, ETH Zürich, Zürich, Switzerland

Summary We present a ferroelectric phase-field model, which has been successfully extended to finite-temperature applications and validated by various measurements of different types of lead zirconate titanate (PZT). The introduced temperature-dependent Ginzburg-Landau potential (GLP) is of importance for a realistic prediction of the temperature-dependent behavior of ferroelectric ceramics, including the spontaneous polarization (predicted accurately over a wide temperature range), and the strain hysteresis during bipolar electric cycling. Furthermore, we use statistical mechanics to account for thermal fluctuations in the ferroelectric constitutive model and show that these lattice vibrations, accounted for by a stochastic Allen-Cahn evolution equation, lead to realistic ferroelectric microstructures with nucleation of needle-shaped domains at locations with high stress concentrations.

STATE OF THE ART

Ferroelectrics are a frequently-used class of active materials whose mechanical and electrical properties are coupled: applying an electric field results in deformation, whereas an applied deformation produces an electric voltage in turn. This is a strongly nonlinear thermo-electro-mechanically coupled phenomenon caused by atomic-level interactions of the electric dipole moments and the lattice distortion. While the linear piezoelectric response under small applied fields is well described by phenomenological models, the complex nonlinear, time-dependent behavior, and the long-term stability threatened by material fatigue and failure are far from being understood nor reliably predictable. The current lack of understanding stems primarily from the large range of length and time scales involved (from atomic-scale interactions to macroscopic samples, from fast switching events to the experimentally-observed hysteresis). This makes the underlying phenomena difficult to model computationally and hard to access experimentally. Much prior work has focused on thin films, where both experimental TEM imaging of ferroelastic switching and atomistic simulations have helped understand the relation between domain wall motion and the collective switching behavior under electrical and mechanical loads. Less is known about bulk ferroelectrics. Predictive insight has been gained from first-principles [1] but is applicable only at zero temperature and has been used to derive energetic equilibrium properties but not the kinetics of ferroelectric switching.

TEMPERATURE-DEPENDENT PHASE FIELD MODEL

In this work, we emphasize the impact of temperature on the ferroelectric material response of bulk polycrystalline lead zirconate titanate (PZT). To this end, an existing zero-temperature phase-field description of ferroelectric ceramics [2] (solved via spectral homogenization) is extended to account for the influence of temperature. This is realized in two steps. First, the underlying DFT-informed Ginzburg-Landau potential is modified to depend on temperature by interpolating linearly between the known non-convex potential at zero Kelvin and the convex potential at the Curie temperature. Second, the ferroelectric constitutive model is extended by a new statistical mechanics-based approach to account for thermally induced lattice vibrations at the atomic level. This results in a stochastically perturbed Allen-Cahn equation with a space-time Gaussian noise contribution as the evolution law for the polarization, now accounting for thermal fluctuations.

RESULTS

We demonstrate that the finite-temperature Ginzburg-Landau potential predicts the temperature-dependent spontaneous polarization reasonably well in comparison with measurements of various types of lead-based perovskite ferroelectrics over a broad range of temperature. Furthermore, a more accurate prediction of the strain hysteresis is accomplished, as verified through a comparison of the bipolar cycling hysteresis with measurement from [3]. The stochastic Allen-Cahn equation with the random noise term results in a more realistic evolution of the ferroelectric domain pattern formation based on the nucleation of sharp need-like domains at local stress concentrations (such as grain boundaries and grain triple junctions), as illustrated in Fig. 1.

POST BULGE BUCKLING OF A FINITE HYPERELASTIC TUBE: THEORY AND EXPERIMENTS

Masoud Hejazi*[1] and A. Srikantha Phani[1]
[1]Department of Mechanical Engineering, University of British Columbia, Vancouver, BC, Canada

Summary A pre-stressed finite hyperelastic tube subjected to an internal pressure can bulge at a critical pressure. For a fixed axial stretch the bulge can either propagate or buckle before it ruptures, depending on the boundary conditions. We report experiments on the inflation of a finite rubber tube under tension and use bifurcation theory to construct a failure map in the stretch parameter space to delineate post bulge deformation regimes. We compare the experiments and theoretical predictions in the stretch parameter space. We find that buckling occurs when the pre-tension is insufficient to sustain a propagating bulge.

PROBLEM FORMULATION AND METHODOLOGY

It is well known that a pre-tensioned hyperelastic tube exhibits a spatially localized bulge instability under gradual inflation [1, 2, 3]. Earlier studies have addressed the conditions under which a bulge initiates and propagates. However the bulge propagation may no longer be sustained if the tension is insufficient for a fixed axial stretch: buckling of the initially straight bulged tube occurs under displacement control. The setup for the inflation test is shown in Fig 1. The tube is fixed at one end and the other end is attached to a tensile tester jaw (Instron 5969) in order to apply a fixed pre-tension and then hold the displacement during the inflation test. A compressed air supply inflates the tube quasi-statically leading to the initiation of a bulge at a local imperfection: in the post bulge regime it can propagate or buckle. A digital camera records the deformation of the tube during inflation and the pressure transducer records the internal pressure. An edge detection algorithm is used for calculating the internal volume and to extract the bulge profile and buckling amplitudes for different thicknesses and lengths of the tube, and for different initial pre-tension. Here, bulging is accompanied by a sudden reduction in the measured internal pressure, and buckling is observed through a sudden reduction in the axial load as measured by the tensile tester.

Earlier bifurcation analyses have identified the effect of aspect ratio, the validity of membrane assumption, and the effect of the stretch gradient in a diffuse interface model [4]. In this study, we employ a diffuse interface model to analyze the axisymmetric bifurcation condition (bulge formation). Nonlinear Euler buckling analysis is performed by extending an earlier study in [5] to include pre-tension and the existence of a propagating bulge.

Bifurcation analysis

We use two cylindrical polar co-ordinate systems: $R-\Theta-Z$ in the undeformed configuration and $r-\theta-z$ in the deformed configuration. The later is shown in Fig. 1c.

Axisymmetric bifurcation: To analyze the bifurcation condition for bulge formation, we use a diffuse interface model [4] for an axisymmetric membrane. The membrane energy per unit reference (undeformed) volume is

$$g_0(p,\lambda_z,\lambda_\theta) = w - p\frac{e}{2}\lambda_z{\lambda_\theta}^2, \tag{1}$$

where w is the strain energy density function, p is the internal pressure, λ_z is the longitudinal stretch, λ_θ is the circumferential stretch, and $e = R_i/H$ is the internal radius to thickness ratio. The axial equilibrium is set by $\partial g_0/\partial\lambda_z = 0$, which yields the longitudinal stretch as a function of internal pressure and circumferential stretch $\lambda = \lambda_0(p,\lambda_\theta)$. Introducing the circumferential stretch gradient, $\lambda_\theta^{'} = d\lambda_\theta/dZ$ in the Green-Lagrange strain the circumferential equilibrium condition follows as

$$h_l(p,\lambda_\theta(Z)) - \frac{1}{2}\frac{\partial G_l}{\partial\lambda_\theta}(p,\lambda_\theta(Z)){\lambda_\theta^{'}}^2(Z) + \frac{d}{dZ}(G_l(p,\lambda_\theta(Z))\lambda_\theta^{'}(Z)) = 0, \tag{2}$$

where $G_l = R_i^2/\lambda_0\,[\partial w/\partial\lambda_0(\lambda_0,\lambda_\theta Z)]$, and $h_l = \partial g_0/\partial\lambda_\theta(p,\lambda_0,\lambda_\theta)$. Under displacement (fixed boundary) control, the linear bifurcation analysis gives the bifurcation condition for the global axisymmetric deformation is

$$\frac{\partial h_l}{\partial\lambda_\theta}(p,\bar{\lambda}_\theta) = G_l(p,\bar{\lambda}_\theta)\frac{\pi^2}{L^2}. \tag{3}$$

which expresses the balance between the energy needed for radial expansion of the tube (left hand side in the above) and the energy required for bulge initiation.

Lateral bifurcation: The Buckling analysis begins with defining the incremental equilibrium based on Ogden's formulation $div\dot{\tilde{\mathbf{S}}}_0 = 0$. Where incremental nominal stress $\tilde{\boldsymbol{S}}_0$ is defined based on the gradient of the displacement field $\tilde{\boldsymbol{\eta}} = grad(\boldsymbol{U})$, strain energy function w, and Lagrange multiplier P to enforce incompressibility.

$$\dot{\tilde{\boldsymbol{S}}}_0 = \tilde{\boldsymbol{B}}\tilde{\boldsymbol{\eta}} + P\tilde{\boldsymbol{\eta}} - \dot{P}\boldsymbol{I}, \tag{4}$$

*Corresponding author. E-mail: masoud.hejazi@mech.ubc.ca

where $\dot{P}$ is the increment in Lagrange multiplier and $\tilde{\boldsymbol{B}}$ is the fourth-order tensor of instantaneous elastic moduli defined by strain energy function. We can construct an eigenvalue problem by defining the displacement vector components $\boldsymbol{U} = [u_r(\rho)\cos(m\theta)\cos(n\pi\zeta),\ u_\theta(\rho)\sin(m\theta)\cos(n\pi\zeta),\ u_z(\rho)\cos(m\theta)\sin(n\pi\zeta)]^T$, where m is the circumferential mode number, and n is the longitudinal mode number. $\rho = r/R_i$ and $\zeta = z/L$ are respectively the dimensionless radial and longitudinal coordinates. Solving with respect to boundary conditions (at inner $\boldsymbol{U}(0)$ and outer $\boldsymbol{U}(R_o)$ surfaces) by employing the state space approach and layer-wise method for laminated in-homogeneous tubes we obtain

$$\tilde{\boldsymbol{C}}\,[u_r(0), u_\theta(0), u_z(0), u_r(R_o), u_\theta(R_o), u_z(R_o)]^T = \boldsymbol{0}. \tag{5}$$

For non-trivial solution, the bifurcation condition is obtained by having $|\tilde{\boldsymbol{C}}| = 0$, where the elements of $\tilde{\boldsymbol{C}}$ are the functions of the longitudinal mode number, derivatives of strain energy function with respect to principal stretches ($\lambda_{r,\,\theta,\,z}$), and internal pressure.

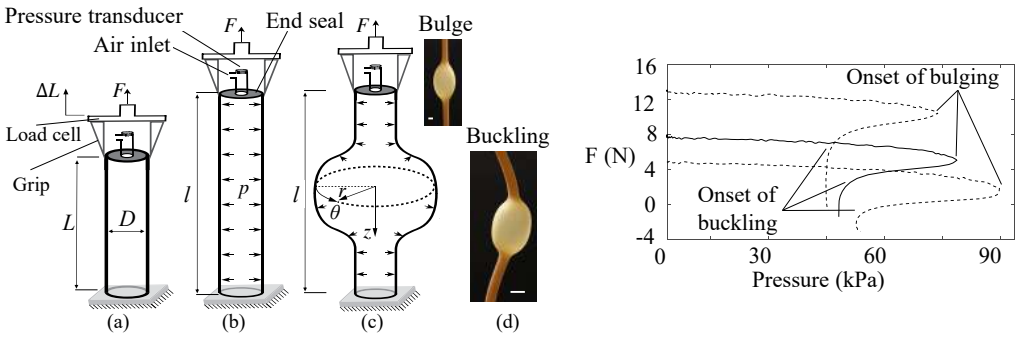

Figure 1: Left) Experiment overview. (a) Applying pre-tension by increasing the length from L to $l = L + \Delta L$; (b) Inflation due to internal pressure(p) while keeping the length constant; (c) Bulge formation and coordinate system. (d) Buckling; Scale bar indicates 1 cm. The axial force F is measured by Instron's load cell during inflation. Right) Longitudinal force vs. internal pressure for three different pre-stretches.

RESULTS AND CONCLUSION

Fig. 2a portrays different bifurcation regimes (axisymmetric and lateral) calculated using equations 3 and 5. The blue region (see color figure) right to the dashed line is the regime of bulge formation and the yellow region under the solid line is the buckling zone. The tube follows the path indicated by the dotted-dashed line during inflation, and the corresponding experimental data points are shown for three independent experiments. Experiments confirm the validity of our analysis. It is to be noted that the longitudinal and circumferential stretches have been measured during the inflation for section A-A (see Fig. 2a). Fig. 2b shows the stress distribution suggesting that the rupture is more likely to occur in the transition region (peak of the hoop stress calculated using strain energy function) between the uniform and the bulged portions of the tube. Our study shows the possible bifurcation behaviour of finite hyperelastic tubes. The critical and post-critical analysis for bulging has been addressed here. Post-bifurcation failure analyses are in progress and will be addressed in the future.

JACOBI CONJUGATE POINTS, STABILITY AND COMPUTING END-TO-END PROBABILITIES FOR ELASTIC RODS

Giulio Corazza*, Raushan Singh, and John H. Maddocks
Laboratory for Computation and Visualization in Mathematics and Mechanics (LCVMM) Institute of Mathematics, Swiss Federal Institute of Technology (EPFL), CH-1015 Lausanne, Switzerland

Summary It is widely known how to efficiently compute equilibria of (hyper-)elastic rods subject to prescribed two-point boundary conditions, for example using the Hamiltonian form of the Euler-Lagrange equations for the associated energy [4, 6]. The classification of which equilibria are also stable in the sense of realising local minima of the energy can then be carried out using conjugate point theory, specifically, counting the number of zeros of a determinant evaluated on Jacobi fields associated with the second variation of the energy. What is less well-known is that the energy of equilibria combined with the actual value of the same Jacobi field determinant can be used to estimate probability densities for the distribution of end-to-end displacements when the rod is interacting with a heat bath (as is the case for example in elastic rod models of DNA). We demonstrate how to derive such an approximate conditional probability density function governing the relative location and orientation of the two ends, when the rod is subject to a prescribed external end-loading, in addition to external stochastic forcing from the heat bath (as happens in many single molecule experiments).

INTRODUCTION

Recent interest in the theory of special Cosserat rods has surged in part due to its applicability in molecular biophysics and modeling polymers. Starting from an assumed Boltzmann distribution on rod configurations, it is widely understood that a conditional probability can be expressed as the ratio of a Boltzmann weighted integral over all rod configurations or paths satisfying the desired end conditions, to the analogous weighted path integral over all admissible configurations. In turn these path integrals can be explicitly evaluated [3] if they can be transformed to be quadratic in appropriate variables, or if they can be approximated by a quadratic expansion about a minimum energy configuration satisfying prescribed end conditions. In particular, the contribution of local quadratic fluctuations around that minimum is captured by an appropriate modification of a conjugate point stability analysis. Our motivation for the present work is to exploit continuum mechanics models in order to evaluate conditional probability densities related to a wide range of applications, providing an extension of [1, 2] for dealing with systems driven by more general energies, e.g. including prescribed external end loadings, as arise for example in molecular tweezer experiments.

THE METHOD

Following the Cosserat theory of elastic rods, the configuration of the system is given by $\boldsymbol{q}(s) := (\boldsymbol{R}(s), \boldsymbol{r}(s)) \in SE(3)$, $s \in [0, L]$, where $\boldsymbol{r}(s)$ is the centerline vector in $\mathbb{R}^3$ and $\boldsymbol{R}(s) \in SO(3)$ is defined as the proper rotation relating a fixed, right-handed, orthonormal frame to the directors frame in $\mathbb{R}^3$, modeling the cross-section orientation of the rod. Under the assumption of linear hyper-elasticity, we consider a Lagrangian formulation of the problem, driven by the energy functional $E(\boldsymbol{q}(s)) = \int_0^L W(\boldsymbol{q}'(s), \boldsymbol{q}(s), s)\, ds$. The energy density W takes into account both the strain energy and the contribution coming from an external end loading $\boldsymbol{\lambda}$ at $\boldsymbol{q}_L := \boldsymbol{q}(L)$. When the system is at thermodynamical equilibrium, the conditional probability density in the variable $\boldsymbol{q}_L$ is given in terms of path integrals as

$$\rho(\boldsymbol{q}_0, \boldsymbol{q}_L; 0, L) := \frac{\int e^{-\beta E(\boldsymbol{q}(s))}\, \mathsf{D}[\boldsymbol{q}(s)]_{\boldsymbol{q}(0)=\mathbf{0}}^{\boldsymbol{q}(L)=\boldsymbol{q}_L}}{\int e^{-\beta E(\boldsymbol{q}(s))}\, \mathsf{D}[\boldsymbol{q}(s)]_{\boldsymbol{q}(0)=\mathbf{0}}}, \tag{1}$$

where $\beta = \frac{1}{k_B T}$, k_B is the Boltzmann constant, T is the temperature of the system and D is defined by discretization as a measure on the space of rod configurations. Notice that we can assume $\boldsymbol{q}_0 := \boldsymbol{q}(0) = (\mathbb{1}, \mathbf{0})$ for invariance under rigid body motions. The approximation method relies on a Laplace asymptotic technique for both numerator and denominator of (1) and it requires the existence of the following minima of the energy, respectively local (l) and global (g).

1. $\boldsymbol{q}^l(s)$ satisfying the boundary conditions $\boldsymbol{q}^l(0) = \boldsymbol{q}_0 = (\mathbb{1}, \mathbf{0})$, $\boldsymbol{q}^l(L) = \boldsymbol{q}_L = (\boldsymbol{R}_L, \boldsymbol{r}_L)$,
2. $\boldsymbol{q}^g(s)$ satisfying the boundary condition $\boldsymbol{q}^g(0) = (\mathbb{1}, \mathbf{0})$ and the natural boundary condition at $s = L$.

In particular, it is possible to show that $\rho(\boldsymbol{q}_0, \boldsymbol{q}_L; 0, L)$ is given by a component depending on the "distance" between the solutions of the Euler-Lagrange equations for the minima and another component depending on the "distance" between the solutions of the Jacobi equations on the minima. Specifically, we have that the approximation of $\rho(\boldsymbol{q}_0, \boldsymbol{q}_L; 0, L)$ is given by

$$\left(\frac{\beta}{\pi}\right)^3 \exp\left\{-\beta\left[E(\boldsymbol{q}^l) - E(\boldsymbol{q}^g)\right] - \frac{1}{2}\left[\ln Det[\boldsymbol{J}^l(0)] - \ln Det\,[\boldsymbol{J}^g(0)]\right]\right\},$$

where the Hamiltonian version of the Jacobi equation for $s \in [0, L]$ is driven by the symplectic skew-symmetric matrix

*Corresponding author. E-mail: giulio.corazza@epfl.ch

$\mathbb{E}$ and the symmetric matrix $\boldsymbol{S}$ coming from the second variation of the energy for the two minima. The boundary conditions determine a complete set of linearly independent solutions, which fully characterise the system by mean of linear differential equations as follow:

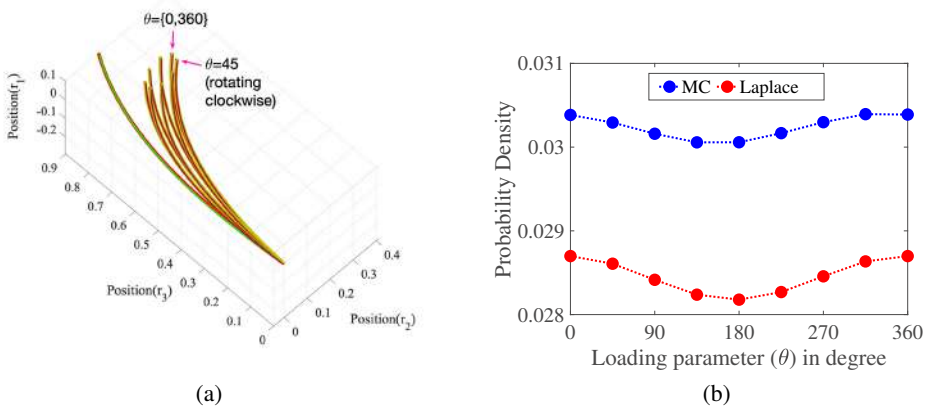
$$\begin{cases} \begin{pmatrix} \boldsymbol{J}^l \\ \boldsymbol{M}^l \end{pmatrix}' = \mathbb{E}\boldsymbol{S}^l \begin{pmatrix} \boldsymbol{J}^l \\ \boldsymbol{M}^l \end{pmatrix}, \\ \begin{pmatrix} \boldsymbol{J}^l \\ \boldsymbol{M}^l \end{pmatrix}(L) = \mathbb{E} \begin{pmatrix} \mathbb{1} \\ \mathbf{0} \end{pmatrix}, \end{cases} \qquad \begin{cases} \begin{pmatrix} \boldsymbol{J}^g \\ \boldsymbol{M}^g \end{pmatrix}' = \mathbb{E}\boldsymbol{S}^g \begin{pmatrix} \boldsymbol{J}^g \\ \boldsymbol{M}^g \end{pmatrix}, \\ \begin{pmatrix} \boldsymbol{J}^g \\ \boldsymbol{M}^g \end{pmatrix}(L) = \mathbb{E} \begin{pmatrix} \mathbf{0} \\ \mathbb{1} \end{pmatrix}. \end{cases}$$

A NUMERICAL EXAMPLE

We consider a family of cycling loadings applied to the L-tip of a rod deforming in the 3-dimensional space. As a roulette, there will be a configuration maximizing/minimizing the density. The end-loadings are given by

$$\boldsymbol{\lambda}_i = \frac{1}{20}\left(\sin(\theta_i), \cos(\theta_i), 0\right), \quad \theta_i = \frac{\pi}{4} i \ \text{ for } \ i = 1, ..., 8.$$

Thus we have 8 different global minima indexed by the related force, which are located around the minimizer of the elastic energy part, i.e the intrinsic configuration of the rod. Finally, for each load we are computing the conditional probability density for the end of the rod to be in a fixed prescribed configuration. Notice that the latter boundary condition determines the shape of the local minimum through the Euler-Lagrange equations. The experimental set up is shown in Fig. 1(a). Moreover, a Monte Carlo (MC) implementation [5] of the problem is provided in order to assess the accuracy level of the proposed approximation (Laplace). The comparison is displayed in Fig. 1(b).



(a) (b)

Figure 1: (a) Profiles of global minima (red-yellow) for each load parametrized in degree. The local minimum is determined by the chosen boundary condition (red-green) (b) Conditional probability densities: comparison between Laplace theoretical values and Monte Carlo simulations.

CONCLUSIONS

We have described a new theory to estimate end-to-end probability distributions for an elastic rod that is subject to both a stochastic interaction with a heat bath and a deterministic end-loading. We have illustrated our analysis with a 3-dimensional example and computed an approximate probability density which gives a good agreement with direct Monte Carlo numerical simulations. The new method is of quite general applicability as no assumption is made on either uniformity, nor on the intrinsic shape, of the elastic rod model. Consequently our results can be exploited in a variety of interesting applications, such as the computation of looping probabilities for a DNA fragment of given sequence subject to end-loading, or other conditional probability densities for more general polymer systems.

LOSS OF ELLIPTICITY IN SOFT COMPOSITES WITH FIBERPLASTICITY

Fernanda F. Fontenele[1], Michalis Agoras[2], and Nikolaos Bouklas*[1]
[1]Sibley School of Mechanical and Aerospace Engineering, Cornell University, Ithaca, NY, USA
[2]Department of Mechanical Engineering, University ot Thessaly, Volos, Greece

Summary This paper presents a modeling effort to capture global instability events, such as kink-band formation, during non-monotonic loading conditions of soft composites driven by fiber plasticity. This study brings new insight to damage initiation of biological fibrous tissues and engineered soft composites. To this end, a finite-strain phenomenological model that captures the effects of fiber plasticity by means of a back stress is proposed first and then the model is used to track the emergence of discontinuity fronts in the context of loss of ellipticity. It is confirmed that upon initial tensile loading in the direction of the fibers, and plastic deformation of the fibers, the composite can exhibit macroscopic localization during unloading. Contrary to past studies, loss of ellipticity in this case can occur as the composite is still under tensile loading; it is noteworthy that while the fiber stretch is tensile at loss of ellipticity, the elastic fiber stretch is contractile.

INTRODUCTION

Biological fiber-reinforced composites such as tendon, undergo cyclic loading and exhibit a complex damage response—from damage initiation in the form of kink band formation, fiber/matrix debonding, fiber rupture and to ultimate failure—and collagen fibril plasticity is known to play a crucial role in that damage cascade. In engineered fiber-reinforced soft composites, it is important to investigate the effects of fiber plasticity to optimize the strength and toughness of these materials. Localized deformation patterns of the kink-band type have been observed in biological composite materials such as mamalian tendon tissue, with uni-directional collagen-fibril reinforcement when subjected to tensile fatigue loading [3]. In the relevant literature, the formation of these kinks is not well understood, and they are only treated as a precursor to material failure. In parallel, apart from the finite elastic strains that are apparent in these materials, there is evidence of plastic deformation mechanisms present in collagen fibrils when loaded in uniaxial tension [4]. From a modeling perspective, loss of ellipticity of the governing equations of equilibrium, allows the prediction of emergence of macroscopic localization fronts. Loss of ellipticity of both phenomenological and micro-mechanical models has been extensively analyzed to investigate localized deformation patters in several classes of materials, including fiber-reinforced composites with hyperelastic or elastoplastic constituents ([5], [6], [2]). Most of these studies, however, focus on monotonic loading conditions involving compressive or tensile stresses along the fiber direction. In this paper, we focus in the emergence of localization in fiber-reinforced soft composites with elastoplastic fibers and elastic matrix under non-monotonic loading conditions.

CONSTITUTIVE MODELING

The soft materials of interest in this work are treated as fiber-reinforced composites, consisting of an elastic matrix reinforced by elastoplastic fibers at the microscopic scale, and assumed to be homogeneous, transversely isotropic, and incompressible solids at the macroscopic scale.

Consider a macroscopically homogeneous, but otherwise arbitrary, deformation of the composite from a given reference configuration described by a constant deformation gradient tensor $\mathbf{F}$, let $\mathbf{C} = \mathbf{F}^T\mathbf{F}$, and define the following set of independent transversely isotropic invariants of $\mathbf{C}$

$$I_1 = \mathrm{tr}\mathbf{C}, \quad I_2 = \frac{1}{2}\left[(\mathrm{tr}\mathbf{C})^2 - \mathbf{C}^2\right], \quad I_3 = \det\mathbf{C}, \quad I_4 = \mathbf{A}\cdot(\mathbf{C}\mathbf{A}) = \mathbf{C}:\mathbf{A}\otimes\mathbf{A}, \quad I_5 = \mathbf{A}\cdot(\mathbf{C}^2\mathbf{A}) \tag{1}$$

where $\mathbf{A}$ denotes the unit vector along the fiber direction in the reference configuration. For any given deformation path, we assume that the elastic part of the macroscopic constitutive relation of the composite is completely determined by means of the following strain energy density function

$$W(I_1, I_3, I_4, p; \lambda_f^p) = \frac{\mu}{2}(I_1 - 3) + p(I_3^{1/2} - 1) + \gamma(I_4 - (\lambda_f^p)^2)^2, \tag{2}$$

where μ and γ are the elastic moduli of the composite in the linearly-elastic regime, p is the Lagrange multiplier enforcing the incompressibility constraint, and λ_f^p is some effective measure of the accumulated plastic stretch in the fibers along $\mathbf{A}$ from the reference to the current configuration along the deformation path. Note that, in the context of (2), λ_f^p plays the role of an internal variable, which induces a back stress on the macroscopic response of the composite, and which may have a dramatic effect on the overall stability of the composite, as illustrated in the following section.

*Corresponding author. E-mail: nbouklas@cornell.edu

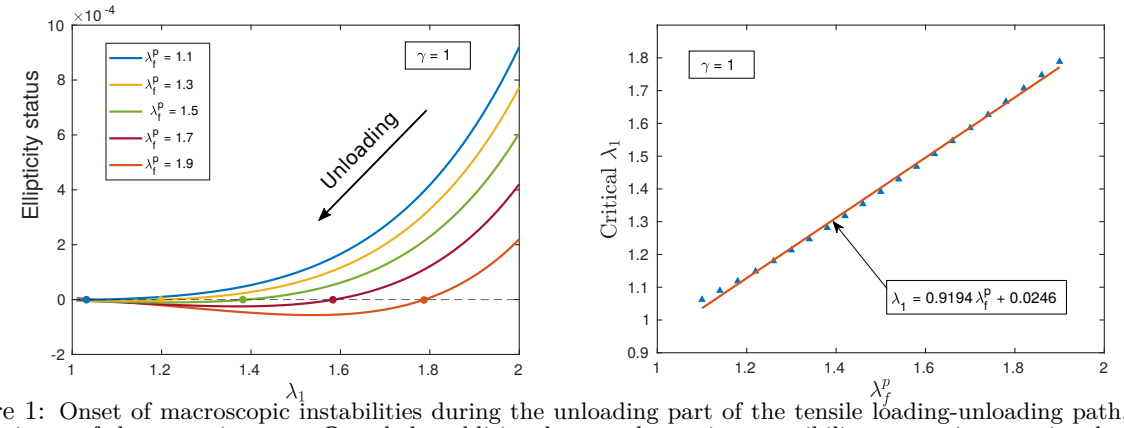

Figure 1: Onset of macroscopic instabilities during the unloading part of the tensile loading-unloading path. (a) The determinant of the acoustic tensor $\mathbf{Q}$ and the additional terms due to incopressibility constraint associated with (2) is shown as a function of the applied stretch λ for different values of the accumulated plastic stretch in the fibers λ_f^p. (b) The critical stretch λ_1^{cr} as a function of the plastic fiber stretch λ_f^p.

RESULTS AND DISCUSSION

For the purpose of this work, and given the space limitations, in the sequel we focus on the investigation of the overall stability of fiber-reinforced composites defined (partially) by (2) under a loading-unloading path of uniaxial tension along the fiber direction $\mathbf{A}$. In addition, we assume that the response of the composite is elastoplastic, stable, and known during loading and purely elastic, possibly unstable, and unknown during unloading. Hence, following the formulation by [7], [8], [2], we investigate the strong ellipticity condition for the strain energy function (2) during unloading, by treating the plastic stretch of the fibers λ_f^p as a known parameter. We remark that, the associated macroscopic stretch λ along the fiber direction may be decomposed as $\lambda = \lambda_f^e \lambda_f^p$, where λ_f^e is the elastic stretch of the fibers along $\mathbf{A}$.

Specific results for the loss of strong ellipticity of (2) during tensile unloading are shown in Fig. $1(a)$. These results illustrate that macroscopic strain localization is possible in the composite and occurs closer to the reference state for lower values of the plastic stretch λ_f^p. Fig.$1(b)$ shows results for the critical macroscopic stretch λ^{cr} at the onset of localization as a function of the plastic fiber stretchλ_f^p, also showing a linear fit between the two variables $\lambda^{cr} = 0.9194\lambda_f^p + 0.0246$. This allows the approximation of the critical elastic stretch $\lambda_f^{e,cr}$ of the fibers at loss of ellipticity as $\lambda e, cr_f = 0.9194 + 0.0246/\lambda_f^p$ which allways leads to $\lambda e, cr_f < 1$, as also verified by the exact results. We observe that the elastic stretch $\lambda_f^{e,cr}$ of the fibers at the onset of localization is contractile, even though the corresponding macroscopic stretch λ^{cr} is extensive. This is a critical detail, highlighting the effect of having an elastic mismatch between the plastically deforming fibers and the elastic matrix, which leads to the emergence of the localization fronts in the composite.

CONCLUSIONS

In this work, we have proposed a phenomenological, transversely isotropic model for the finite-strain, macroscopic response of soft fiber-reinforced composites, incorporating the effects of elastic deformations in the matrix and elastoplastic deformations in the fibers. In the context of this model, we found that plastic deformation induced to the fibers during tensile loading leads to loss of strong ellipticity during unloading while, macroscopically, the material is still in tension. However, when ellipticity is lost, it is observed that the elastic part of the fiber deformation is already contractile. The outcome of this analysis provides a first investigation and insight to an exciting new class of problems with significant biomechanical relevance.

Summary In this work, we study the microscopic and long-wave instabilities in a class of non-Gaussian hyperelastic fiber composites with Gent phases. In particular, we investigate the influence of stiffening of phases on the onset of instabilities and the associated wavelengths. We derive an analytical expression to predict the onset of long-wave instabilities. By employing Bloch-Floquet analysis, we determine the critical parameters corresponding to the microscopic instabilities. The stiffening behavior of phases strongly defines the wavelength of the buckling patterns, together with the onset of instabilities. As a consequence, the interplay between long-wave and microscopic instabilities is highly dictated by the extent of phase stiffening. Hence, phases with pre-designed properties enable us to tailor the instability-induced patterns in soft fiber composites.

INTRODUCTION

Elastic instability phenomenon in soft microstructured materials has gained significant attention, since it can be used to trigger sudden microstructure transformations [1]. These transformations often accompany several unusual material properties, such as – instability-induced elastic wave band gaps [2], auxetic behavior [3], and the emergence of negative group velocity in marginally stable soft composites [4].

The onset of instabilities and the associated buckling patterns in soft composites are strongly defined by their microstructure [5,6] and contrast in the initial stiffness of the phases [7]. Additionally, the rich and complex behavior of soft phases, such as, viscoelasticity and stiffening effect, can further increase the admissible range of tunable microstructures. In this work, we study the influence of stiffening effects – stemming from the non-Gaussian statistics of polymer chains – on the stability of 3D fiber composites. Specifically, we examine the fiber composites with the phases characterized by the Gent model. We also study the interplay between the microscopic and macroscopic instabilities. To this end, we derive the analytical expression corresponding to the onset of long-wave instabilities using loss of ellipticity analysis, and employ Bloch-Floquet analysis superimposed on finite deformations to detect microscopic instabilities and associated buckling modes.

ANALYSIS

Consider the fiber composites being subjected to uniaxial deformation along the direction of fibers ($\mathbf{e_3}$) with macroscopic deformation $\bar{\mathbf{F}}$ gradient given as

$$\bar{\mathbf{F}} = \lambda^{-1/2}\left(\mathbf{e_1}\otimes\mathbf{e_1} + \mathbf{e_2}\otimes\mathbf{e_2}\right) + \lambda\mathbf{e_3}\otimes\mathbf{e_3}. \tag{1}$$

Next, we discuss the method used for detecting the onset of macroscopic and microscopic instabilities in fiber composites with Gent phases having strain energy density function: $\psi_G^{(f,m)} = -\frac{1}{2}\mu^{(f,m)}J_m^{(f,m)}\ln\left(1-\frac{I_1^{(f,m)}-3}{J_m^{(f,m)}}\right)$, where μ is the initial shear modulus, (f,m) corresponds to fiber or matrix phase and J_m is the dimensionless locking parameter, which accounts for the limiting polymeric chain extensibility. The lock-up phenomenon appears in the limit $(I_1-3)\to J_m$.

Long-wave instability

To predict the onset of long-wave instability, we use loss of ellipticity analysis. First, we calculate the effective elastic moduli tensor $A_{\alpha i\beta j}$ for transversely isotropic incompressible hyperelastic fiber composite with Gent phases for the uniaxial deformation (1). In the current configuration the effective elastic moduli is obtained as $A^0_{piqj} = J^{-1}\bar{F}_{p\alpha}\bar{F}_{q\beta}A_{\alpha i\beta j}$. Application of strong ellipticity condition on A^0_{piqj} results in a explicit polynomial in the critical stretch (λ_{cr}), namely $\sum_{i=0}^{12} a_i\lambda_{cr}^i = 0$, where coefficients a_i are the functions of material and geometry parameters [8].

Microscopic Instability

To predict the onset of microscopic instabilities, we have used a two-step analysis. First, we apply the macroscopic deformation gradient (1) by imposing the periodic boundary condition. Then, we superimpose the Bloch-Floquet periodicity conditions on the deformed state with incremental displacement as $\mathbf{u}(\mathbf{X}+\mathbf{R}) = \mathbf{u}(\mathbf{X})e^{i\mathbf{K}\cdot\mathbf{R}}$, where $\mathbf{K}$ is the Bloch-wave vector and $\mathbf{R}$ being the spatial periodicity vector. The corresponding eigenvalue problem is solved at each deformation level for a range of $\mathbf{K}$ until a non-trivial eigenvalue is detected. The strain level for which $\omega(\mathbf{K})=0$ appears, corresponds to the onset of instabilities. For detailed description, please see reference [7]. Note that the same scheme can be used for long-wave instability analysis [9].

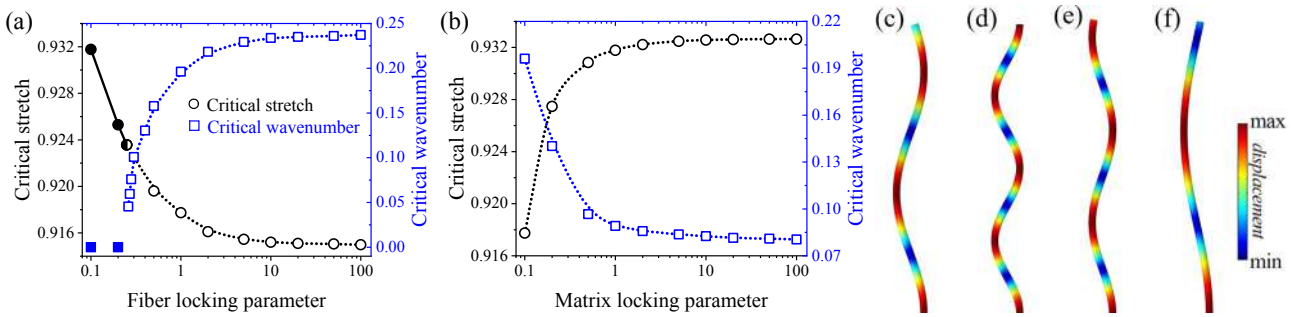

Figure 1: Dependence of critical stretch and normalized critical wavenumber on the fiber (a) and matrix (b) locking parameters; (c), (d), (e) and (f) represent the buckling modes of fibers for composites with various phase locking parameters. The color shows the magnitude of in-plane displacement.

RESULTS

Fig. 1 illustrates the dependence of critical stretch and the associated wavelengths (inverse of critical wavenumber) on the fiber locking parameter ($J_m^{(f)}$) (a) and matrix locking parameter ($J_m^{(m)}$) (b). The results are shown for the fiber composites with fiber volume fraction = 0.048, shear modulus contrast = 100, and $J_m^{(m)} = 0.1$ for subfigure (a) and $J_m^{(f)} = 1$ for subfigure (b). The filled and hollow symbols correspond to macroscopic and microscopic instabilities, respectively. The half-filled symbol marks the point corresponding to the transition of instability mode. We observe that the stability of the composites increases (critical stretch decreases) with an increase in the fiber locking parameter and/or decrease in the matrix locking parameter. Moreover, the critical wavelength corresponding to the microscopic instabilities increases with a decrease in the fiber locking parameter and/or with an increase in the matrix locking parameter. As a consequence, the composites with stiffening fibers tend to develop long-wave instabilities, whereas the composites with stiffening matrix phase are more prone to microscopic instabilities.

The subfigures (c), (d), (e) and (f) represent the buckling mode of fibers, which develop as a result of microscopic instabilities in the composites with various phase locking parameters. In particular, the locking parameters are: $J_m^{(f)} = 0.4$ and $J_m^{(m)} = 0.1$ (c); $J_m^{(f)} = 2$ and $J_m^{(m)} = 0.1$ (d); $J_m^{(f)} = 1$ and $J_m^{(m)} = 0.1$ (e); and $J_m^{(f)} = 1$ and $J_m^{(m)} = 1$ (f). The height of all the buckling modes is identical. It is evident from these buckling modes, that even a small variation in the locking parameters of phases results in significant changes in the shape of these patterns.

CONCLUSIONS

We have investigated the microscopic and long-wave instabilities in 3D fiber composites with Gent phases. Our results indicate that the critical strains and the associated wavelengths are significantly affected by the locking parameters of the phases. In summary, we show that the stiffening effect (stemming from the accurate non-Gaussian based models) together with instability phenomenon lead to the widening of admissible pool of tunable microstructures. Finally we note that practically, the extent of stiffening behavior can be regulated by varying the level of cross-linking.

STABILITY OF NONLINEARLY ELASTIC SPHERE WITH DISTRIBUTED DISLOCATIONS

Evgeniya Goloveshkina *and Leonid Zubov
Institute of Mathematics, Mechanics, and Computer Science, Southern Federal University, Rostov on Don, Russia

Summary The formulation and solution of the stability problem for a three-dimensional elastic body is given, taking into account the microstructure. The buckling of a hollow nonlinear elastic sphere from a semi-linear (harmonic) material with edge dislocations is investigated. The study was carried out in the framework of the continuum theory of continuously distributed dislocations using the linearization method (the static Euler method). By solving a homogeneous linear boundary value problem, the minimum pressure value at which the sphere loses stability for the first time is found. The effect of dislocations on the buckling of thin and thick shells is analyzed.

Acknowledgments: The reported study was funded by the Russian Foundation of Basic Research, project number 19-31-90045.

INTRODUCTION

Dislocations, which are defects in a solid microstructure, have a significant effect on the deformation and strength properties of materials. Using dislocation models, one can describe other defects of crystalline materials, as well as such mechanical phenomena as inelasticity, crystal growth, fatigue, and some others [1, 2, 5]. In this paper, within the framework of the continuum theory of continuously distributed dislocations, we consider the stability problem for a nonlinearly elastic sphere with dislocations. Most studies concern the stability of thin rods, plates, and shells [6, 7, 8, 9]. However, the phenomenon of stability loss is advisable to study for three-dimensional elastic bodies too [3, 10].

STABILITY PROBLEM

In the framework of the three-dimensional nonlinear elasticity theory, the influence of distributed dislocation on the equilibrium stability of a thick-walled closed spherical shell loaded with external hydrostatic pressure is studied. The system of equations of the nonlinear dislocation theory consists of equilibrium equations

$$\mathrm{div}\mathbf{D} = 0,$$

constitutive equations of the material

$$\mathbf{D} = \mathrm{d}W(\mathbf{C})/\mathrm{d}\mathbf{C},$$

and incompatibility equations

$$\mathrm{rot}\mathbf{C} = \boldsymbol{\alpha}, \tag{1}$$

where $\mathbf{C}$ is the distortion tensor, $\mathbf{D}$ is the Piola stress tensor, W is the specific strain energy, and $\boldsymbol{\alpha}$ is the dislocation density tensor satisfying the solenoidality condition

$$\mathrm{div}\boldsymbol{\alpha} = 0\,.$$

In this paper, the gradient, rotor, and divergence operators are written in the reference configuration.

We consider a spherically symmetric distribution of edge dislocations defined by the dislocation density tensor

$$\boldsymbol{\alpha} = \beta(r)\left(\mathbf{e}_\varphi \otimes \mathbf{e}_\theta - \mathbf{e}_\theta \otimes \mathbf{e}_\varphi\right)\,. \tag{2}$$

Here $\beta(r)$ is a given function, r, φ, θ are the spherical coordinates, $\mathbf{e}_r$, $\mathbf{e}_\varphi$, $\mathbf{e}_\theta$ are the unit vectors tangent to coordinate lines.

For an isotropic material, by virtue of (2), the incompatibility equation (1) has a solution [4]

$$\mathbf{C}_0 = C_1(r)\mathbf{e}_r \otimes \mathbf{e}_r + C_2(r)\left(\mathbf{e}_\varphi \otimes \mathbf{e}_\varphi + \mathbf{e}_\theta \otimes \mathbf{e}_\theta\right), \tag{3}$$

and the Piola stress tensor according to (3) takes the form

$$\mathbf{D}_0 = D_1(r)\mathbf{e}_r \otimes \mathbf{e}_r + D_2(r)\left(\mathbf{e}_\varphi \otimes \mathbf{e}_\varphi + \mathbf{e}_\theta \otimes \mathbf{e}_\theta\right)\,.$$

Boundary conditions

$$D_1(r_0) = -p_0 C_2^2(r_0), \quad D_1(r_1) = 0 \tag{4}$$

*Corresponding author. E-mail: evgeniya.goloveshkina@yandex.ru.

mean the loading of the outer sphere's surface $r = r_0$ with the hydrostatic pressure p_0.

The equilibrium stability is studied by the static Euler method based on the linearization of a nonlinear boundary value problem in a neighborhood of a subcritical (unperturbed) state. The unperturbed state of the sphere is a spherically symmetric deformation and, in the case of a semi-linear (harmonic) material with constitutive equations [3]

$$\mathbf{D} = \frac{2\mu}{1-2\nu}\left(\nu \operatorname{tr}\mathbf{U} - 1 - \nu\right)\mathbf{A} + 2\mu\mathbf{C},$$

is described by the exact solution found earlier [5]. Here, $\mathbf{U}$ is the symmetric positive defined stretch tensor, $\mathbf{A}$ is the properly orthogonal rotation tensor, μ and ν are the constants. The linearized equilibrium and incompatibility equations are reduced to a system of three partial differential equations with respect to the components of the quasi-displacement vector field

$$\mathbf{w} = u(r,\theta)\mathbf{e}_r + v(r,\theta)\mathbf{e}_\theta\,.$$

For a semi-linear material, the linearized constitutive equations we obtain in the form

$$\dot{\mathbf{D}} = \frac{2\mu}{1-2\nu}\left(\nu \operatorname{tr}\mathbf{C}_0 - 1 - \nu\right)\frac{\dot{C}_{\theta r} - \dot{C}_{r\theta}}{C_{\theta\theta} + C_{rr}}\left(\mathbf{e}_\theta \otimes \mathbf{e}_r - \mathbf{e}_r \otimes \mathbf{e}_\theta\right) + \frac{2\mu}{1-2\nu}\left(\nu \operatorname{tr}\dot{\mathbf{C}}\right)\mathbf{E} + 2\mu\dot{\mathbf{C}},$$

where the distortion tensor in the unperturbed state $\mathbf{C}_0$ is determined according (3), $\mathbf{E}$ is the unit tensor, and

$$\dot{\mathbf{C}} = \frac{\partial u(r,\theta)}{\partial r}\mathbf{e}_r \otimes \mathbf{e}_r + \frac{\partial v(r,\theta)}{\partial r}\mathbf{e}_r \otimes \mathbf{e}_\theta + \frac{u(r,\theta) - v(r,\theta)\tan\theta}{r}\mathbf{e}_\varphi \otimes \mathbf{e}_\varphi$$
$$+ \left(\frac{\partial v(r,\theta)}{r\partial\theta} + \frac{u(r,\theta)}{r}\right)\mathbf{e}_\theta \otimes \mathbf{e}_\theta + \left(\frac{\partial u(r,\theta)}{r\partial\theta} - \frac{v(r,\theta)}{r}\right)\mathbf{e}_\theta \otimes \mathbf{e}_r\,.$$

Using Legendre polynomials for axisymmetric forms of the sphere's buckling, the variables r and θ are separated and the stability problem is reduced to finding nontrivial solutions of the linear homogeneous boundary value problem for the system of ordinary differential equations and determining the critical external pressure. The latter is solved numerically.

The effect of dislocations on critical pressure corresponding to the stability loss of both thin and thick-walled shells is analyzed. In particular, it is found that with increasing the dislocation density in a thick shell, the absolute values of the quasi-displacements in the meridian plane decrease. Inside the sphere there are spherical surfaces on which these displacements do not depend on the dislocation density. For a thin shell in different parts of it in the radial direction, an increase in density either increases displacements or decreases. A negative dislocation density decreases the critical pressure, while a positive one increases it. Cases when the shell loses stability in the absence of an external load due to eigenstresses caused by dislocations have been revealed.

CONCLUSIONS

The stability problem for a hollow sphere with edge dislocations is solved. The minimum value of the external hydrostatically distributed pressure at which the sphere loses stability for the first time is found. For thick and thin shells, the forms of stability loss corresponding to the found critical pressure values are determined. The effect of dislocations on the buckling of a spherical shell is analyzed. It has been established that edge dislocations have a nonlinear effect on displacements. Also, the shell buckling in the absence of an external load due to eigenstresses caused by dislocations is studied.

CONTACT STABILITY OF ACTIVE MECHANICAL LINKAGES

Neelima Sharma*[1] and Madhusudhan Venkadesan†[1]
[1]Department of Mechanical Engineering and Materials Science, Yale University, New Haven, USA, 06511

Summary For animals and robots, compliant limb joints are needed to safely interact with the environment. However, excessive compliance compromises stability and the limb may buckle under contact forces. Here we address the problem of designing compliant and stable limbs during static operation by analyzing actively driven kinematic chains with external contacts. We show that the minimum joint stiffness for stability is an affine function of the torques driving the joints. Thus driving the joints using muscle-like actuators, with stiffness linearly proportional to force, lends stability without feedback control. Furthermore, we show that designing open-loop stable controllers is a convex problem, thus enabling efficient solution methods. We demonstrate the method on a model of the human index finger and discuss the implications for robots, prosthetics, and the neural control of limbs.

INTRODUCTION

Actively-driven mechanical linkages with compliant joints are ubiquitous in physical and biological systems. Like hinged columns that buckle when compressed, a self-driven mechanical linkage could also buckle because of external forces. Unlike passive columns, the external forces on these active linkages typically arise as a result of internal actuation. In passive and active systems, having joints with high stiffness could prevent buckling and stabilize a desired static configuration. However, excessive joint stiffness impedes free motion and adaptability of active limbs. We present here a mathematical analysis of general actively-driven linkages and show how to manage the trade-off between stability and adaptability using variable stiffness actuators. We first find a lower bound for the stiffness needed to remain stable and derive a formulation to incorporate the stiffness-based stability condition as a convex constraint within a optimization framework. By applying our formulation to tendon-driven linkages, we find that the use of muscle-like variable stiffness actuators yields open-loop control strategies that are stable. We demonstrate these results using an anatomically detailed model of a human index finger that is pushing on a surface with the fingertip.

MODELING AND RESULTS

The governing equations for linkages with Pfaffian constraints and springy, actuated joints are,

$$\mathrm{M}(\vec{q})\ddot{\vec{q}} + \vec{c}(\vec{q},\dot{\vec{q}}) + \vec{\gamma}(\vec{q}) + \mathrm{A}^T(\vec{q})\vec{\lambda}(\vec{q},\dot{\vec{q}}) = \vec{\tau} - K(\vec{q}-\vec{q}_0), \quad \mathrm{A}(\vec{q})\dot{\vec{q}} = 0. \tag{1}$$

Pfaffian constraints admit all holonomic constraints, but restrict generalized nonholonomic constraints like $\vec{g}(\vec{q},\dot{\vec{q}}) = 0$ to the case $\partial\vec{g}/\partial\vec{q} = A(\vec{q})$. Many known physical nonholonomic systems such as the rolling penny or the Chaplygin sleigh are Pfaffian [1]. The other terms are the generalized actuation forces $\vec{\tau}$, stiffness K, neutral configuration $\vec{q}_0$, generalized constraint forces $\vec{\lambda}(\vec{q},\dot{\vec{q}})$, inertia matrix $\mathrm{M}(\vec{q})$, Coriolis and centripetal terms $\vec{c}(\vec{q},\dot{\vec{q}})$, and external forces $\vec{\gamma}(\vec{q})$ (e.g. gravity).

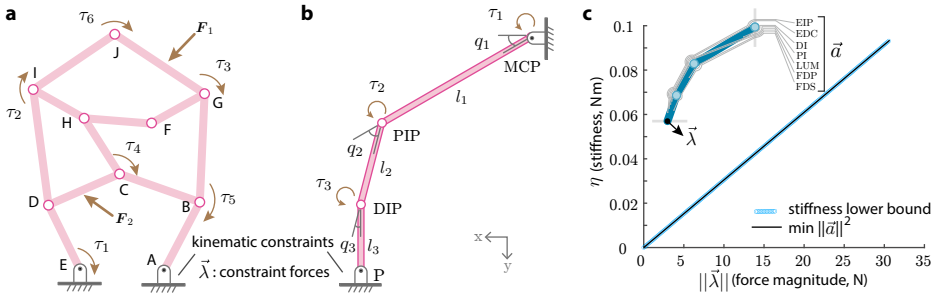

Figure 1: **a.** We consider open-loop stability of a prescribed configuration for general mechanical linkage networks with joint actuators (τ_{1-6}), external forces ($\vec{F}_{1-2}$) and kinematic constraints (A and E). In such active networks, actuation can induce constraint forces that destabilize the configuration, but the static pose can be stabilized if the joint stiffness matrix K is greater than a minimum stabilizing stiffness K_m. We show that this constraint can be incorporated within an optimal control framework as a set of linear convex constraints, formulated as a linear matrix inequality [2]. **b.** We apply this formulation to an index finger pushing on a surface by modeling the finger as a planar four-bar linkage driven by seven muscles. Muscle activation induces joint torques $\vec{\tau}$ and a joint stiffness matrix K. **c.** In a numerical demonstration of the index finger model, the stiffness matrix of a planar four-bar linkage that has only a single degree of freedom is parameterized by a scalar stiffness η. Solving an optimization problem to find a minimal effort solution, $\min\|\vec{a}\|^2$, results in activation patterns that satisfy $\eta > \eta_m$, as needed for open-loop stability (blue markers versus solid black line).

THEMATIC SESSION SM

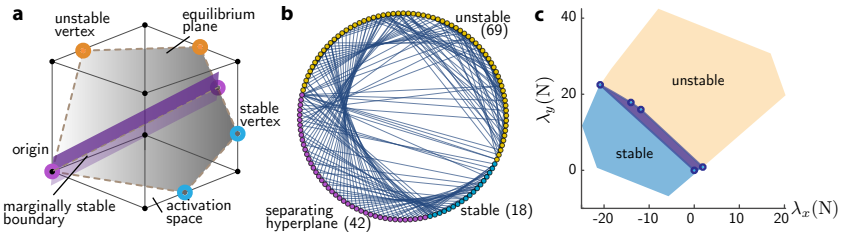

Figure 2: **a.** A cartoon to illustrate the geometric underpinnings of the control problem. The unit cube of normalized activations contains a lower-dimensional plane representing the torque-force equilibrium. A second lower dimensional plane shows marginal stability of the system and divides the equilibrium plane into stable and unstable regions with stable (blue), unstable (orange), and marginally stable (pink) vertices at the intersection with the unit cube. **b.** Circular embedding of the vertices of the equilibrium plane in 7D, showing the feasible muscle activations for an index finger and 18 stable, 69 unstable, and 42 marginally-stable vertices. **c.** The projection of the stable and the unstable regions from the 7D activation space onto the 2D fingertip force space. For every direction of force production, the boundaries of the marginally stable region show the largest force that can be stably produced.

The actuator torques $\vec{\tau}_0$ and stiffness K_m needed for stability depend on the desired static posture $\vec{q}_0$ and the desired contact forces $\vec{\lambda}_0$. With the definition $\mathrm{A}_0 = \mathrm{A}(\vec{q}_0)$, we find that $\vec{\tau}_0$ and K_m are affine functions of $\vec{\lambda}_0$ as given by,

$$\vec{\tau}_0 = \mathrm{A}_0^{\mathrm{T}} \vec{\lambda}_0 + \vec{\gamma}(\vec{q}_0), \quad \mathrm{K}_m = -\left(\frac{\partial \vec{\gamma}}{\partial \vec{q}} + \frac{\partial \mathrm{A}^T(\vec{q})\vec{\lambda}}{\partial \vec{q}} \right). \tag{2}$$

Inspired by biological limbs, we now focus on tendon-driven linkage networks with muscle-like actuators. The normalized vector $0 \leq \vec{a} \leq 1$ parametrizes muscle activations, which in turn induce joint torques $\vec{\tau} = \mathrm{RT}\vec{a}$ and joint stiffness $\mathrm{K} = \mathrm{R}\,\mathrm{K}_t\,\mathrm{diag}(\vec{a})\,\mathrm{R}^{\mathrm{T}}$. Normalized muscle activations are scaled to muscle forces by T, the matrix R that consists of the moment arms of the tendons about each joint maps muscle forces to torques, and the diagonal matrix K_t maps normalized muscle activations to muscle stiffness.

The problem is to find activations $\vec{a}$ that satisfy mechanical equilibrium between the torques and contact forces, and also stabilize the posture using muscle-induced stiffness. Typically, there are additional goals such as minimizing effort that are sought by the controller while subject to the mechanical constraints of equilibrium and stability. For a desired static limb posture $\vec{q}_0$ and desired contact forces $\vec{\lambda}_0$, the constrained optimization problem is given by,

$$\min \text{(objective function)}, \text{ subject to: } \mathrm{R}\,\mathrm{K}_t\,\mathrm{diag}(\vec{a})\,\mathrm{R}^{\mathrm{T}} - \mathrm{K}_m \succeq 0, \text{ and } \vec{\tau}_0 = \mathrm{RT}\vec{a} = \mathrm{A}_0^{\mathrm{T}}\vec{\lambda}_0 + \vec{\gamma}(\vec{q}_0). \tag{3}$$

Remarkably, the constraint of stability appears as a linear matrix inequality, which is convex in nature and thus can be solved by using established efficient numerical methods [2].

To demonstrate this formulation, we use a published model of an index finger that is applying a force with its tip such as during precision grips in humans [3]. The model is a planar three-link chain driven by 7 muscles and hinge constraints at both ends, making it a four-bar linkage with 1 net degree of freedom. Thus the joint stiffness K has only one non-zero eigenvalue η, which we use to quantify stiffness of the finger. We consider a convex (quadratic) objective function $\|\vec{a}\|^2$ and ignore gravitational forces. In this numerical example, we verify that the minimum stiffness for stability η_m is indeed a linear function of the tip force magnitude $\|\vec{\lambda}\|$, as is the muscle-induced stiffness η for the activation patterns found from the optimization (Fig. 1c). Furthermore, we use the constraint equations to map out the entire space of feasible activation patterns that satisfy equilibrium and stability constraints within the 7D space of activations (Fig. 2). This computation in 7D took 3 seconds on a 1.7 GHz 2-core Intel i7 running MATLAB version 9.8.0.1323502.

The projection of the stable and unstable equilibrium sets from 7D onto the 2D space of contact forces shows that larger forces are generally destabilizing (Fig. 2c). Such a comprehensive evaluation of the entire space of control strategies is made possible by formulating the open-loop control design problem as a linear convex problem. Future work could extend our formulation to dynamic conditions and to problems with nonholonomic constraints.

CONCLUSIONS

We derived the conditions for an active mechanical linkage that is stable and yet the softest possible. In the context of tendon-driven systems, such as prevalent in animals and some robots, the set of stable solutions form a convex polytope. Therefore, convex objective functions subject to the stability constraint may be easily solved, as we demonstrate for a 7D control space for an anatomically detailed model of the index finger.

TRANSITIONS IN WRINKLING PATTERNS OF THIN ELASTIC FILMS ON COMPLIANT VISCOELASTIC SUBSTRATES

Jan Zavodnik*[1] and Miha Brojan[1]
[1]Laboratory for Nonlinear Mechanics, University of Ljubljana, Ljubljana, Slovenia

Summary Many viscoelastic structures are modelled in elastic (usually in short or long time) limits due to the considerable computational complexity. This way, a wide range of interesting phenomena from transient states is omitted. In this contribution we keep the time dependence of the viscoelastic material and study the transient states in large deformation regime during active deformation process, such as drying, swelling or growth of elastic films on viscoelastic substrates. We investigate the influence of viscous components on the deformation state of this structure and describe the transient deformation phenomena. We show that if the active deformation process is much faster than the viscous relaxation, the system can be driven out of equilibrium and in certain cases the transient shape modes can be "frozen" and remain in an "out of equilibrium" state for a considerable amount of time.

WRINKLING OF ELASTIC FILMS ON COMPLIANT VISOELASTIC SUBSTRATES

Wrinkling of thin elastic films on compliant viscoelastic substrates under compressive loads is an great toy model for studying interaction between the effects of the kinematic nonlinearity and viscoelastic material properties, because it is simple enough for analytical treatment and at the same time still maintains the effects of the viscoelasticity-nonlinear kinematics interaction. This kind of interaction occurs when the structure transitions from the initial, short time-limit to the final, long time-limit. The transition is essentially governed by the viscoelastic properties of the material. In the regime of the infinitesimal deformations the transition is trivial and therefore unsubstantial, but in the presence of nonlinear kinematic effects the transition becomes highly complex and more strongly dependent on initial conditions, perturbations and boundary conditions.

While the purely elastic theory offers discrete wrinkling deformation patterns as the solutions, the viscoelastic theory provides a framework to describe also the transition from the deformation patterns, e.g. from a pattern with a large number of wrinkles to the pattern with a small number of wrinkles. The complexity of this transition is a direct consequence of kinematic nonlinearities, because any rearrangement of wrinkles during the transition causes an energy dissipation while it does not affect the final elastic limit state. However, it can have an influence when the system arrives to the long time-limit state. If the initial energy dissipation during rearrangement of wrinkles is too large the system can become “frozen” in a non-equilibrium deformation state, which can be distinctly different from the purely elastic one. The system can remain there permanently if the system loses more energy than needed to overcome an energy barrier. Alternatively, the system can also transition so slowly that the environmental parameters change during the process and it can therefore remain in the out-of-equilibrium state permanently. Note that in general, these deformation states are unreachable for the elasticity alone [1]. In fact, this deformation patterns are very common in nature, e.g. in microbiology [2-4] and morphogenesis [5].

We analyse the elastic film and the viscoelastic compliant substrate decomposed, as displayed in Fig. 1. The elastic film is modelled with the use of Főppl-von Karman (weakly) nonlinear plate kinematic assumptions. On the other hand, the viscoelastic substrate is modelled as a continuum with infinitesimal deformation theory. Both elements are connected through the continuity of deformations and stresses in the structure.

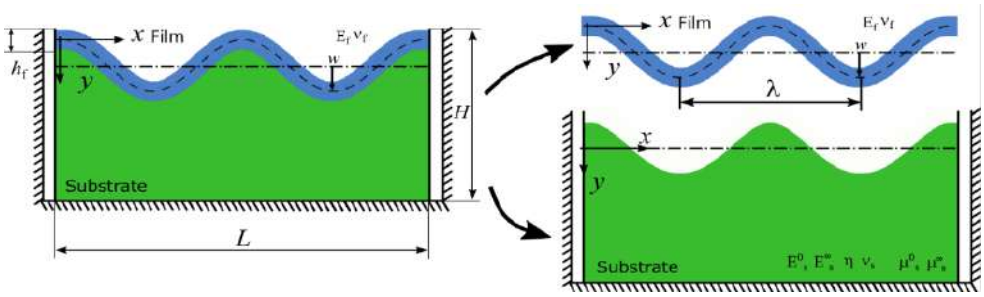

Figure 1: Elastic film and the viscoelastic substrate as separate structural elements.

To solve the obtained system of differential equations we approximate the wrinkles as a harmonic function of the form $w(x,t) = A(t)\cos k\,x$.

*Corresponding author. E-mail: jan.zavodnik@fs.uni-lj.si.

The system load in the form of confined growth, external forces etc. can be applied differently in the given time frame. We first analyse a step load. We show that an analytical implicit relation between the wrinkle amplitude A and time t and the wave number k can be obtained on an infinitely long structure with the use of total strain energy minimization,

$$t = \frac{C_1(\log A - \log A_0) - 12E^*_{s,ee}(1-\nu_f^2)\left(\log C_2(A) - \log C_2(A_0)\right)}{r\left(E_f h_f k\left(-h_f^2 k^2 + 12\varepsilon_g^0\right) - 24E^*_{s,e}(1-\nu_f^2)\right)}, \qquad k = 2\sqrt{\frac{\varepsilon_g^0}{3A^2 + h_f^2}}.$$

Here the C_1 and C_2 are some auxiliary functions made of material and geometric parameters, A_0 is the initial perturbation amplitude, E is Young's modulus, h is film thickness, ν is Poisson's ratio and r is a viscous relaxation rate. The indices "f" and "s" label the film and substrate properties, respectively. The time at which the wrinkles start to appear depends on the film growth amplitude ε_g^0. We show that if the growth amplitude is subcritical with respect to the long time-limit the wrinkles never appear and alternatively, if it is supercritical with respect to the long time-limit and supercritical with respect to the short time-limit then the wrinkles grow shortly after the growth is applied. Furthermore, if the growth amplitude is supercritical with respect to the short time-limit then wrinkles appear instantly and then continue to grow and transition towards the long time-limit deformation state. If the short time elastic equilibrium deformation pattern is qualitatively different from the long-time time deformation pattern, then the nontrivial transition will occur and the structure may become "frozen" in an out-of-equilibrium state.

In the case where the film growth is a ramp function the ratio between the compliant substrate relaxation rate and the active film growth rate is vitally important. In this case we performed numerical simulation where the growth magnitudes and elastic parameters of the structure were the same, only the ratio between the growth rate and viscoelastic relaxation rate were different. The long-time deformation patterns of two such structures are shown in Fig. 2. We observed that the two simulated structures converged to qualitatively different final deformation pattern.

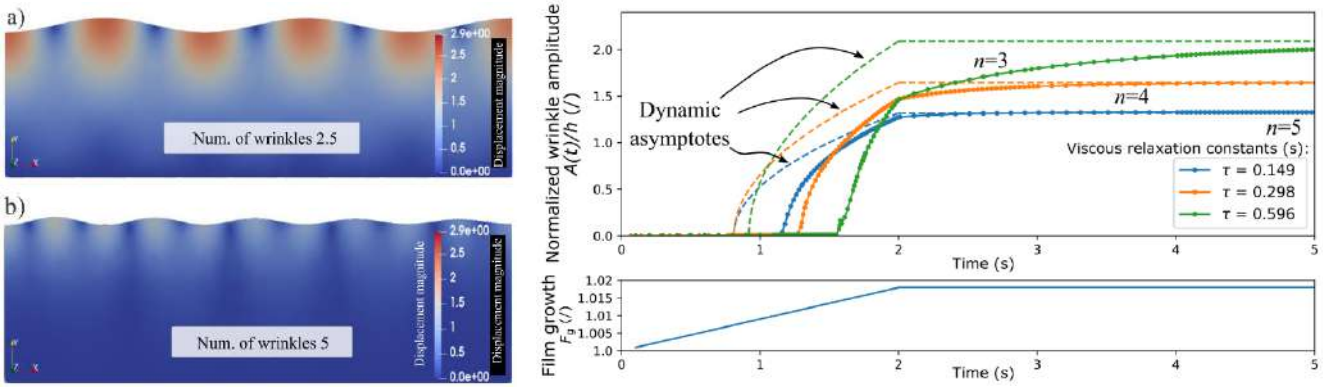

Figure 2: Left: Final deformation states of structures with the same elastic and different viscoelastic properties. Right: Wrinkle amplitude as a function of time for structures with the same elastic and different viscoelastic properties.

CONCLUSIONS

In this contribution, we show that viscoelastic properties of the material are crucially important for the final development of the pattern even though they seemingly affect only the transition period between the elastic short and long-time equilibrium states of the structure. The interaction between the viscoelastic material properties with the nonlinear kinematics produces interesting deformation patters otherwise unattainable for purely elastic systems. The theory and the principles described are also extremely useful in engineering applications because they allow much simpler fabrication of smart surfaces and coatings that at some point in fabrication behave viscoelasticity.

COMPETITION BETWEEN MULLINS AND CURVATURE EFFECTS IN THE WRINKLING OF STRETCHED SOFT SHELLS

Ting Wang, Yifan Yang, Chenbo Fu, and Fan Xu*
Institute of Mechanics and Computational Engineering, Department of Aeronautics and Astronautics, Fudan University, Shanghai, China

Summary A highly stretched hyperelastic shell experiences a coupled nonlinear behavior of local wrinkling and global bending within the stability boundary. Recently, we observed an interesting phenomenon that there are no wrinkles but global bending in the first loading for the stretched curved shell with certain curvature, while local wrinkling will appear in the first unloading process experimentally. Here, we investigate the effect of stress softening and residual strain, namely Mullins effect, in the cyclic loading process on this nonlinear response. To quantitatively explore the Mullins effect in the curved shell, we develop a pseudo-elastic shell model and our numerical results are consistent with the experimental phenomenon. Our findings reveal the competition between Mullins and curvature effects in the wrinkling behavior of a stretched shell.

INTRODUCTION

Recent research observed the inelastic behavior that there exists a permanent change in length of stretched sheets upon first loading experimentally, especially, a interesting Mullins effect was revealed in the cyclic loading process of stretched membrane [1]. Among many works established models to study the Mullins effect, Ogden and Roxburgh, Dorfmann and Ogden [2, 3] proposed a phenomenological model based on the theory of incompressible isotropic elasticity revised by incorporation of a damage parameter, which is a single continuous parameters, to account for the Mullins effect appearing in filled rubber elastomers. Based on the work of [2, 3], Feher *et al.* [1] developed a pseudo-elastic model to explain the longitudinal stress softening and residual strain occurring in the experiments of tensile membrane in the cyclic loading process. While their work is constraint to planar membrane. The mechanism and phenomenon of Mullins effect on the curved shell is under to be clarified.

This work experimentally and numerically investigates the Mullins effect in the cylindrical shell. We design an experiment of stretching cylindrical shells under cyclic loading. A pseudo-elastic shell model is established and numerical implementation through coupling *Asymptotic Numerical Method* (ANM) for nonlinear resolution and Chebyshev spectral collocation method for spatial discretization is adopted. The competition between Mullins and curvature effects in the instability behavior of a stretched shell is carefully examined.

PSEUDO-ELASTIC SHELL MODEL

Based on general differential geometry, the membrane strain tensor for cylindrical shell reads

$$E_{\alpha\beta} = \frac{1}{2}(u_{\alpha,\beta} + u_{\beta,\alpha} + 2wb_{\alpha\beta}) + \frac{1}{2}(u_{\gamma,\alpha}u_{\gamma,\beta} + u_{\gamma,\beta}wb_{\gamma\alpha} + u_{\gamma,\alpha}wb_{\gamma\beta} + wb_{\gamma\alpha}wb_{\gamma\beta}) + \frac{1}{2}w_{,\alpha}w_{,\beta}, \tag{1}$$

where Greek indices $\alpha, \beta, \ldots$ take values in $\{1, 2\}$, u_α denote the in-plane displacements, while w is the out-of-plane deflection. We employ Einstein's convention for implicit summation on repeated indices. The linearized bending strain tensor for cylindrical shell with finite curvatures reads

$$K_{\alpha\beta} = -w_{,\alpha\beta} + \frac{1}{2}\left(u_{\gamma,\alpha}b^{\gamma}_{\beta} + u_{\gamma,\beta}b^{\gamma}_{\alpha}\right) + wb_{\gamma\alpha}b^{\gamma}_{\beta}. \tag{2}$$

We consider pseudo-elastic model accounting for the stress-softening/residual strain [2, 3], the corresponding strain energy density function can be written as

$$\Psi = h\Psi_m(\mathbf{C}_s, \eta) + \Psi_b + h\Phi(\eta), \tag{3}$$

in which Ψ_m and Φ_b represent respectively the in-plane membrane strain energy density and volumetric bending energy density, η is a state variable with $\eta \leq 1$ and Φ is dissipation function, and $\mathbf{C}$ represents the right Cauchy-Green deformation tensor. The corresponding strain energy density function can be written as [1]

$$\Psi_m(\mathbf{C}_s, \eta) = p_1\left[\left((1+p_3)\,\eta - p_3\right)(C_{11} - 1) + \eta\,(C_{22} - 1) + \frac{1}{\det\mathbf{C}_s} - 1\right] + p_2\eta\left[\frac{\mathrm{tr}\mathbf{C}_s}{\det\mathbf{C}_s} + \det\mathbf{C}_s - 3\right], \tag{4}$$

where p_1 and p_2 are material constants, and $p_3 > 0$ is a fixed scalar parameter tuning the anisotropic damage ratio ($p_3 = 0$ corresponds to isotropic damage). When $\eta = 1$, the strain energy density function reduces to the Mooney-Rivlin (MR) model.

RESULTS

For the hyperelastic stretched cylindrical shells, Wang *et al.*[4] has provided the 3D phase diagram (aspect ratio and curvature) of stability boundary. First, we consider the case with aspect ratio lower but close to the stability boundary and curvature is smaller than the critical value. Obviously, in the first loading process, there is no wrinkles but global bending when increasing stretching strain. After we stretch the shell to the maximum strain 0.66, the shell experiences the cyclic loading. Besides global bending is observed, the wrinkles will occur when the strain is unloaded to about 0.2 and the residual strain will appear. The evolutions of first loading and cyclic loading are displayed in Fig. 1, and the numerical phenomenon is consistent with the experimental results.

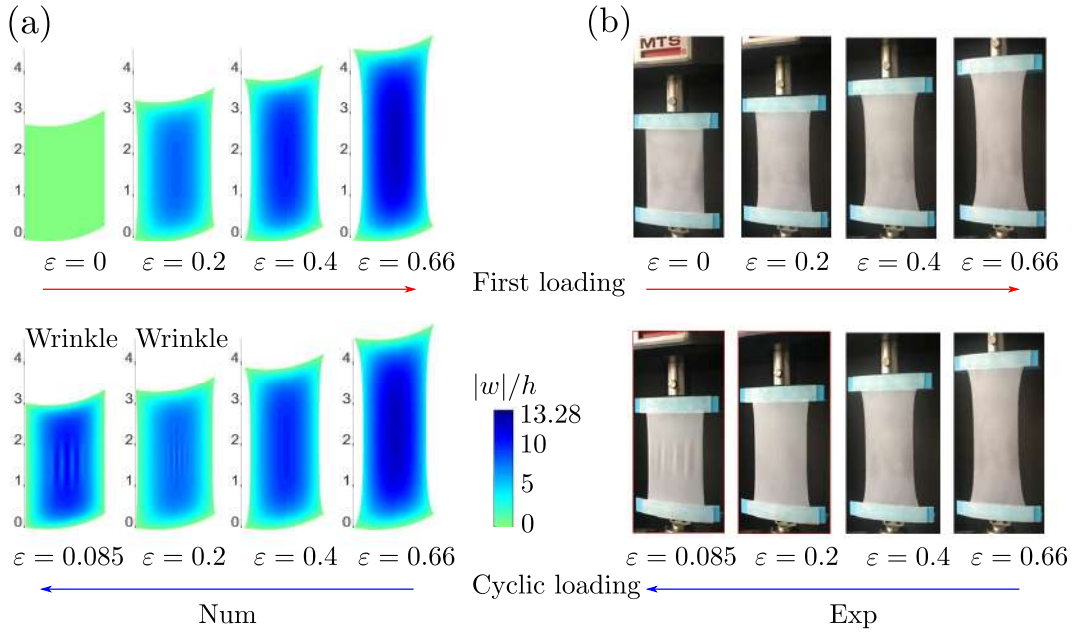

Figure 1: Evolutions in the first loading and cyclic loading process: (a) numerical results, (b) experimental results. The wrinkles will appear in the cyclic loading process. Geometric parameters: $W/h = 1600$, $L/W = 1.4$, $\kappa = 0.0002$.

CONCLUSIONS

we have experimentally and numerically revealed the Mullins effect in the cylindrical shell. For a curved shell with certain aspect ratio lower than the threshold or curvature larger than critical value, there is no wrinkles but global bending when increasing stretching strain, while in the unloading process, local wrinkling instability coupled with global bending is observed and residual strain occurs. We have established a pseudo-elastic shell model to quantitatively explore the Mullins effect in the curved shell. Our results clarified not only the inelastic behavior of the shells with cyclic loading but also the curvature effect on the response.

Summary The structural stability and mechanical properties of the potential structures of PdH_2 under pressure were studied based on the ab initio calculation. The Fm-3m phase is the most stable in thermodynamics at ambient pressure, and it is dynamically stable and mechanical stability. When the pressure up to 25.5 GPa, the structure transfer to mechanical instability. The P63mc phase is dynamic stability at pressures greater than 10 GPa. In the pressure range of 5.5-23.8 GPa, the P63mc phase is mechanical stability. When the pressure is greater than 75 GPa, the P63mc phase is the most thermodynamic stable. When PdH_2 is formed, it will decomposition into Pd and H_2. Therefore, the PdH_2 is a metastable structure under pressure. In addition, the single-crystal bulk modulus, shear modulus, Young's modulus, Poisson's ratio, and anisotropic properties of PdH_2 are obtained.

Results and discussions

Palladium hydrogen (Pd-H) system has been concerned since 1866, mainly due to large amount of hydrogen storage, reversible hydrogen absorption and desorption, and high superconducting transition temperature[1,2]. Previous studies focused on PdH_x ($x \leq 1$) with low hydrogen concentration. Theoretical and experimental studies on Pd-H structure with high hydrogen content show that the perfect stoichiometric palladium dihydride (PdH_2) structure cannot exist stably [3,4]. The calculation shows that PdH_2 will decompose rapidly into PdH and H_2 [5]. Although several PdH_2 structures, have been studied. However, the stability of PdH_2 is still an open question.

A crystalline structure is stable, in the absence of external load and in the harmonic approximation, if and only if (i) all its phonon modes have positive frequencies (dynamical stability), and (ii) the elastic energy, is always positive (Born stability criterion). The enthalpy differences and formation enthalpy are used to explain the favourable structure and reaction direction under pressure.

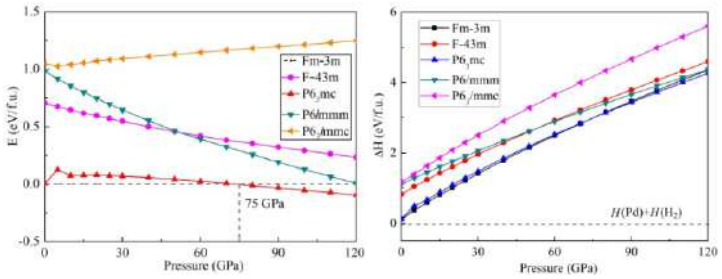

Figure 1. Thermodynamic stability: enthalpy difference and formation enthalpy.

The enthalpy differences for F-43m, P6/mmm, $P6_3/mmc$ structure is positive, indicating that these structures are unstable relative to the Fm-3m structure. It is noteworthy that the enthalpy difference between $P6_3mc$ and Fm-3m is negative when the pressure is greater than 75 GPa, indicating that $P6_3mc$ phase is more stable when the pressure is greater than 75 GPa. The formation enthalpy shows that all of the PdH_2 structures directly dissociate into Pd and H_2, and the higher the pressure, the easier the decomposition.

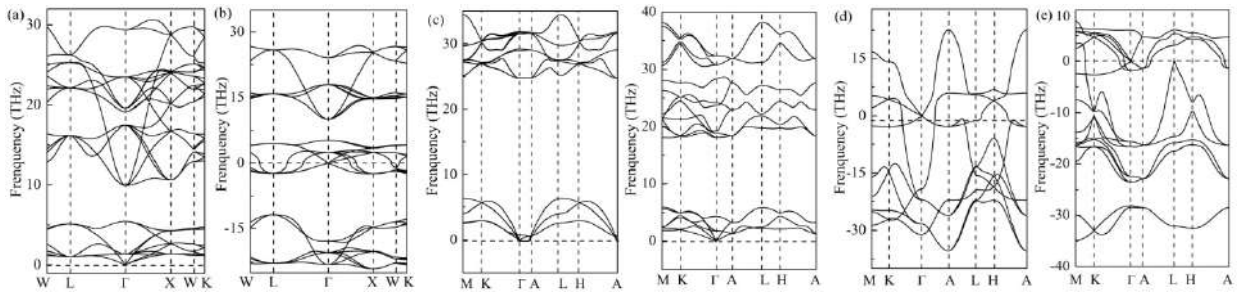

Figure 2 Dynamic stability: phonon dispersion (a) Fm-3m, (b) F-43m, (c) $P6_3mc$, (d) P6/mmm and (e) $P6_3/mmc$

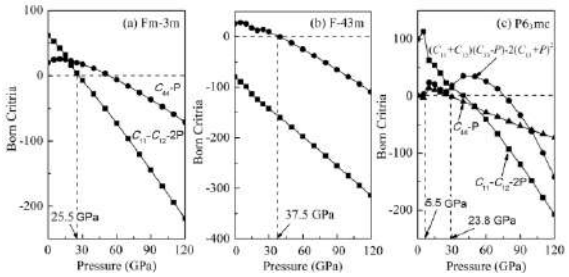

Figure 3. Mechanical stability: elastic constants

The inexistence of imaginary frequencies in phonon dispersion indicates the dynamic stability. The results show that Fm-3m phase is dynamic stable under environmental pressure. When the pressure increases to above 10 GPa, $P6_3mc$ phase is dynamic stable. The F-43m, $P6_3mc$, P6/mmm and P63/mmc phase are dynamic unstable under the environmental pressure. According to born stability criterion, when the pressure is less than 25.5 GPa, the Fm-3m phase is mechanically stable. In the pressure range of 5.5-23.8 GPa, the $P6_3mc$ phase is mechanically stable.

The elastic properties of Fm-3m and $P6_3mc$ phase PdH_2 are listed in table 1. The bulk modulus and Young's modulus increases with the increase of pressure. With the increase of pressure, the shear modulus increases little, and the Poisson's ratio remains about 0.42. Pugh ratio B/G is greater than 1.75, the material is generally ductile, otherwise it is brittle. The results show that the Fm-3m PdH_2 exhibits good ductility. The $P6_3mc$ PdH_2 shows ductility when the pressure up to 5 GPa, and with the increase of pressure, the ductility increases.

Table 1 The elastic properties of Fm-3m and $P6_3mc$ phase PdH_2

	Fm-3m					$P6_3mc$				
P (GPa)	*B* (GPa)	*G* (GPa)	*B*/*G*	*E* (GPa)	*v*	*B* (GPa)	*G* (GPa)	*B*/*G*	*E* (GPa)	*v*
0	150.9	24.2	6.2	68.9	0.42	30.5	19.2	1.6	47.6	0.24
5	169.6	30.3	5.6	85.8	0.42	63.8	18.6	3.4	50.9	0.37
10	186.3	33.9	5.5	95.9	0.41	155.5	32.1	4.8	90.0	0.40
15	202.6	36.2	5.6	102.4	0.42	172.6	33.4	5.2	94.1	0.41

25	230.6	36.8	6.3	104.7	0.42	202.1	32.0	6.3	91.3	0.42
30	245.5	37.7	6.5	107.6	0.43	221.4	35.0	6.3	99.8	0.42

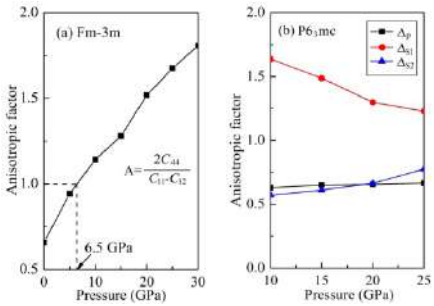

Figure 4. The anisotropic factor of Fm-3m phase and F-43m P63mc phase PdH_2 as a function of pressure

The anisotropy factor equal to 1, that is, the material is isotropic. For Fm-3m phase, PdH_2 is isotropic at 6.5 GPa. The farther the pressure is away from 6.5 GPa, the stronger the anisotropy is. For $P6_3mc$ phase, the anisotropy factors deviate from 1, indicating that PdH_2 is anisotropic. It should be noted that the pressure leads to a decrease in anisotropy.

CONCLUSIONS

Based on the density functional theory, the potential stable structure of PdH_2 is studied by the first principle theory. The thermodynamic stability, dynamic stability and mechanical stability under different structural pressures were calculated. The results indicate that PdH_2 is metastable under pressure. The elastic properties of Fm-3m and $P6_3mc$ PdH_2 under pressure are also reported, including bulk modulus, shear modulus, Young's modulus, Poisson's ratio and anisotropic properties.

A NOVEL BIFURCATING FORCE-LIMITING ELASTIC STRUCTURE

P. Koutsogiannakis*[1], F. Dal Corso[1], and D. Bigoni[1]
[1]Department of Civil, Environmental and Mechanical Engineering, University of Trento, Trento, Italy

Summary Force limiters have a wide range of uses, from car industry to medical fields. In the present work, a novel force-limiting mechanism is introduced, based on the instability related to a buckling elastic element. When the load applied to one end of the structure surpasses a critical value, the elastic element buckles and the mechanism is unlocked. By constraining the tip of the elastic element to move on a predefined curve, the response of the system can be controlled. The shape of the constraint curve can be optimized for specified behaviours by an optimization loop. The design can define a zone of greatly increased reaction forces at large deflections, providing a smooth transition towards the maximum allowable displacement.

Force limiting mechanisms find application in industrial problems. They are used where precise force control is critical, such as in medical tools, or where limiting loads is crucial to protect structures or humans from harm, like in the case of belt retractors, car seat belts, and seismic isolation devices. Various operational principles are deployed for different designs. These include the constricted displacement of air and the yielding of energy absorption elements.

In the present work, it is shown how a force limiting mechanism can be realized by exploiting buckling elastic elements. The proposed system consists of an elastic element connected to a moving clamp on one end and constrained to slide along a curve on the other end; see Fig. 1. The shape of the constraint curve can be selected so that the desired behavior of the device is achieved [1, 2]. Here this concept is used for producing force-limiting effects. More specifically, the elastic element remains straight until the external applied force surpasses a critical buckling value. This critical load depends on the curvature of the constraint curve at the position corresponding to the initial configuration. The resulting design is simpler than current commercial systems. In order to retain simplicity, a helicoidal spring is used as the elastic element, meaning that there will be a slight displacement before buckling happens. This effect is desirable as it can introduce tolerance for slight movements that should not activate the device. To the authors' knowledge no published studies on this concept can be found.

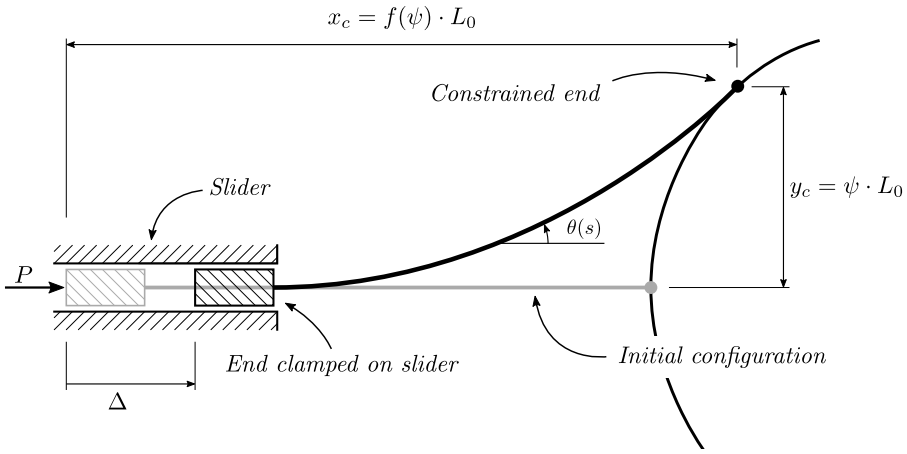

Figure 1: Drawing of the proposed design. The elastic element is connected to a movable clamp on one end, while at the other end is constrained to move along a predefined curve. In the undeformed configuration the slider remains locked until the load P exceeds a critical value.

For the fast and effective calculation of the response of the system, the spring is approximated by an elastic rod with bending stiffness B and axial stiffness K. These stiffnesses can be related to the parameters of the spring as follows

$$B = \frac{4L_0 EIG}{n\pi D(2G+E)}\,, \qquad K = \frac{Gd^4 L_0}{8D^3 n} \tag{1}$$

where L_0 is the free length of the spring, d the wire diameter, D the mean coil diameter, n the number of coils, G the shear modulus, E Young's modulus and EI the flexural rigidity of the wire cross section. The deformation of the spring is defined by the rotation $\theta(s)$ and the displacement $\delta(s)$, being $s \in [0, L_0]$ the curvilinear coordinate along the undeformed spring.

The shape of the constraint curve (in non-dimensional form) is considered to be represented by the even polynomial

$$f(\psi) = 1 + \frac{1}{2}\psi^2\, f''(0) \;+\; \sum_{i=0}^{n} c_i\, \frac{1}{(2i+1)(2i+2)}\, \psi^{2i+2} \tag{2}$$

*Corresponding author. E-mail: p.koutsogiannakis@unitn.it

where $\psi = \int_0^{L_0} \sin(\theta(s))ds$ is the vertical deflection of the elastic rod at the constrained tip. Considering function f given by eq. (2) ensures a null slope at the origin, $f(\psi = 0) = 0$, and a symmetric constraint curve, $f(-\psi) = f(\psi)$.

Assuming quasi-static conditions, the total potential energy of the system is

$$\mathcal{V} = \frac{1}{2}\int_0^{L_0} B\,(\theta'(s))^2\ ds\ +\ \frac{1}{2}\int_0^{L_0} K\,\delta^2(s)\ ds\ +\ P\,\Delta\,, \tag{3}$$

where Δ is the displacement of the movable clamped end, depending on the rotation $\theta(s)$ and the displacement $\delta(s)$ fields and the constraint curve shape $f(\psi)$. In this way, an extra equation can be derived that enforces the constraint on the elastic rod. The deformed shape of the spring will then be given by the configuration that minimizes the energy $\mathcal{V}$ of the system.

For the purposes of this work, the elastic element is modeled numerically by discrete springs, following the Discrete Element Method. An additional constraint is added to the resulting nonlinear system of equations to impose a specified displacement Δ. Then by varying the parameter Δ we can calculate the load P as a reaction force. Additionally, an outer optimization loop is used in order to adapt the response of the system to a reference Force-Displacement curve; see Fig. 2 (Left).

Finally, a smooth transition to a maximum allowable displacement can be achieved by introducing an additional term to the previous constraint shape,

$$f(\psi) = 1 + \frac{1}{2}\psi^2\ f''(0)\ +\ \sum_{i=0}^{n} c_i\ \frac{1}{(2i+1)(2i+2)}\ \psi^{2i+2} + f_a(\psi), \tag{4}$$

which has an effect only at deflection ψ greater in modulus than a specified value α as follows

$$f_a(\psi) = \begin{cases} 0, & \psi < |\alpha|, \\ c_a \cdot \left[\frac{1}{6}|\psi|^3 - \frac{\alpha}{2}\psi^2 + \frac{\alpha^2}{2}|\psi| - \frac{\alpha^3}{6}\right], & \psi \geq |\alpha|, \end{cases} \tag{5}$$

and preserves continuity of the second derivative of the constraint curve. By controlling this additional term $f_a(\psi)$, a zone can be designed, where the reaction force P gradually increases to values that are multiple times larger than the bifurcation load; see Fig. 2 (Right). Provided that the load P remains within a range of values close to the critical load, a maximum displacement exists. This property provides a 'cushioning effect' in the case that a maximum allowable displacement has to be imposed by external design constraints.

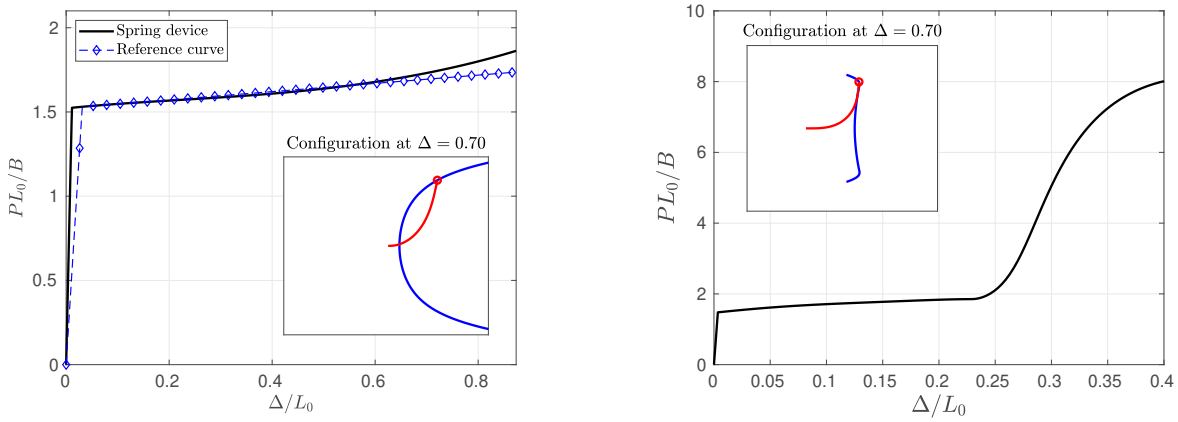

Figure 2: (Left) Force-Displacement curve of the proposed system adapted to a reference one by optimizing the constraint curve shape. The reference curve specifies a critical load and a small slope in order to keep the overall stiffness of the device positive at all displacements. (Right) Force-Displacement curve of the proposed system showcasing a secondary "locking" zone.

TENSILE BUCKLING AND POSTBUCKLING BEHAVIOUR OF TRIANGULAR STRUCTURAL ELEMENTS UNDER DEAD LOADS

Nikolin Hima*[1], Francesco Dal Corso [1], and Davide Bigoni [1]
[1]Department of Civil, Environmental and Mechanical Engineering, University of Trento, Trento, Italy

Summary An elementary triangular frame structure comprised of rigid bars, a rotational spring, and a slider, is investigated under vertical and horizontal loading conditions. The slider in one of the bars of this structure enables for tensile bifurcation of the corresponding substructure element to occur. The overall mechanical response of the structure shows that it remains undeformed until a certain critical horizontal load is attained and the post-critical behaviour can be tuned to develop horizontal displacement without significant increase in load, until eventually locking occurs. The behaviour of this structure is driven by its base angles and the vertical load applied on it. The present work paves the way towards the design of a new generation of seismic isolators which provide protection for frequent seismic events without compromising the overall stability of the structure.

By implementing a slider in the middle of a bar (a slider is a device that imposes the same rotations angles and axial displacements to the connected parts, vanishing the shear force, and allowing only a relative sliding), Bigoni et. al. [1,2] have shown that bifurcation under tensile dead loading can occur. The present work makes use of this elementary device by incorporating it in a simple structure which is comprised of rigid bars connected to each other with hinges in a triangular shape. In the lower right node of this triangular truss-like structure a rotational spring is incorporated, and the bar in front of it is divided into two equal parts with a slider, as reported in Figure 1-a.

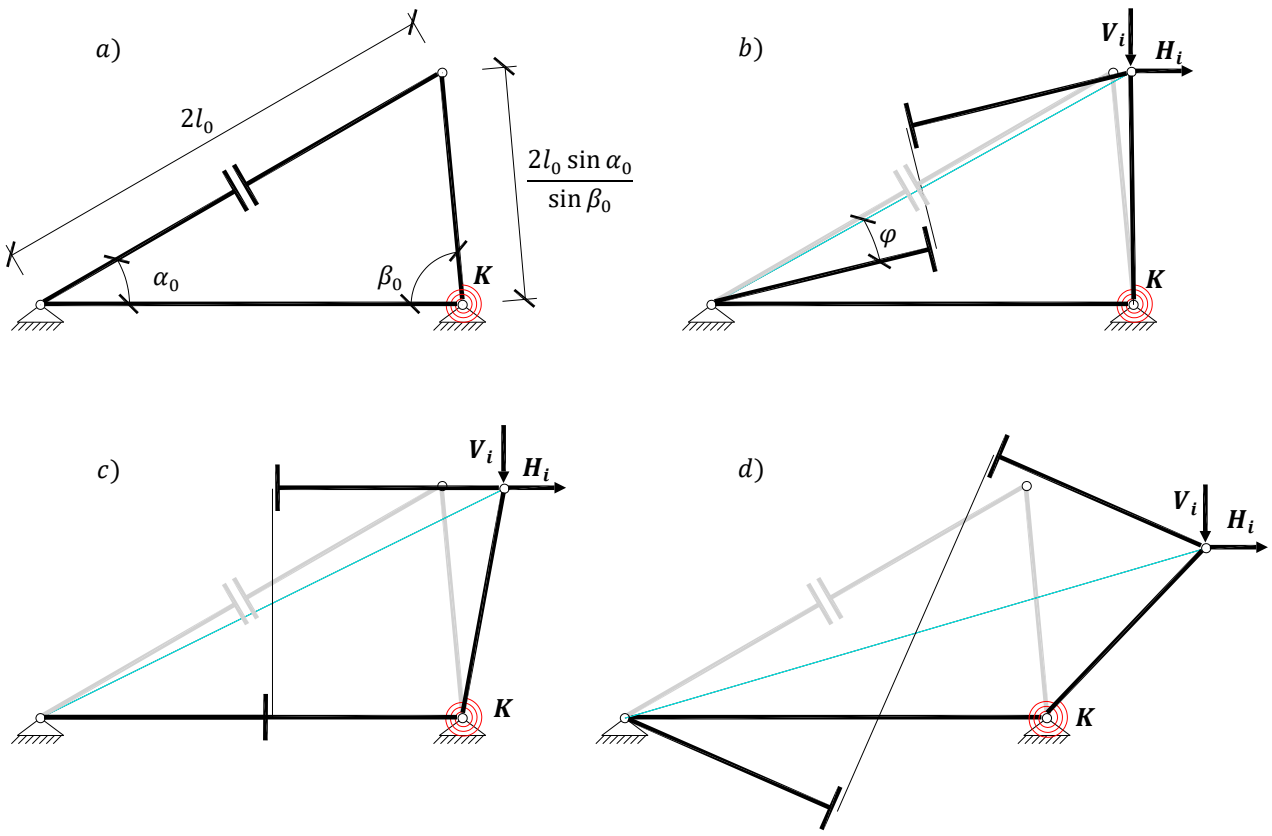

Figure 1: a) Undeformed triangular structure comprised of rigid bars connected with hinges, a rotational spring in the lower right node and a slider incorporated in the middles of the bar in front of the rotational spring. b) c) and d) Deformed configurations of the structure under vertical and horizontal loadings at the bifurcation angle $\varphi = \{15, 26, 40\}°$.

Theoretical formulation predicts that for a given vertical load (V) acting on the top node of the structure and a certain rotational stiffness (K) at the right lower node, the horizontal load applied at the top node, when large enough, can move the system towards the right, as reported in Figure 1-b. The movement occurs because the bar containing the slider, changes from a compressive (H=0) to a tensile state (for H=H_{crc}), so that the structure bifurcates, allowing the two parts of the bar to rotate with respect to one another (bifurcation angle φ). The structure develops the kinematics as reported in Figure 1-b,c,d.

*Corresponding author. E-mail: **nikolin.hima@unitn.it**

The mechanical response of the analysed structure depends on the initial angles between the bars at the base and on the vertical load. More specifically, the critical horizontal load necessary to bifurcation, is a function of the vertical load and the right base angle of the structure, $H_{i,crc} = V_i \cot \beta_0$. Moreover, the post buckling behaviour of the structure is also highly influenced by these parameters. Depending on the vertical load and the base angles the structure can return a force displacement curve that can range from softening to a flat and/or hardening curve, until eventually locking occurs. Through the rotational spring stiffness K and the reference bar half-length l_0, dimensionless horizontal and vertical forces can be introduced as:

$$H_i = \frac{H l_0}{K} \qquad V_i = \frac{V l_0}{K}$$

and the theoretical prediction for the dimensionless horizontal force – horizontal displacement curve is depicted in Figure 2 for initial base angles $\alpha_0 = 30°$ and $\beta_0 = 85°$ and vertical load $V_i = 1$ (so that $V_i/H_{i,crc} = \tan \beta_0 = 11.34$).

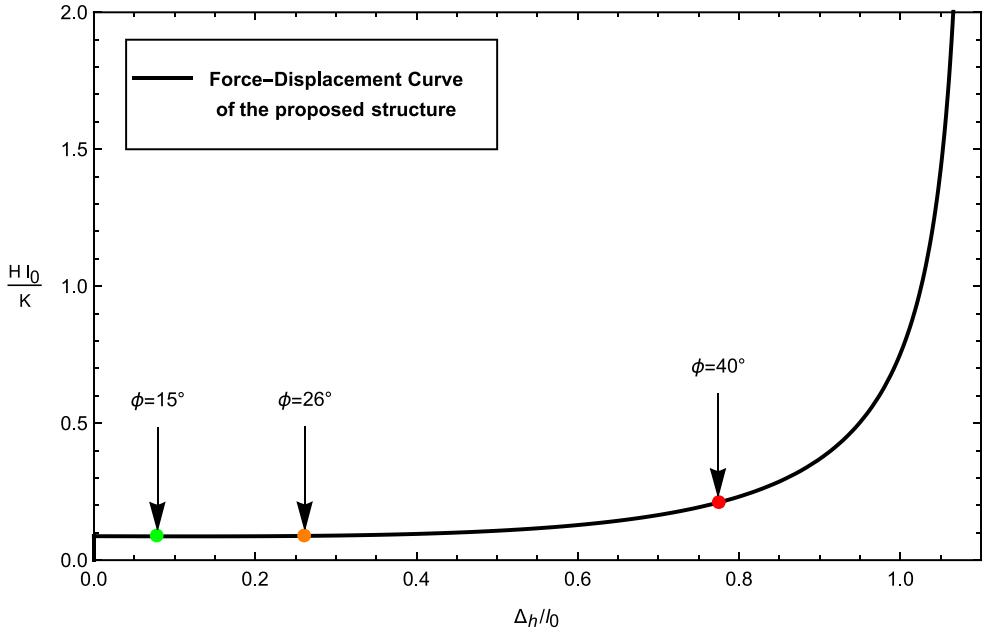

Figure 2: Dimensionless horizontal force-horizontal displacement curve for initial base angles $\alpha_0 = 30° \,\&\, \beta_0 = 85°$ and dimensionless vertical load $V_i = 1$. Force-displacement pairs corresponding to bifurcation angles $\varphi = \{15°, 26°, 40°\}$ displayed in Fig. 1 are highlighted.

The present work paves the way towards a new generation of seismic isolators which can self-activate and provide protection for frequent seismic events, without compromising the overall stability of the structure, and remaining rigid when exposed to other accidental loads such as wind or small impacts.

Acknowledgments. The authors gratefully acknowledge financial support from the European Union's Horizon2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement 'INSPIRE – Innovative ground interface concepts for structure protection' PITN-GA-2019-813424-INSPIRE.

STRAIN GRADIENT PLASTICITY SIMULATION OF STRAIN LOCALIZATION AT LARGE STRAINS

Jean–Michel Scherer[1,2], Samuel Forest*[1], Jacques Besson[1], Jeremy Hure[2], and Benoit Tanguy[2]
[1]MINES Paris Tech,PSL University,Centre des matériaux,CNRSUMR7633,BP8791003 Evry,France
[2]DEN-Service d'Etudes des Matériaux Irradiés,CEA,Université Paris-Saclay,F-91191, Gif-sur-Yvette,France

Summary A micromorphic crystal plasticity model is used to simulate slip band localization in single crystals under simple shear at finite deformations. Closed form analytical solutions are derived for single slip in the case of positive, zero and negative strain hardening. Linear negative strain hardening, i.e. linear softening, leads to a constant localization slip bandwidth, while non linear softening and saturating behaviour results in an increasing bandwidth. An enhanced model is therefore proposed in order to maintain a bounded localization slip band-width when considering an exponential softening behaviour. Analytical solutions are used to validate finite element computation of the same boundary value problems. The enhanced micromorphic crystal plasticity model is then applied to predict the interaction between localized slip bands and voids encountered in porous irradiated materials. For that purpose, periodic porous unit cells are loaded in simple shear with a strain gradient crystal plasticity matrix material. The finite element simulation results show that, for a given void volume fraction, the larger the voids, the wider the localization band. However, for a given void size, the larger the void volume fraction, the narrower the localization band. In addition a satisfactory qualitative agreement of the rotation and elongation of the voids with the experimental observations made in irradiated materials is observed, where small voids are shown to remain ellipsoidal for larger shear strains. Large voids deform into peanut-like shapes.

REDUCED MICROMORPHIC MODEL

This work investigates the responses given in single slip for a strip in simple shear by a recently developed micromorphic crystal plasticity model [1, 2, 6]. It is used to simulate slip band localization in single crystals under simple shear at finite deformations. It is formulated at finite deformations as an extension of Mandel's classical theory based on a multiplicative decomposition of the deformation gradient. It involves a single microslip degree of freedom in addition to the usual displacement components. Two main variants of the constitutive equations were proposed. The first one relies on a Lagrangian microslip gradient and leads to a Laplace term in the isotropic hardening law. In contrast, the second formulation, based on a generalized strain measure defined with respect to the intermediate configuration, is shown to induce both isotropic and kinematic enhanced hardening. The first formulation is implemented in a 3D finite element code. The model is applied first to strain localization phenomena in a single crystal in tension undergoing single slip. The regularization power of the model is illustrated by mesh-independent simulations of the competition between kink and slip bands [4].

CONTROLLING SHEAR BAND WIDTH AT LARGE STRAINS

Closed form analytic solutions are derived for single slip in the case of positive, zero and negative strain hardening. Linear negative strain hardening, i.e. linear softening, leads to a constant localization slip band width, while non linear softening and saturating behavior results in an increasing band width. An enhanced model is therefore proposed in order to maintain a bounded localization slip band width when considering an exponential softening behavior. Analytic solutions are used to validate finite element computation of the same boundary value problems.

APPLICATION TO SHEAR BAND–VOID INTERACTION

The enhanced micromorphic crystal plasticity model is then applied to predict the interaction between localized slip bands and voids encountered in porous irradiated materials [3]. For that purpose, periodic porous unit cells are loaded in simple shear with a strain gradient crystal plasticity matrix material. Then the mechanism of dislocation channel deformation observed in irradiated steels and its interaction with voids is studied on a numerical perspective. The enhanced model is used to simulate the interaction of voids and localization bands in a softening material. Periodic perforated plate and cubic unit-cells are loaded in simple shear for different void content and characteristic length scales versus void radius ratios. The finite element simulation results show that, for a given void volume fraction, the larger the voids, the wider the localization band. However, for a given void size, the larger the void volume fraction, the narrower the localization band. In addition a satisfactory qualitative agreement of the rotation and elongation of the voids with the experimental observations made in irradiated materials is observed, where small voids are shown to remain ellipsoidal for larger shear strains. Large voids deform into peanut-like shapes [5].

A MICROMORPHIC COMPUTATIONAL HOMOGENIZATION FRAMEWORK FOR PREDICTING MICRO AND MACRO BUCKLING OF MECHANICAL METAMATERIALS

Ondřej Rokoš[1,2], Sylviavan Bree[1], Martin Doškář[2], Ron Peerlings*[1], and Marc Geers[1]
[1]Department of Mechanical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands
[2]Faculty of Civil Engineering, Czech Technical University in Prague, Prague, Czech Republic

Summary Mechanical metamaterials generally exhibit their unusual mechanical response by virtue of a coordinated local buckling of their microstructure. Capturing this behaviour in a mean sense presents a challenging problem for (computational) homogenization methods – particularly if the structural dimensions are such that the structure may also buckle globally. In this paper we develop a methodology which meets this challenge. It employs dedicated fluctuation functions which represent the potential local buckling patterns. The amplitudes of these patterns appear as micromorphic fields which need to be solved for at the macroscale – together with the conventional mean deformation. When solved by a full Newton solver, the resulting governing equations can capture local buckling, global buckling, as well as their interaction.

INTRODUCTION

Mechanical metamaterials feature engineered microstructures designed to exhibit exotic, and often counter-intuitive, effective behaviour such as negative Poisson's ratio or negative compressibility. Such a specific response is often achieved through instability-induced transformations of the underlying periodic microstructure into one or multiple patterning modes [1]. Due to a strong kinematic coupling of individual repeating microstructural cells, non-local behaviour and size effects emerge, which cannot easily be captured by classical homogenization schemes. In addition, the individual patterning modes can mutually interact in space as well as in time, while at the engineering scale the entire structure can buckle globally. For efficient numerical predictions of macroscale engineering applications, a micromorphic computational homogenization scheme has recently been developed by Rokoš et al. [2]. In follow-up work, a full Newton solver has been developed for the methodology, including derivations of the tangent operators at the microscale, macroscale and linking the two scales. The Newton solver renders simulations more efficient by ensuring quadratic convergence. But perhaps more importantly, the availability of the tangents allows one to perform a proper bifurcation analysis – at the macroscale as well as at the microscale – and in fact at both levels simultaneously when this is relevant.

In this contribution we demonstrate the performance of the developed methodology by a number of examples in which a competition between local and global buckling exists or where multiple patterning modes (local buckling modes) emerge.

METHODOLOGY

The micromorphic homogenization framework which we employ is founded on the following Ansatz for the full-scale displacement field $\vec{u}$:

$$\vec{u} = \vec{v}_0 + \sum_{i=1}^{n} v_i \vec{\varphi}_i + \vec{w} \tag{1}$$

where $\vec{v}_0$ and v_i, $i = 1, 2, \ldots, n$ vary slowly in space, i.e. at the scale of the macroscopic structure, whereas $\vec{\varphi}$ and $\vec{w}$ are rapidly fluctuating, at the scale of the metamaterial's microstructure. $\vec{v}_0$ represents the mean displacement, which one usually aims to capture by homogenisation. The fluctuation functions $\vec{\varphi}$ represent characteristic modes of deformation, or patterns, which the microstructure exhibits – typically the periodic local buckling modes which underly the metamaterial's particular response. They are defined either as analytical estimates or computed numerically in an off-line buckling analysis on a periodic cell. In either case, for the homogenisation they are known functions. It is the presence of these modes, and the terms in which they appear in (1), which renders the framework nonlocal and allows it to capture the interaction between adjacent microstructural cells. The fluctuation functions $\vec{\varphi}_i$ are modulated by the smooth amplitude functions v_i, which hence indicate how 'active' the individual modes are in the neighbourhood of a particular point of the (macro-)structure. $\vec{w}$, finally, is a remainder term which captures local features of the solution at the microscale. It is computed, as in conventional computational homogenization, on a periodic cell which is subjected to the average response as dictate by the other terms of expression (1).

The governing equations are established by formulating the total potential energy as a functional of $\vec{u}$, substituting the Ansatz (1) and minimizing with respect to $\vec{v}_0$, v_i and $\vec{w}$ (remember that $\vec{\varphi}$ are known functions). Minimizing with respect to $\vec{v}_0$ results in the conventional homogenized equilibrium equation, in which the stress however depends not only on the gradient of $\vec{v}_0$, but also on the amplitude functions v_i and their gradients, as well as $\vec{w}$. The minimization with respect to v_i, where $i = 1, 2, \ldots, n$, results in n additional, micromorphic equilibrium equations in terms of non-standard stresses. The minimization with respect to $\vec{w}$, finally, gives rise to microscale problems on a periodic cell attached to each macroscopic point. For details on these equations and their numerical implementation, we refer to Reference [2] and a forthcoming publication on the formulation of the Newton solver.

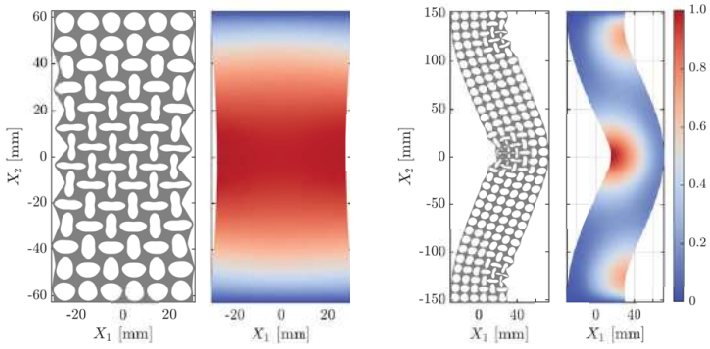
EXAMPLE

An example of the results obtained with the framework, using the novel Newton solver, is shown in Figure 1. A rectangular domain of dimensions $W \times H$ is considered, where W and H are both multiples of the unit cell size l. It is loaded by a vertical compressive strain. The microstructure considered consists of an elastomer with a periodic array of circular holes in a square stacking. Under compressive loading, this arrangement is known to result in a periodic local buckling pattern in which the 'islands' between the holes alternatingly rotate clockwise and anti-clockwise. As a result, the incremental stiffness of the material is reduced drastically compared with its initial, unbuckled stiffness, cf. Reference [1].



(a) DNS, $6\ell \times 14\ell$ (b) MM, $6\ell \times 14\ell$ (c) DNS, $6\ell \times 34\ell$ (d) MM, $6\ell \times 34\ell$

Figure 1: Comparison of the deformed shapes obtained from Direct Numerical Simulations (DNS) and from the micromorphic (MM) computational homogenization scheme. (a) DNS and (b) MM results for a $6l \times 14l$ specimen. (c) DNS and (d) MM results for a $6l \times 34l$ specimen. Local buckling emerges in (a) and (b), whereas global buckling occurs in (c) and (d). The colour in the MM plots indicates the magnitude of the v_1 field normalized by its extreme value. The results are shown for the overall applied strain $u/H = 0.1$.

Figures 1(a) and (c) show full-scale Direct Numerical Simulations (DNS) of the problem for two different aspect ratios H/W. For the smaller ratio, in Figure 1(a), we indeed observe the anticipated periodic local buckling pattern – except for boundary layers along the top and bottom boundaries of the domain, which are restricted in adopting the local buckling pattern by the kinematic boundary conditions along them. Notice also the auxetic effect, which is visible as a horizontal contraction of the sample at mid-height under vertical compression. Figure 1(c) shows that for a larger aspect ratio, i.e. a more slender sample, a global buckling deformation may be obtained which is similar to classical Euler beam buckling. In regions which are under compression, however, also some local buckling (patterning) is observed.

The predictions of the micromorphic computational homogenization framework for the two cases considered are shown in Figures 1(b) and (d), in which the mean deformation $\vec{v}_0$ is visualized by means of the deformed shape of the sample, and the amplitude of the local buckling mode v_1 by the color code. For both aspect ratios the homogenized solutions pick up the main features of the DNS. For the low aspect ratio, Figure 1(b) shows activation of the pattern (given by v_1) in most of the sample, except for two boundary layers at the top and bottom. The auxetic effect is also visible in the mean deformation. And for the slender beam, in Figure 1(d), global buckling is predicted into a mode which is not unlike that of the DNS, while local buckling is also predicted in the correct regions of the beam.

CONCLUDING REMARKS

A more extensive numerical study of the above example, not shown here, indicates that the micromorphic homogenization predicts the local to global buckling transition 4% of relative error in terms of the applied strain. Simulations of a microstructure with hexagonally stacked holes, for which three distinct patterns may be activated, show that the expected pattern combinations are triggered. The revised methodology employing the full Newton solver thus presents a powerful tool for the analysis and design of structures made of mechanical metamaterials.

Summary A graph theoretic view is taken for continuum physics, described by partial differential equations and solved by high-fidelity computations. We consider graph theoretic representations that are made possible by low-dimensional states, typically functionals of the high-dimensional solutions, that therefore retain important aspects of the high-fidelity information. Each state defines a vertex on a graph and edges are induced either by numerical solution strategies, or by the physics. Correspondences are drawn between the sampling of stationary states, or the time evolution of dynamic phenomena, and the analytic machinery of graph theory. A collection of computations is examined in this framework and new insights to them are presented through the graph theoretic representation. Additionally, we present a rigorous framework for reduced order modelling based on these graphs.

BACKGROUND

In this communication, we explore the casting of large-scale computations of continuum physics in the framework of graph theory. The motivation is to work with low-dimensional representations that encode the fidelity of very high-dimensional, computed solutions, and to develop effective methods to explore and extract further information that could have relevance to decision-making on natural or engineered systems. In this first presentation of ideas, the treatment is deterministic. No probabilistic considerations are invoked.

Of specific interest here are initial and boundary value problems (IBVPs) that span the range from stationary or steady-state systems through first- and second-order dynamics. Each computation of the IBVPs is at high spatial and/or temporal resolution, making for a high-dimensional and/or long time series numerical solution. While dimensionality reduction techniques such as proper orthogonal decomposition or tensor decomposition methods and their variants have been widely applied to high-dimensional problems, and compelling progress continues to be made on them, our approach is different. With an ultimate view to decision-making on these systems, we consider functionals defined on the high-dimensional numerical solutions, and that are induced by physics on the system-wide scale. Examples of these functionals include the lift, drag and thrust in computational fluid dynamics, the average strain, load at yield, failure strain or dissipated energy in computational solid mechanics, and phase volumes, total and interfacial free energies in computational materials physics. We consider as the state of the physical system, a low-dimensional Euclidean vector (typically of dimension $\sim \mathcal{O}(10^1)$) whose components are such functionals. The crux of our approach is to treat the states as vertices on a graph, which can then be completed by identifying edges between vertex pairs. We seek additionally to introduce edges that are induced by either (a) the numerical solution technique, or (b) a transition guided by some physical property. In the first case the existence of an edge is determined by convergence of a solution step between states. More alternatives present themselves for edge definition via the physics. We present examples that help make these notions more precise. The edges enable graph traversal by time as well as by enumeration of states guided by the numerics or physics in the low-dimensional space.

Graph theory has a well-appreciated relevance to physical systems, due in some measure to the fact that it underlies network analysis. Applications including traffic flow, electric power grids and neural circuits are well-known. However, its direct use in representing and analyzing physical phenomena that are described by partial differential equations appears relatively under-explored except for the following work: Graph vertices and edges have been used to represent vortices and their interactions, respectively, for the analysis of turbulent flows in computational fluid dynamics. Recently, graphs have been used to represent problem components such as governing equations, constitutive relations and initial/boundary conditions in the numerical framework of IBVPs. Graph vertices and edges also have been used to represent variables and relations between them, respectively, in a game theoretic approach to discovering constitutive response functions for material failure.

GRAPH THEORY FOR COMPUTATIONAL PHYSICS

We make the case that graph theory offers a framework for representation, exploration and analysis of large scale computed solutions. The fundamental insight required is that high-dimensional field solutions typically admit functional representations of low-dimensional states, which are the vertices of a graph. Transitions between states, which could

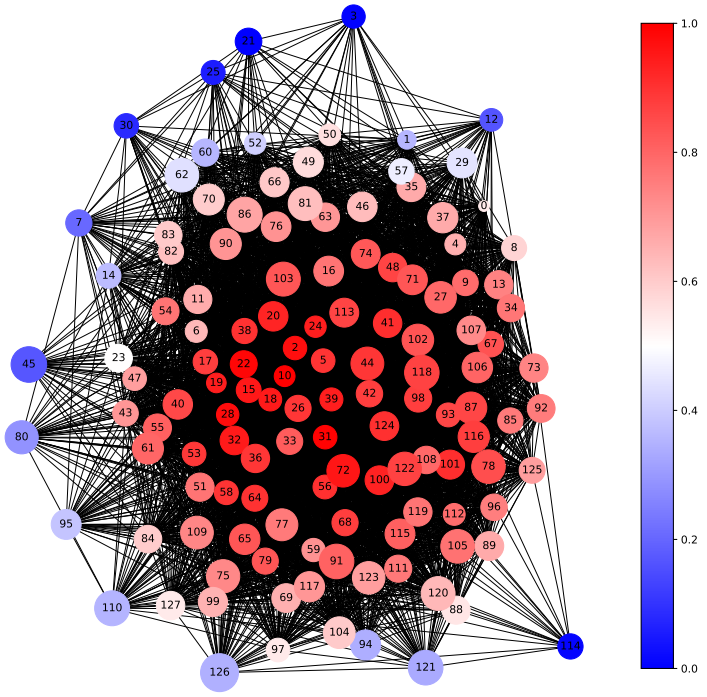

Figure 1: A graph of strain states in Kamada-Kawai layout. The vertices are shaded by their eigenvector centrality, while the area of each vertex symbol is proportional to the Frobenius norm of the strain.

either be a (nonlinear) solution step, or be defined by the change in a physical property, are the edges of the graph. With this foundation, isomorphisms can be identified between the computational and physical framework of states and transitions on one hand, and graph vertices and edges on the other. In this isomorphism, many properties of the numerical solution procedure and of the dynamical physical system are in correspondence with properties of graphs. This includes standard notions of weights, directedness of edges, connectedness of graphs, components, cliques and cycles. Other correspondences arise when considering specific dynamical systems as graphs.

In recent work [1] we have considered computations of IBVPs for stationary and steady-state systems, non-dissipative dynamics and dissipative dynamics, and connected them to specific types of graphs (see Figure 1). The standard machinery of graph theoretic definitions and results was invoked for this purpose. Specific examples were then drawn from computed solutions, and extensive Inferences and insights, not directly available from the high-dimensional numerical solutions, were drawn from analysis of the graphs using well-established concepts from graph theory, as well as algorithms that are motivated by the numerical solution or physics specific to each system.

CONCLUSIONS

Graph theory has, until recently, not had much impact on computational physics, and *vice versa*. Here we have proposed and demonstrated that there is a rich correspondence between these fields that presents many opportunities for representation, exploration and analysis.

MECHANICS OF INFLATABLE AND BISTABLE STRUCTURES

Katia Bertoldi*[1], David Melancon[1], Benjamin Gorissen[1], Ahmad Zareei[1], and Bolei Deng[1]
[1]1School of Engineering and Applied Sciences, Harvard University, Cambridge, United States

Summary Although the study of the effect of shape and geometry on the mechanical response of solid objects has a long history, the surge of modern techniques to fabricate structures of complex form paired with our ability to simulate and better understand their non-linear response has created new opportunities for the design of system with novel functionalities. In this talk I will focus on multistable structures (i.e. structures with multiple stable configurations) and show that they provide an ideal platform for the design of systems with new modes of functionality.

In recent years we have witnessed the emergence of soft structures for which the non-linear response has a prominent role and results in enhanced functionality. Here, I will focus on multistable structures (i.e. structures with multiple stable configurations) and show how numerical simulations can be used to identify new modes of functionality.

Harnessing snapping to make a soft actuator jump

Soft robots comprising several inflatable actuators made of compliant materials have drawn significant attention over the past few years because of their ability to produce complex and adaptive motions through nonlinear deformation. The simplicity of their design, ease of fabrication, and low cost sparked the emergence of soft robots capable of walking, crawling, camouflaging and assisting humans in grasping. However, the actuation speed of soft inflatable actuators is typically limited by the influx of fluid, resulting in slow moving soft robots. To overcome this limitation, we have developed a bistable elastic actuator with an isochoric snap-through (see Figure 1). As no external fluid input is needed to pass through this instability, the resulting actuator deformation happens quasi-instantaneous and is characterized by energy release. Besides optimizing the actuator's design for energy release, we also demonstrate its ability to be reset to the initial, undeformed state, enabling cyclic energy release.

Harnessing transition waves to realize deployable structures

From foldable chairs, and umbrella to tents and solar panels, many structures are capable of quickly changing their shape and, therefore, function. The design of these deployable structures pose two main challenges. First, the transformation needs to be reliable and autonomous and, second, the systems have to be stable and locked in place in the deployed state. Using a combination of experiments and analyses, we demonstrate that bistable linkages and transition waves provide a powerful platform for realizing deployable structures. We first carefully design the bistable joints, so that the transition wave propagates through the entire linkage, transforming the initial straight structure into a curved one. Then, we use these elements as building blocks to create deployable 3D structures of arbitrary shape (Figure 2).

Summary In order to understand elastoplastic deformation behaviour of aluminum alloy sheets under the biaxial stress condition, the biaxial stress-strain (SS) curves of the sheets have been measured by experimental biaxial tensile test using a cruciform specimen and predicted by numerical biaxial tensile test (NBT) based on the crystal plasticity finite element method. This study propose a new computational methodology for efficiently estimating the biaxial SS curves of the sheets using the deep neural network (DNN) with the convolution neural network. The results obtained in this study demonstrates that the DNN trained with the over 50000 training datasets generated by the NBTs quantitatively estimate the biaxial SS curves from an image of (111) pole figure of the crystallographic texture in the sheet.

INTRODUCTION

Aluminium alloy sheets have been widely used for lightweight automotive body. However, low formability of aluminium alloy sheets causes cracking and wrinkle of the sheets during plastic forming. To prevent the failures, we need to predict elastoplastic deformation behaviour of the sheets under biaxial stress condition. Kuwabara *et al.* [1] developed biaxial tensile testing method using a cruciform specimen as shown in Fig. 1(a) and (b). Although the experimental biaxial tensile test provides accurate stress-strain (SS) curve of sheet metals, the test have to be performed for various biaxial stress conditions. On the other hand, Hashimoto *et al.* [2] proposed virtual biaxial tensile testing method using crystal plasticity finite element method (CPFEM), called numerical biaxial tensile test (NBT). NBT enables us to predict SS curves under the biaxial tensile deformation only from crystallographic texture data (*e. g.* orientation distribution functions and pole figures) and uniaxial SS curve. However, NBT needs source code for CPFEM and is computationally expensive.

The purpose of this study is to propose a new computational methodology for efficiently estimating the biaxial SS curves of aluminium alloy sheets using the machine learning technique based on deep neural network (DNN). We develop a DNN with the convolution neural network (CNN) to estimate the biaxial tensile SS curves from an image of (111) pole figure which shows the crystallographic texture in the aluminium alloy sheet.

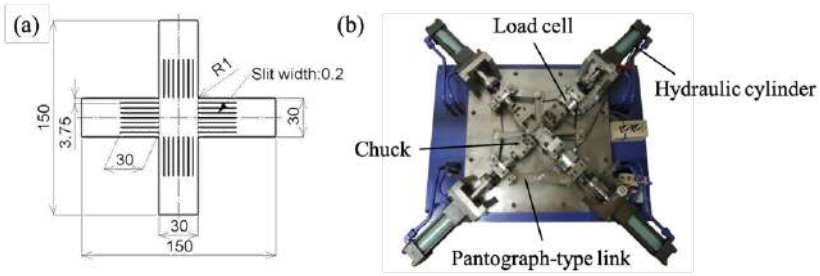

Figure 1. (a) Cruciform specimen and (b) experimental apparatus used for experimental biaxial tensile test [1].

DEEP NEURAL NETWORK

The DNN developed in this study is illustrated in Fig. 2. Input data of the DNN is the image of (111) pole figure of the texture in aluminum alloy sheet and a stress ratio between the true stresses along rolling direction (RD) and transverse direction (TD) of the sheet. The output data of the DNN is SS curves for RD and TD of the sheet. The DNN consists of two CNNs to capture the feature of (111) pole figure image.

A large amount of training datasets is needed for training the DNN. We generate synthetic datasets of crystallographic textures containing Cube, S, Copper, Brass, Goss and random components [3]. Total 5944 synthetic textures are generated by changing volume fraction, V_i, and standard deviation (SD), ξ_i, of the texture component i (i = Cube, S, Copper, Brass, Goss and random). The image files of (111) pole figure for the synthetic textures are generated in Portable Network Graphics (PNG) format with 128^2 pixels.

In order to obtain the biaxial SS curves which include the training datasets, we perform NBTs using the synthetic textures as the initial crystal orientation. The crystal plasticity constitutive equations [4,5] and those parameters used for the NBT are calibrated by SS curve obtained by experimental uniaxial tensile test of A5182-O aluminum alloy sheet. Using the calibrated parameters, NBTs for all the synthetic textures are performed to obtained SS curves for 9 linear stress paths: σ_{RD} : σ_{TD} = 1:0, 4:1, 2:1, 4:3, 1:1, 3:4, 1:2 and 0:1 where σ_{RD} and σ_{TD} denotes the true stress along RD and TD, respectively. Therefore, the NBTs are performed for 53496 times in total.

*Corresponding author. E-mail: a-yamana@cc.tuat.ac.jp.

In the training of the DNN, the mean squared error is used for the loss function. Adam [6] is used for optimization algorithm. Further information for the training of the DNN will be presented in the conference.

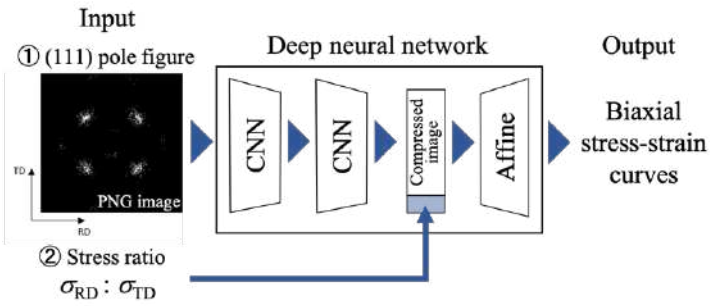

Figure 2. Schematic illustration of the deep neural network (DNN) developed in this study.

RESULTS

The trained DNN are validated by comparing the SS curves calculated by the NBT with those estimated by the trained DNN. Figure 3(a) shows the (111) pole figure of the synthetic texture used for the validation. The synthetic texture are generated based on real texture of the aluminium alloy sheet reported in the literature [6]: V_{Cube} = 18 %, V_S = 8 %, V_{Goss} = 10 %, V_{Brass} = 2 %, V_{Copper} = 4 % and V_{Random} = 58 %, ξ_{Cube} = 3.6°, ξ_S = 2.8°, ξ_{Goss} = 3.4°, ξ_{Brass} = 3.6° and ξ_{Copper} = 2.2°.

Figure 3 (b), (c) and (d) show the true stress-logarithmic plastic strain curves estimated by the DNN for the true stress ratio σ_{RD} : σ_{TD} = 1:0, 1:1, and 0:1, respectively. The result reveals that the trained DNN can quantitatively estimate the SS curves obtained by the NBT based on the CPFEM. Using the trained DNN, the biaxial SS curves can be estimated within a few seconds. In the conference, we will present the SS curves estimated for other synthetic textures and stress ratios.

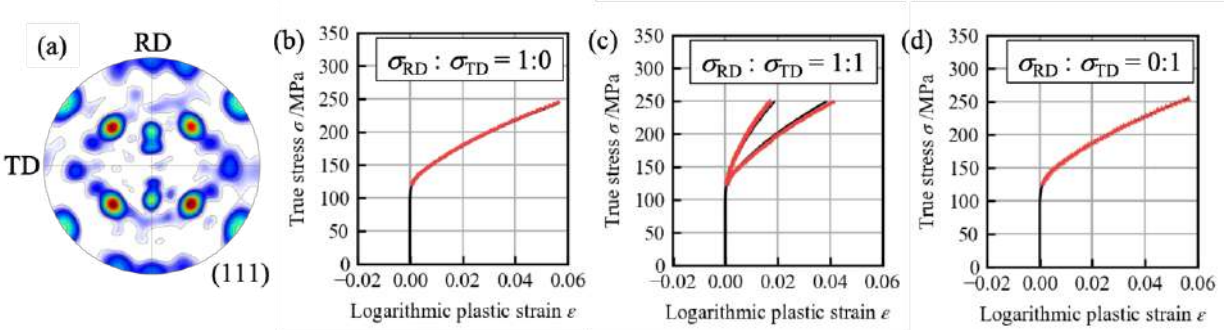

Figure 3. (a) (111) pole figure of the synthetic texture used for the validation of the DNN. Biaxial stress-strain curves obtained by the NBT (black line) and estimated by the trained DNN (red symbols) for the true stress ratios, σ_{RD} : σ_{TD} = (a) 1:0, (b) 1:1 and (c) 0:1.

CONCLUSIONS

In this study, we have proposed the efficient methodology for estimating the biaxial SS curves of aluminium alloy sheets from an image of (111) pole figure based on the machine learning using the DNN. To generate the training data for the DNN, over 5000 synthetic texture datasets were generated and over 50000 NBTs were performed based on the CPFEM. By training the DNN with the massive training data, the trained DNN shows a potential for quantitatively estimating the biaxial SS curves of aluminium alloy sheets.

CHEMO-MECHANICS MODELLING OF LITHIUM-ION BATTERY ELECTRODES

Bai-Xiang Xu*, Yang Bai, and Peter Stein
Division Mechanics of Functional Materials, Technische Universitaet Darmstadt, Darmstadt, Germany

Summary Research on the capacity loss of Lithium-ion batteries have highlighted a rich field of diffusion-induced mechanical phenomena. We summarize firstly our chemo-mechanical phase-field model and finite element simulations for the bulk. The study on the chemo-mechanical interplay at grain boundaries and at interface between the solid electrolyte and electrode is insufficient. We report then our recent progress on developing a chemo-mechanical interface model, which includes both the damage-dependent across-grain transport and the mechanical cohesive zone law. We show that the enhanced intergranular chemical inhomogeneity challenges the grain boundary mechanical strength, while the grain boundary damage influences or even blocks the across grain transport. Results explain well the experimentally observed features like chemical hot spots and surface layer delamination.

Chemo-Mechanics and its Modelling

Rechargeable Lithium-Ion Batteries (LIBs) are widely used in portable electronic devices and electric vehicles, and are also prominent solutions for the storage of intermittent renewable energies. Mechanics can have a critical influence on the performance and the lifetime of LIBs. Materials in LIBs experience breathing-like deformation during cyclic charging and discharging and suffer from considerable chemo-mechanical degradation. Understanding and controlling the effects of stress and strain on ion transport, phase transformations, and catalytic pathways in energy materials can be a key for improving the performance and the durability of battery devices. Figure 1 highlights the (a) mechanistic and (b) mechanical degradation in a typical battery cell.

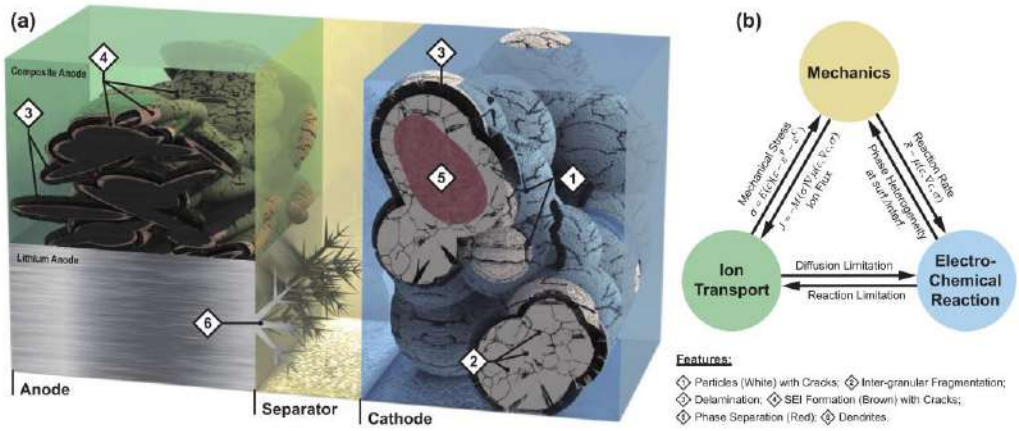

Figure 1. Schematics of (a) mechanistic and (b) mechanical degradation mechanisms of a lithium-ion battery cell with a composite anode and a lithium metal anode, respectively. [1]

To study the deformation of the active electrode materials in the framework of finite deformation elasticity, one can decompose the deformation gradient into the elastic distortion part (indicated by the superscript e) and the (de-)intercalation-induced swelling part (indicated by the superscript c). For the derivation of the coupled constitutive relation and the mass transport equation, we propose the following free energy density in the reference configuration (denoted by the subscript R), considering the Neo-Hookean elasticity, the dilute solution chemical bulk free energy and possible phase interface energy. From the thermodynamics and the phase-field theory, we obtain the second Piola–Kirchhoff stress tensor and the chemical potential contributions.

$$\psi_R(c_R, \nabla_R c_R, \mathbf{C}) = \psi_R^c(c_R) + \psi_R^i(\nabla_R c_R) + \psi_R^e(c_R, \mathbf{C})$$

$$\psi_R^c = c_R \ln c_R + (1 - c_R)\ln(1 - c_R) + \chi c_R (1 - c_R)$$

$$\psi_R^i(\nabla_R c_R) = \frac{1}{2}\kappa |\nabla_R c_R|^2$$

$$\psi_R^e(c_R, \mathbf{C}) = J^c[\frac{K}{2}(\frac{J}{J^c} - 1)^2 + \frac{G}{2}(\bar{I}_1 - 3)]$$

$$\mathbf{S} = \frac{\delta \psi_R}{\delta \mathbf{E}} = \frac{2\partial \psi_R^e}{\partial \mathbf{C}} = J^c[KJ^c(J^c - 1)\mathbf{C}^{-1} + GJ^{-\frac{2}{3}}(\mathbf{1} - \frac{1}{3}I_1\mathbf{C}^{-1})]$$

$$\mu^c = \frac{\partial \psi_R^c}{\partial c_R} = \ln c_R - \ln(1 - c_R) + \chi(1 - 2c_R)$$

$$\mu^i = \frac{\delta \psi_R^i}{\delta c_R} = -\kappa \nabla_R^2 c_R$$

$$\mu^e = \frac{\partial \psi_R^e}{\partial c_R} = \frac{\Omega K}{2}[1 - (J^e)^2] + \frac{\Omega G}{2}(\bar{I}_1 - 3)$$

The stress equilibrium and the mass conservations lead to the following governing equations, along with the boundary conditions:

$$\nabla \cdot \boldsymbol{\sigma} = \mathbf{0} \quad \text{in} \quad B \times (0, \mathcal{T})$$

$$\frac{\partial c}{\partial t} = \nabla \cdot (\mathrm{M} \nabla \mu) \quad \text{in} \quad B \times (0, \mathcal{T})$$

$$\mu = \mu^c + \mu^i + \mu^e \quad \text{in} \quad B \times (0, \mathcal{T})$$

$$-\mathrm{M} \nabla \mu \cdot \boldsymbol{n} = J_s \quad \text{on} \quad \partial B_c \times (0, \mathcal{T}),$$

$$\nabla c \cdot \boldsymbol{n} = 0 \quad \text{on} \quad \partial B \times (0, \mathcal{T}),$$

$$c(\mathbf{x}, 0) = c^0(\mathbf{x}) \quad \text{in} \quad B \times (0, \mathcal{T}),$$

$$\boldsymbol{u} = \hat{\boldsymbol{u}} \quad \text{on} \quad \partial B_u \times (0, \mathcal{T}).$$

More details can be found in our previous publication [2]. Thereby the ion flux *Js* is the (de-)intercalation of Lithium, which can be described by a phenomenological Butler-Volmer model in dependence on the (electro)chemical potentials of the particle and the electrolyte, as described in [1,2]. If the fracture inside the particles is addressed, one can make use additionally the phase-field fracture theory, by adding the damage-like order parameter and the related bulk and interface energies[3]. Through regularization, we considered even the (de-)intercalation of Lithium ion on the freshly created fracture surface denoted by the high gradient of the damage order parameter [4].

Chemo-Mechanical Grain Boundary Model

More recently, we studied also the grain boundary (GB) effect, since most electrode materials have a polycrystal or multi-grains structure. The unique mechanical or chemical properties of the grain boundary has been long recognized, but the chemical process and the mechanical degradation of the grain boundary are fully coupled and go hand-in-hand: the enhanced intergranular chemical inhomogeneity challenges the GB mechanical strength, while the GB damage influences in return the across grain ion transport as it is sensitive to or can be even blocked by GB delamination. For this purpose, we present here a chemically coupled cohesive zone GB model, which includes both the damage-dependent across-grain transport and the mechanical traction-separation cohesive law:

$$J^+ = -J^- = J^d, \quad J^d = (1-d)\left[M^+\nabla\mu^+ - M^-\nabla\mu^-\right]\vec{\mathbf{n}}$$

$$T_n^+ = T_n^- = T_n(\Delta_n, \Delta_t), \quad T_t^+ = T_t^- = T_t(\Delta_n, \Delta_t)$$

whereby d is the damage parameter of the grain boundary. For the grain interior, we employ a chemo-mechanical model described in the last subsection. The outlined chemo-mechanical models for the grain interior and grain boundaries were implemented in the finite element framework MOOSE. In particular, the Discontinuous Galerkin (DG) method is applied for the discontinuity of displacement and concentration at GBs. Numerical simulations were carried out for polycrystalline $Li(Ni_xMn_yCo_z)O_2$ cathode materials, comprising 89, 174 and 413 grains, with radius R = 5 µm, respectively. The 1C-rate discharge process is applied. Simulation examples on demonstrate the capability of our models. In particular, we reproduce the experimentally observed features including chemical hot spots and surface layer delamination (Fig.2), which otherwise cannot be understood using the conventional cohesive zone modelling.

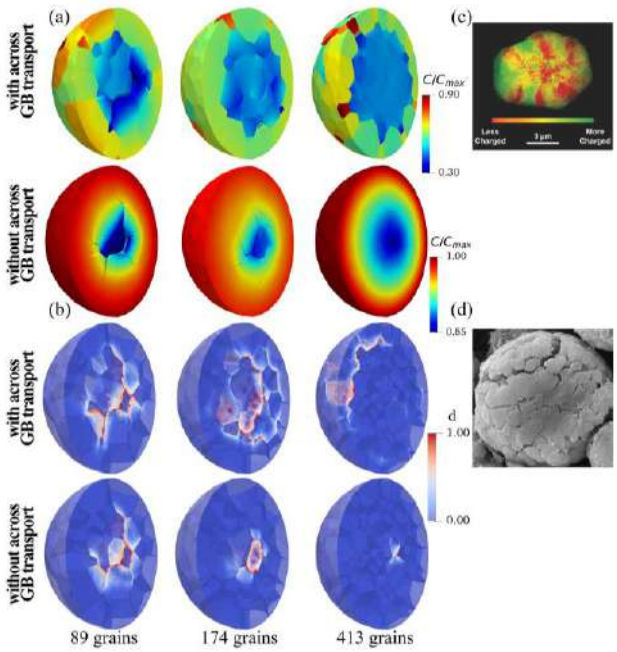

Figure 2. Comparison of the concentration distribution and the crack patterns between the cases with (a) and without (b) across GB transport. The simulated concentration hot spots and surface layer delamination demonstrate similarity to the experimental results (c,d) by Gent et al. Advanced Materials, 28, 2016; Sun et al. Extreme Mechanics Letters 9, 2016).

MODEL-FREE DATA BASE-DRIVEN RVE WITHIN FE²: ANALYSIS OF CRACKED MEDIA

Georgios A. Drossopoulos [1], and Georgios E. Stavroulakis*[21]
[1]Department of Civil Engineering, University of KwaZulu-Natal, Durban, South Africa
[2]School of Production Engineering and Management, Technical University of Crete, Chania, Greece

Summary Fusion of data mining and computational mechanics is a modern approach for the exploitation of available data within rigorous modeling. Previous attempts have been focused on the usage of neural networks and other soft computing tools as metamodeling tools. This framework seems suitable for numerical homogenization techniques realized within the so-called FE² environment, where the lower level FEM of a detailed RVE is replaced by a data base. Extraction of homogenized material properties from the data base is based on classical interpolation or artificial neural networks. We investigate this approach here for the analysis of structures with distributed cracks including unilateral contact behaviour.

INTRODUCTION

Neural networks provide an effective approximator which can be used within nonlinear computational mechanics and replace classical material constitutive models. Replacement of lower level FEM analysis of a representative volume element, as used in multi-scale numerical homogenization, is proposed and tested here. Difficulties of implementing this approach will be discussed and comparison with previously published results, which used classical interpolation, will be shown.

DATA-DRIVEN HOMOGENIZATION ALGORITHM

Numerical homogenization and FE²

Within the classical multilevel approach based on FE² a detailed RVE model is used to calculate the mechanical response of every wished loading. The result is integrated into the nonlinear finite element analysis of macroscopic level, which does not contain all details (cracks, composite structure, microstructure) and is based on the homogenized properties. The authors proposed this scheme for the treatment of unilaterally affected structures in [1]. Due to the high computational cost of classical FE², the lower level has been replaced by an approximation based on a FEM-generated data base in [2]. A more efficient neural network approximator is used here, see Figure 1.

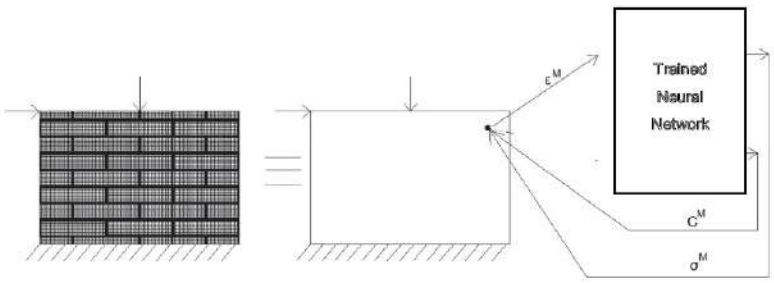

Figure 1. The proposed multilevel approach using a neural network approximation of RVE results.

Homogenized properties using data-base with RVE data

The mechanical response of the RVE is an unknown mapping between the deformation and stress tensors. Various realizations of this mapping have been calculated by a finite element RVE model and stored within a backpropagation artificial neural network of the type 3-10-10-3. The performance of the trained network on unknown deformation inputs is shown in Figure 2. On a randomly selected sample of 1000 inputs the neural network requires an average of 0.009926s for each calculation, in comparison to the 4.251175s required by the interpolation function of MATLAB, which has been used in [2].

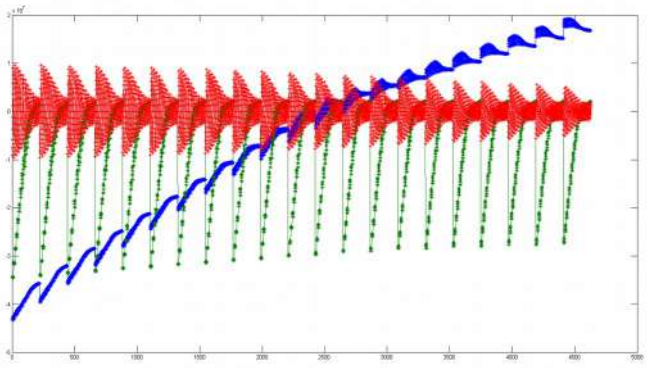

Figure 2. Approximation of RVE results for various load levels using neural networks. NN prediction of stresses for various strain levels.

ANALYSIS OF A CRACKED STRUCTURE

A masonry wall with cracks has been calculated by using the proposed algorithm. Results, like the ones shown in Figure 3, have been compared with previously published in [2].

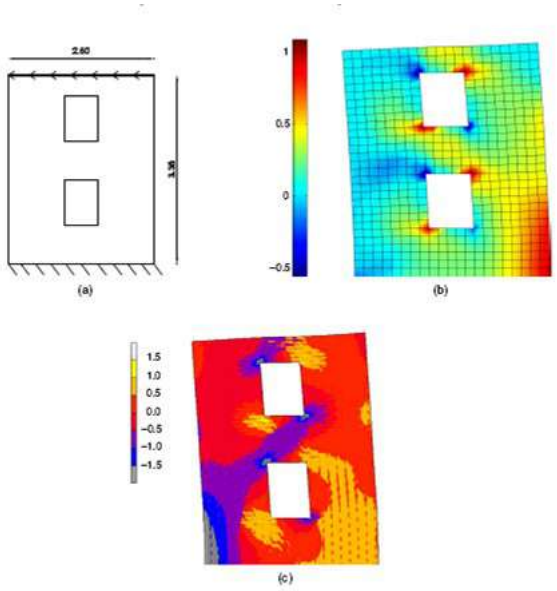

Figure 3. Solution of a cracked wall using the proposed multilevel approach (see [2] for details).

CONCLUSIONS

Data-driven, model-free computational mechanics is a modern approach which promises to give flexibility in using experimental data in the form of data bases [3]. It can be incorporated to make classical FE^2 more efficient by using numerically generated data and classical [2] or neural interpolation.

EFFECT OF MAGNETIC FIELD ORIENTATION ON MAGNETOELECTRIC RESPONSE IN LAYERED COMPOSITES

S. Sudersan *[1] and A.Arockiarajan[1]
[1]Department of Applied Mechanics, Indian Institute of Technology Madras, Chennai, India

Summary Composites of magnetostrictive and piezoelectric systems find applications as gyrators, sensors, etc. These magnetoelectric (ME) composites develop voltage across the piezoelectric phase under applied magnetic field. A number of 1D models quantify the voltage, wherein effect of magnetic field orientation on ME response is often overlooked. Hence, a 2D nonlinear magnetostrictive constitutive relation coupled with First Order Shear Theory (FOST) is used to model the behavior of an ME composite under inplane magnetic fields. A finite element procedure is used to determine the static and resonant response of the structure. The influence of bias as well as AC field orientation on the net output voltage and a correlation between the two is determined in order to ensure maximum coupling. The resonant ME coupling under bending, twisting and axial vibrations has also been quantified.

INTRODUCTION

Magnetoelectric composites have been widely pursued for device applications due to their unique coupling behavior. These materials exhibit a nonlinear response under high magnitudes of applied magnetic fields and hence research has been focused on understanding their constitutive behavior [1]. While symmetric laminates offer the advantage of high ME coupling, they often have resonant frequencies of several kHz, making them difficult to use in practice. Unsymmetric laminates, though offering lower static ME coefficient, can be operated in bending resonant mode at much lower frequencies, thus compensating for weaker static coupling and hence resulting in a comparable response. Hence research works have focused on quantifying the resonant behavior of these laminates at bending and axial resonance [2]. Much of these works approximate the structure as a beam, restricting the magnetic field to the longitudinal direction. The objective of this work is thus to explore the effect of in-plane magnetic field orientation on the static and dynamic ME response of an ME bilayer. Finite element analysis in conjunction with First Order Shear Theory (FOST) is used to determine the nonlinear ME voltage as a function of the applied magnetic field.

CONSTITUTIVE RELATIONSHIP

The magnetostrictive layer is governed by nonlinear constitutive relations, relating the magnetic field vector and the magnetization vector as well as the strain tensor and the magnetic field vector. The piezoelectric layer is assumed to be governed by linear constitutive equations since the electric fields developed are too small to cause nonlinearity. These constitutive relations are linearized about the DC (bias) magnetic field, in order to determine the AC component of the magnetostrictive strain.

$$M_i = M_s f(k||\underline{H}||)\frac{H_i}{H} \quad ; \quad \lambda_{ij} = \frac{3}{2}\frac{\lambda_s}{M_s^2}M_i M_j \tag{1}$$

$$\delta\lambda_{ij} = \left.\frac{\partial\lambda_{ij}}{\partial H_k}\right|_{\underline{H}_b}\delta H_k = \frac{3f}{H^4}(kHf' - f)H_k\delta H_k H_i H_j + \frac{3}{2}\frac{f^2}{H^2}(H_i\delta H_j + H_j\delta H_i) - ff'k\delta_{ij}\frac{H_k\delta H_k}{H} \tag{2}$$

$$\delta\sigma^m_{ij} = C^m_{ijkl}\delta\epsilon_{kl} - q^m_{ijk}\delta H_k \quad ; \quad \delta\sigma^p_{ij} = C^p_{ijkl}\delta\epsilon_{kl} - e^p_{ijk}\delta E_k \tag{3}$$

$$\delta D_i = e^p_{ijk}\delta\epsilon^p_{jk} + \varepsilon^p_{ij}\delta E_j \tag{4}$$

$$\underline{H} = [\cos(\theta)\ \sin(\theta)\ 0]^T \quad ; \quad \underline{\delta H} = [\cos(\beta)\ \sin(\beta)\ 0]^T \tag{5}$$

An applied DC (bias) magnetic field causes a static deformation of the composite, which is then perturbed by an AC field. A dynamic analysis is thus conducted and the AC components of the resulting strains are determined. The open-circuit AC voltage in the piezoelectric layer is then determined by setting δD=0. The effect of the magnetic field is modeled as pseudo mechanical forces and moments on the beam given by

$$\delta N_{ij} = \int_{t^m} Q_{ij}\delta\lambda_i dz \quad ; \quad \delta M_{ij} = \int_{t^m} Q_{ij}\delta\lambda_i z dz \tag{6}$$

The equilibrium equations are given by

$$\delta N_{ij,j} = I_0\ddot{\delta u}_i + I_1\ddot{\delta\theta}_i \ ; \ \delta Q_{i,i} = I_0\ddot{\delta w} \ ; \ \delta M_{ij,j} - Q_i = I_1\ddot{\delta u}_i + I_2\ddot{\delta\theta}_i \tag{7}$$

The aforementioned equilibrium equations and the boundary conditions are used to set up the finite element equations of the form

$$(K_{ij} - \omega^2 M_{ij})d_i = F_i \tag{8}$$

which is subsequently solved to obtain the nodal degrees of freedom and hence the electric field.

*Corresponding author. E-mail: sudersansridhar@yahoo.co.in .

RESULTS AND DISCUSSION

The variation of the ME coefficient with the bias is shown in Fig. Bias(a) for different AC field orientations,β, at specified bias field orientations, θ. It is seen that that the ME coefficient drops rapidly with increasing β and when θ=0°, the ME coefficient vanishes at β=90°. Hence mutually perpendicular fields result in a vanishing ME coupling. It is also seen that the optimum bias at which the ME coefficient is maximum varies as a function of the AC field angle for nonzero θ values.

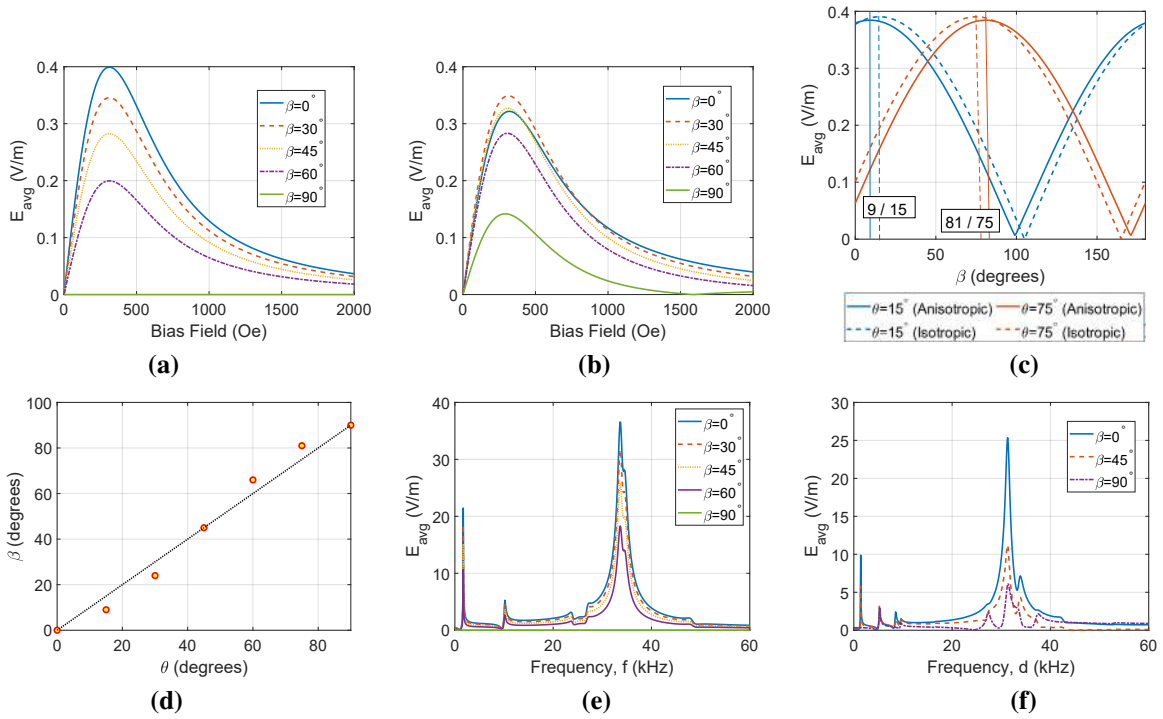

Figure 1: Output electric field at (a) θ=0° and (b) θ=30° (c) Effect of anisotropy of magnetostrictive phase at θ=15° and θ=75°, (d) Corresponding points between θ and β for the peak ME coupling, (e) Resonant electric field at θ=0° and (f) Resonant electric field at θ=45°.

Another point of interest is the effect of the anisotropy of the magnetostrictive phase. This is illustrated at θ=30° in Fig. 1(c) and (d). If the magnetostrictive layer is isotropic, the ME coupling is maximum at β=θ. However, this is not the case when the magnetostrictive layer is transversely isotropic. As can be seen from Fig. 1(c), a difference of about 6° exists between $\theta$and β at θ=15°. It is further noteworthy that at a complementary angle (θ=75°), the difference between θ and β corresponding to the peak values is numerically the same. It is observed that the variation of the ME coupling gets flipped with respect to β. This can be explained on the basis of the decreasing elastic modulus along the longitudinal direction and increasing contribution to the transverse directions. Fig. 1(d) shows the values of β at any given θ corresponding to maximum output electric field. The dotted line indicates the case under isotropic behavior.

The resonant ME electric field is determined at θ=0° and at θ=45°. The combined bending, twisting and axial vibration of the composite results in multiple peaks of the output field with respect to the frequency of the AC field. The results are shown in Fig. 1 (e) and (f) respectively. It is seen that at θ=45°, the bending resonant mode almost disappears as β increases. The additional peaks in comparison to Fig. 1(e) correspond to twisting modes of vibration due to an inclined bias field.

SUMMARY

Thus a nonlinear magnetostrictive constitutive relation has been used in combination with FOST and a finite element framework in order to determine the ME response of laminated magnetoelectric composites. The model predicts the ME coupling at quasi-static as well as resonant conditions. The effect of the bias and AC field orientations and the influence of the anisotropy of the magnetostrictive phase on the observed ME response have been elucidated. A detailed analysis of the system and confirmation of the observations with experiments is planned as future work.

CREEP-FATIGUE LIFE CALCULATIONS FOR TRANSPIRATION COOLED AEROFOILS

Christos Skamniotis*[1], Alan Cocks[1]
[1]Department of Engineering Science, University of Oxford, Parks Road, Oxford, OX1 3PJ,UK

Summary For further increase in gas turbine efficiency, engine temperatures need to exceed the physical capabilities of metals, necessitating advanced cooling technology, such as transpiration cooling systems. Despite their enormous benefits on cooling, these systems come at the cost of thermal stresses which continue to raise thermomechanical performance concerns. To accelerate the industrial implementation-design of such systems, we present new creep-fatigue life calculations of typical double-wall porous aerofoils under thermal cycling conditions. Our analytical, pseudo-analytical and Finite Element (FE) elastic-plastic-creep solutions provide the desirable parameters associated with geometry and thermal cycle characteristics, for which creep-fatigue life is maximized.

THERMOMECHANICAL PROBLEM

We consider the transpiration cooled aerofoil presented by Murray et al [1] (see Fig 1a), which consists of regularly spaced pedestals connecting an outer wall (skin 1) with effusion holes and an inner wall (skin 2) with impingement holes. The latter allow for injecting coolant fluid against the interior of the outer wall, while the effusion holes allow the coolant to escape at an angle (pitch) such that a protective film is formed against the hot mainstream gas flow. Due to convection, a thermal gradient, $\Delta T = T_{max} - T_{min}$, arises in the outer skin 1 (see Fig 1b), while the inner skin is assumed to remain at uniform temperature, T_{min} [2]. To firstly understand how stresses are induced by the gradient, ΔT, and how they can be minimized by first order geometric changes, holes are excluded from the analysis such that the system in Fig 1a can be represented by the repeating unit cell shown in Fig 1b. The latter is cut at its $r-z$ and $r-\theta$ bisectional planes to

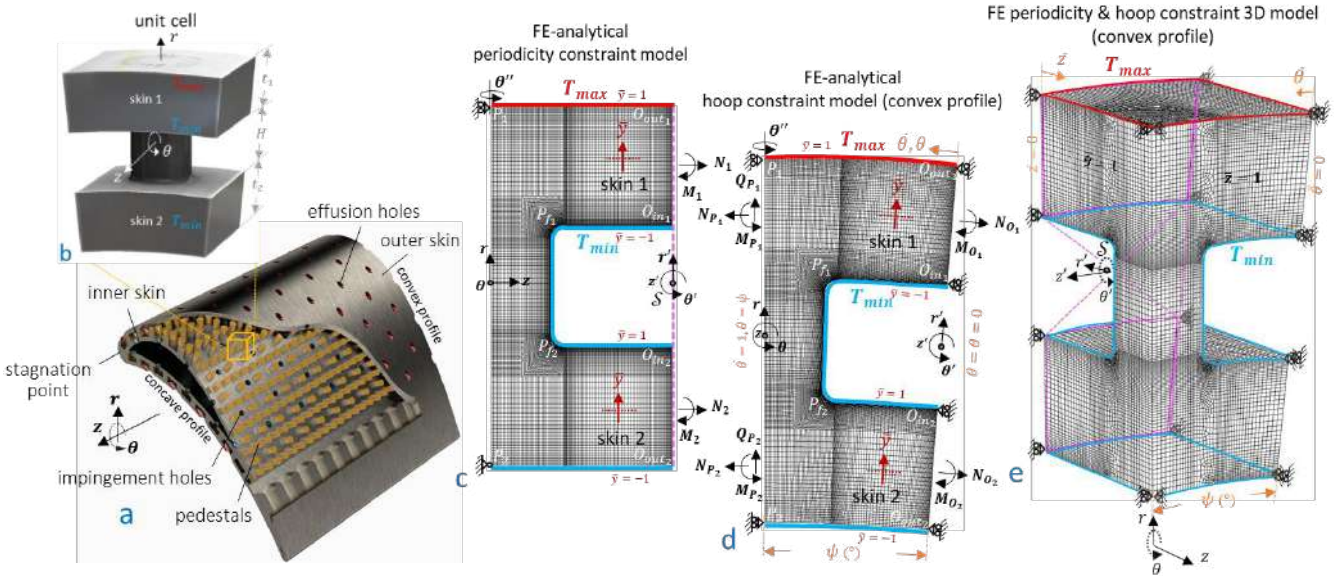

Figure 1. Thermomechanical analysis: (a) double-wall transpiration cooled aerofoil, (b) repeating unit cell, (c) FE-analytical 2D model – periodicity constraint, (d) FE-analytical 2D model – hoop constraint, (e) 3D FE model – combined periodicity and hoop constraints.

produce the 2D models in Fig 1c and Fig 1d, respectively, based on which analytical-FE solutions for stress in the corresponding z and θ directions are derived; the periodicity constraint model (Fig 1c) postulates common θ' −rotation between skins 1-2 at the plane $r'-z'$ [2], whereas the hoop constraint model (Fig 1d) requires zero θ' −displacement and z −rotation the plane $r'-\theta'$. The above conditions co-exist in the 3D unit cell FE model (Fig 1e) i.e. common θ' −rotation between skin 1-2 faces at $\bar{z}=0$ plane (outlined in purple) and symmetry conditions in all other bounding planes. After investigating the relevance of 2D analytical-FE stress field (Figs 1c-d) to the corresponding 3D FE stress field (Fig 1e), holes are added in the 3D model at the location $\bar{z}=\bar{\theta}=0$ (see Fig 2a); the effusion hole pitch is not considered here. The analytical 2D solutions (Figs 1c-d) are obtained based on beam-virtual work theory.

RESULTS: ELASTIC ANALYSIS – EFFECT OF GEOMETRY ON PEAK STRESSES

Based on the analytical-FE 2D analysis alone (Fig 1c-d), we find that minimizing skin spacing, H/t_1, and using low inner wall thickness, t_2, have both beneficial effects, whereas reducing the density of connecting pedestals may reduce compressive stress magnitudes, thus improve creep-fatigue life at the effusion holes at the outer blade surface (at $O_{out_{f_1}}$ location in Fig 2a), yet, it tends to increase tensile stresses at the pedestal-wall filleted corners (at P_{f_1}, P_{f_2} in Fig 2a). These conclusions are found to agree with 3D simulations (Fig 1e) which highlights the advantage of our simplified

*Corresponding author. Email: christos.skamniotis@eng.ox.ac.uk

approach in that it provides analytical relationships for the effect of a range of geometric parameters on nominal stresses. The latter is important because peak stresses at the critical locations of the system i.e. at effusion/impingement holes ($O_{out_{f_1}}$, $O_{in_{f_1}}$, $O_{in_{f_2}}$, in Fig 2a) and at pedestal-skin filleted corners (at P_{f_1}, P_{f_2} in Fig 2a), are found to be a multiple of these nominal stresses and of a stress concentration factor specific to the hole/fillet.

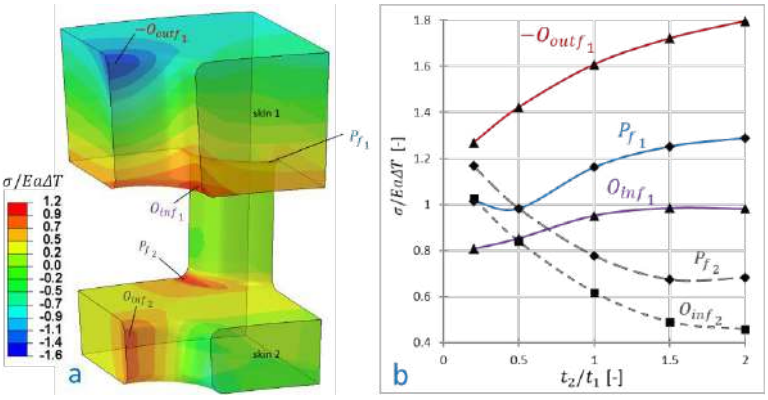

Figure 2. Summary of FE results from 3D model of Fig 1e with added impingement/effusion holes: (a) normalised absolute maximum principal FE stress contours, (b) FE peak stresses at critical points versus skin thickness ratio, t_2/t_1.

RESULTS: INELASTIC ANALYSIS – THE ROLE OF THERMAL CYCLE CHARACTERISTICS

For evaluating creep-fatigue life, we consider that inevitable creep deformation particularly at regions near the external surface of skin 1 (see Fig 1b), will in fact modify the stress field over time. To understand-predict the nature of the long-term stress state at critical points for a given thermal cycling history, we firstly obtain analytical, pseudo-analytical and FE 2D solutions (Fig 1c-d). These account for stress relaxation during the hot part of the thermal cycle i.e. when $\Delta T = T_{max} - T_{min}$ (see Fig 3a) based on a creep power law calibrated for the Nickle based superalloy CMSX-4, and also account for the resulting residual stress profile at the cold part of the cycle i.e. when $\Delta T = 0$ (see Fig 3a); plastic yielding also occurs when a constant Von Mises yield stress, σ_y, is exceeded. Three regimes of behaviour can prevail under these conditions: elastic-creep, reverse plasticity and shakedown; the latter here implies that a cycle state will occur where the total creep strain, ε_c, accumulated during the hot part of each cycle is equal and opposite to the total plastic strain, ε_p, growth at the cold part of each cycle. This gives rise to a cyclic inelastic strain range, $\Delta\varepsilon_i = 2|\varepsilon_p|$, which is related to the number of cycles, N_f, for fatigue failure based on the Coffin-Manson relationship: $\Delta\varepsilon_i = AN_f{}^a$ (A, a material constants). By calculating $\Delta\varepsilon_i$ analytically based on the 'rapid cycle' assumption, in Fig 3b we illustrate how N_f reduces with ΔT and cyclic time at high temperature, Δt_h (see Fig 1a) for a fixed T_{max}, as well as in Fig 3c how N_f decreases with T_{max} and ΔT for fixed Δt_h; less conservative N_f values are found by calculating $\Delta\varepsilon_i$ through other more accurate pseudo-analytical and FE schemes. Our inelastic calculations are extended to account for the 3D case (Fig 1e) including stress concentration at holes as well as for the combined thermal-inertial loading conditions that typically occur in aerofoil components. Our approach aims to reduce the total number of simulations required over the entire design process in double-wall transpiration cooled systems.

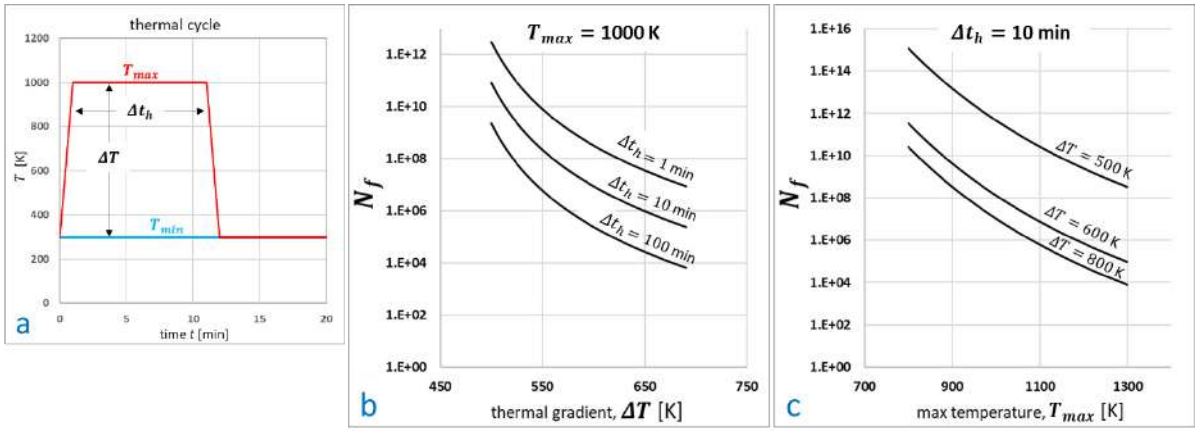

Figure 3. Thermal fatigue calculations: (a) typical thermal cycle, (b) number of cycles to failure, N_f, versus ΔT for varying Δt_h and fixed T_{max}, (c) N_f versus T_{max} for varying ΔT and fixed Δt_h.

TOWARDS THE SIMULATION OF THE FRICTION STIR WELDING PROCESS WITH THE SMOOTHED PARTICLE HYDRODYNAMICS METHOD

Elizaveta Shishova*[1], Florian Panzer[2], Siegfried Schmauder[2], and Peter Eberhard[1]
[1]Institute of Engineering and Computational Mechanics, University of Stuttgart, Stuttgart, Germany
[2]Institute for Materials Testing, Materials Science and Strength of Materials, University of Stuttgart, Stuttgart, Germany

Summary In contrast to common welding processes, Friction Stir Welding does not involve melting of the material. The occurring large deformations and topology changes are problematic to treat by conventional mesh-based discretization methods. Smoothed Particle Hydrodynamics provides an alternative, which is capable of dealing with these issues. This contribution handles various challenges associated with the joining process, combining numerous physical phenomena, such as an appropriate viscoplastic material model, solid-state bonding, thermoplasticity and contact, into one single SPH framework. Different simulation scenarios are performed with the help of the SPH code to ensure the appropriate consideration of each physical effect.

Friction Stir Welding (FSW) is a solid-state joining process [1], where the weld is produced not by melting of the base material like in common fusion processes, but by stirring it at elevated temperatures [2]. The thermal and deformation energies are generated by the tool rotating along the weldline. As a result the material is softened and mixed, producing a non-porous high-quality seam. In experiments, the observation of the material behavior and effects inside the workpiece is not possible, as the tool motion results in a complex, hidden, three-dimensional material flow [3]. Due to that, a vast effort is spent in FSW modeling with the help of different simulation techniques. As there are large deformations present in this joining process, conventional grid-based methods, such as the Finite Element Method, do not provide a reliable simulation model, result in mesh entanglement, and require remeshing. In contrast to that, Smoothed Particle Hydrodynamics (SPH) is a computational method that represents the continuum by discretization points, i.e., particles. This allows the material to follow topology changes and makes it possible to include voids and discontinuities. Besides large deformations, FSW is described by various linked physical phenomena. This contribution provides insight into an accurate implementation of thermo-mechanical simulation, which considers all the effects, which are essential for the FSW process. These include plasticity with high strains and strain rates, inelastic heat generation, friction, and solid-state bonding. In the work presented, the necessary constitutive laws were implemented in the SPH framework, combining thermal, mechanical, and contact effects. The simulation of FSW was performed alongside additional validation examples followed by comparison with analytical solutions, experiments, and conventional simulation techniques.

In literature, there are few examples of FSW simulated using the SPH method [4, 5]. However, a complete and accurate model that considers all of the crucial effects is absent. As an initial test, the existing SPH framework for solids [6] was used to simulate FSW, which can be seen in Fig. 1. However, remaining issues are a lack of a proper material model, the missing transition from contact to continuum during solid-state bonding, as well as the need for an enhanced stabilization technique. These problems have to be addressed separately in order to provide an accurate approximation of the process.

In this study, a new microstructure-based material model was developed in order to reproduce the viscoplastic material behavior in a more complete way, than, for example, the common empiric Johnson-Cook material model [7]. The FSW process is characterized by large strains, large strain rates, and elevated temperatures [8], which requires an improved constitutive law formulation. To do so, a new representation of the yield criteria was composed, which describes yield stress as a function of strain, strain rate, and temperature. In contrast to the Johnson-Cook material model, the influence

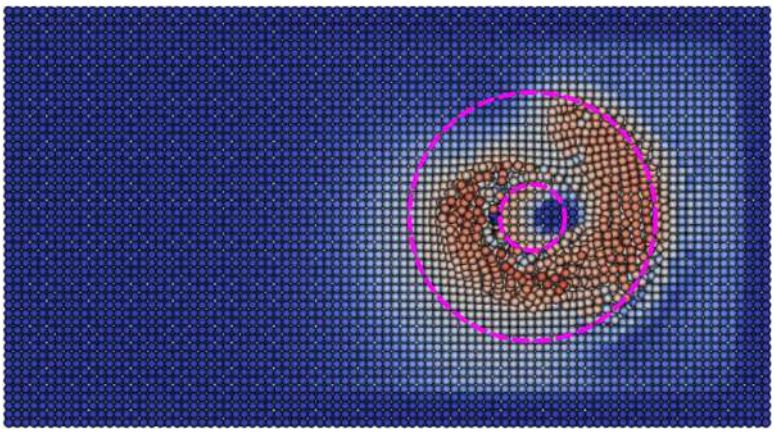

Figure 1: von Mises stress distribution during FSW. Blue: low stresses, red: high stresses.

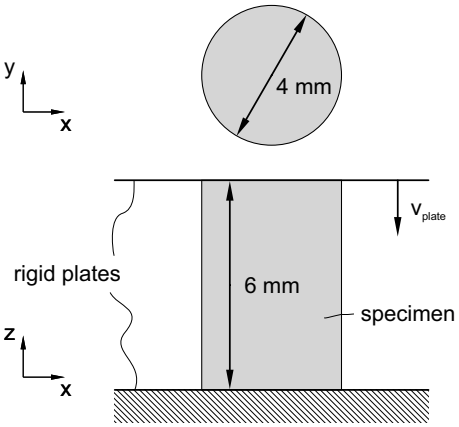

Figure 2: Setup of compression test model

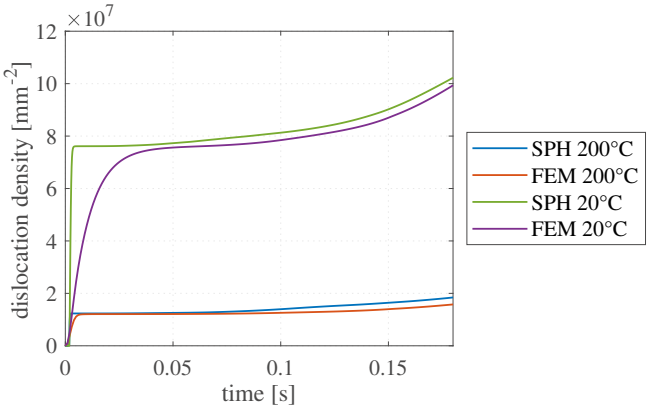

Figure 3: Dislocation density evolution for two different scenarios with isometric temperature $T = 20°\mathrm{C}$ and $T = 200°\mathrm{C}$ for $\dot{\epsilon} = 7\,\mathrm{s}^{-1}$.

of the material condition is not taken into consideration directly, but through a physical description defining the origin of plasticity on a microstructural level. The relationship describes the influence of grain size, dislocation densities, and solid solution on strengthening and softening of the material. In order to produce such a model, the compression tests were performed with different strain rates and temperatures at the Material Testing Institute (MPA). The resulting model was implemented in Abaqus and in the SPH-code Pasimodo [9]. A simple compression test was set up in both simulation frameworks and compared with each other, as well as with experimental results, in order to validate the implementation. The test setup is presented in Fig. 2, where the cylinder is compressed between two rigid planes. Figure 3 shows the evolution of the dislocation density for different temperature scenarios. As it would be expected, the plastic deformation at lower temperatures results in higher amount of dislocations.

There is no FSW model available today, that is able to represent the solid-state bonding, currently the welding interface is already connected before the actual joining happens. That results in an inability of the simulation to predict some specific defects, such as the kissing-bond phenomena. The implemented microstructural material model provides a base for a solid-state bonding criteria. That means that the interaction between SPH particles should be able to change from the normal and friction force interaction into SPH interaction representing a continuum under large deformations and elevated temperatures.

Another crucial aspect of the FSW process are thermal effects. Heat is generated through friction contact of the tool with the workpiece, as well as through large plastic deformations. Heat conduction is responsible for the heat transportation along the workpiece and heat dissipation results in loss of heat to the atmosphere. Additionally, the thermal and mechanical behavior of the model is strongly connected. Therefore, it is essential to simulate the thermal effects correctly. To that end, simulation models with separated effects were created. A nonisothermal compression test was used to validate the contribution of plastic work to thermal energy, as the strain rates can be controlled in this test.

As a final step, the improved SPH framework was used to assemble and simulate an enhanced FSW model, providing deeper insight into the quality and possible improvements of the joining method.

PARAMETRIC REDUCED ORDER MODELLING AND DEEP LEARNING TO ACCOMPLISH PATTERN RECOGNITION AND REGRESSION TASKS

Luca Rosafalco*[1], Andrea Manzoni[2], Stefano Mariani[1], and Alberto Corigliano[1]
[1]Dipartimento di Ingegneria Civile ed Ambientale, Politecnico di Milano, Milano, Italy ù
[2]MOX, Dipartimento di Matematica, Politecnico di Milano, Milano, Italy

Summary The use of high-fidelity physical/numerical models is still challenging when dealing with inverse problems aiming at parameter estimation. To enhance the solution of these problems in computational mechanics, we propose to train statistics-based regressors via input-output data ad-hoc generated from the physics-based model. The goal is to obtain an easy to use data analysis tool capable of performing pattern recognition and regression tasks, in compliance with the governing equations of the model. In particular, we combine: (i) parametric model order reduction techniques, to reduce the computational burden connected to the input-output pairs generation; (ii) deep learning architectures, for the sake of pattern recognition and regression tasks.

PROBLEM DEFINITION

Physics-based high-fidelity models enable the study of complex phenomena and deepen our understanding of reality. In recent times, the development of numerical methods, such as finite elements, have enlarged the domain of applications of such models to attain unprecedented success in building digital twins of real systems. Dealing with model uncertainties also becomes crucial in inverse problems; in several engineering applications, factors like the presence of noise or the redundancy of measurables make inverse problems hard to tackle with customary model updating tools, requiring the use of pattern recognition techniques. To overcome this bottleneck and also attain results in real time, physical models can be empowered by a coupling with statistical tools.

Our proposal consists in training statistics-based regressors via input-output data, ad hoc generated running mechanical models. A regressor is trained using: as input the J_0 displacements and/or acceleration recordings $\mathbf{X}^0 = \left[\mathbf{x}_1^0, \dots, \mathbf{x}_{J_0}^0\right]$ at a discrete locations over the structure in the time interval $[0, I]$; and as output the elastic properties (parametrized by the vector $\boldsymbol{\eta}$). The input $\mathbf{X}^0$ of the regressor is thus the output of the model, while the output $\boldsymbol{\eta}$ of the regressor is the input of the model; for this reason, the regressor is said to operate an output-input mapping.

Dealing with a semi-discretized version of the equations governing structural dynamics, the physical description of a mechanical system is provided by

$$\mathbf{M}\ddot{\mathbf{u}}\left(\boldsymbol{\eta}, t\right) + \mathbf{C}\dot{\mathbf{u}}\left(\boldsymbol{\eta}, t\right) + \mathbf{K}\left(\boldsymbol{\eta}\right)\mathbf{u}\left(\boldsymbol{\eta}, t\right) = \mathbf{f}\left(t\right) \quad t \in (0, T)$$

where: t is the time; $\mathbf{u}\left(\boldsymbol{\eta}, t\right)$ are the degrees of freedom of the mechanical system; $\mathbf{M}$, $\mathbf{C}$, $\mathbf{K}\left(\boldsymbol{\eta}\right)$ are the mass, damping and stiffness matrices, respectively; $\mathbf{f}\left(t\right)$ is the vector of external loads. The displacement/acceleration time recording $\mathbf{x}_j^0$, with $j = 1, \dots, J_0$, is obtained running the model in $[0, I]$ and sampling the structural response in time at the corresponding control points (e.g $x_{1j}^0 = \ddot{u}_n\left(t_1\right), \dots, x_{Ij} = \ddot{u}_n\left(t_I\right)$, where the acceleration of the j-th control point coincides with the n-th degree of freedom of the model).

Given that the generated input-output pairs satisfy the governing equations of the problem, also the regressor enjoys this property. Thanks to the optimization procedure on which the regressor training relies, the regressor acquires the ability of performing pattern recognition. Surrogate or reduced order models can be exploited in place of high-fidelity models, given that the training relies on the generated input-output pairs, and not on the mathematical structure of the model. Parametric model order reduction techniques are then employed due to their capacity of handling the input variability in a straightforward manner, due to the availability of a priori and a posteriori error analyses tools linked to the construction of the reduced order space [3]. Depending on the problem, several deep learning-based architectures may be used for the regressor; in our work [4], neural network architectures have been proven to be extremely powerful and versatile and have therefore been adopted even if, due to the complexity of the non-linear transformation involved, it is generally difficult to describe these algorithms in a close mathematical form.

The described approach has been adopted in numerical benchmarks where the elastic properties $\boldsymbol{\eta}$ of a specimen under partially unknown loading conditions must be determined on the basis of available displacement and/or acceleration recordings, as typically done in vibrational analysis. Given that such measurements are shaped as multivariate time series, fully convolutional networks featuring three convolutional layers have been exploited [1]. The l-th convolutional layer operates a non linear transformation of the incoming signal according to $\mathbf{X}^l = \sigma\left(\mathbf{W}^l * \mathbf{X}^{l-1}\right)$, where $\mathbf{X}^{l-1} = \left[\mathbf{x}_1^{l-1}, \dots, \mathbf{x}_{J_{l-1}}^{l-1}\right]$ is the input matrix; $\mathbf{X}^l = \left[\mathbf{x}_1^l, \dots, \mathbf{x}_{J_l}^l\right]$ is the output matrix; σ is an element-wise activation function, and $\mathbf{W}^l = \left[\mathbf{w}_1^l, \dots, \mathbf{w}_{J_l}^l\right]$ is a kernel matrix, being $\mathbf{w}_j^l$ a kernel with Q_l tunable parameters. The convolutional dot product $*$ reads $\mathbf{x}_j^l = \sigma\left(\mathbf{w}_j^l * \mathbf{X}^{l-1}\right)$ where, at a sliding step centered at i:

$$\left(\mathbf{w}_j^l * \mathbf{X}^{l-1}\right)_i = \sum_{q=0}^{Q_l} \sum_{k=0}^{J_{l-1}} w_{qj} x_{i+q,k}^{l-1} \, .$$

APPLICATION

A numerical benchmark dealing with a classification task is adopted to assess the performance of the proposed approach. A cantilever beam, whose geometry is depicted in Fig.1, is loaded with a uniform load $\mathbf{f}$ that has a sinusoidal dependency on time, and whose magnitude and frequency are described by two uniform probability distributions $\mathcal{U}_1\,(0.075, 1.025)$ kN/m and $\mathcal{U}_2\,(25, 325)$ Hz, respectively. The beam domain Ω is divided into four parts Ω_r, $r = 1, \ldots, 4$, of equal length. The beam deflection is recorded in four points located on the upper surface of the beam at $x = 1, 2, 3, 4$ m. Considering a reference Youngs modulus $E = 210$ GPa, the goal is to understand which of five possible states has generated the pseudo-experimental measurements: in each damage state, E is reduced by 25% in one single domain, while the virgin state (baseline) is considered as state 0.

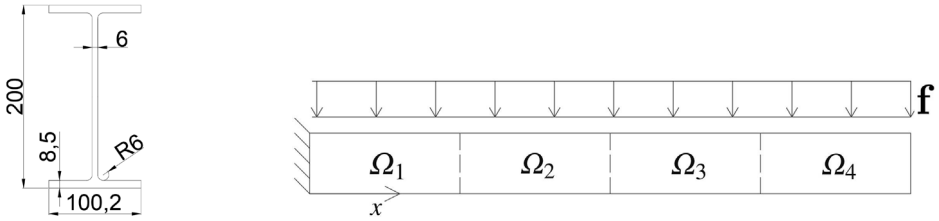

Figure 1: (left) IPE 200 cross section (dimensions in mm); (right) schematic representation of the problem.

Reduced basis techniques [2] have been used for the parametric order reduction of the model to treat the sources of variability of the mechanical system output, depending both on $\boldsymbol{\eta}$ and on the (partially unknown) loading conditions. Whenever non affine dependences on the input has been encountered, hyper-reduction techniques, such as the discrete empirical interpolation method, have been exploited.

The obtained results testify the potentialities of the approach: in Fig.2 the evolution of loss C and accuracy A on the training set $\mathbf{D}_{train}$ (used to train the fully convolutional network) and on the validation set $\mathbf{D}_{val}$ (used to interrupt the training when necessary) are depicted. The evolution of C and A are shown against the number of iterations performed by the training algorithm. In Fig.3 the confusion matrix obtained on the test set $\mathbf{D}_{test}$ (unseen by the network during training) is reported, highlighting an overall accuracy of around 98.7%. $\mathbf{D}_{train}$ and $\mathbf{D}_{val}$ have been constructed using the reduced order model, while $\mathbf{D}_{test}$ has been constructed using the high fidelity model, meant as a replica of reality.

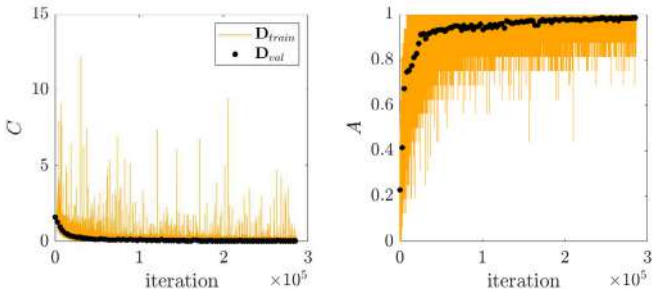

Figure 2: Left: evolutions of C (left) and A (right) on $\mathbf{D}_{train}$ and $\mathbf{D}_{val}$ during the training of the fully convolutional network.

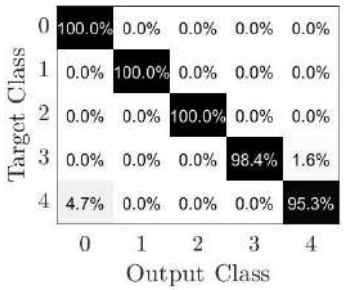

Figure 3: Confusion matrix related to the classification performance of the regressor on $\mathbf{D}_{test}$.

A QUASI-EXTREMAL ENERGY PRINCIPLE IN RATE-INDEPENDENT PLASTICITY OF SINGLE CRYSTALS

Henryk Petryk[1]
[1]Institute of Fundamental Technological Research (IPPT), Polish Academy of Sciences, Warsaw, Poland

Summary A quasi-extremal energy principle has recently been proposed for non-potential problems in rate-independent plasticity for which the known extremal principles do not apply. The principle is extended here to small but finite increments, with the end-point values of displacements and plastic multipliers as unknowns in a computational approach. The aim is to overcome the difficulty related to non-uniqueness of incremental solutions for ductile single crystals characterized by a slip-system interaction matrix that is indefinite and non-symmetric. The extended principle is applied to numerical simulations of large plastic deformation of a single crystal with automatic selection of the currently active slip systems at each time step.

INTRODUCTION

There is a long-standing difficulty in solving incremental problems of rate-independent plasticity, which is related to non-uniqueness of solutions. Commonly known branching phenomena like buckling, necking, shear banding or subgrain formation require a criterion of choice of the post-critical deformation branch in numerical simulations. In crystal plasticity at finite strain [1, 2, 3], the difficulty appears already at the level of selection of active slip systems at a material point. If there exists an incremental potential then a computational approach based on the incremental energy minimization is available [4, 5, 6]. However, a generic rate-problem in crystal plasticity is of non-potential type, therefore the question arises how to select a physically meaningful solution among multiple possibilities when the known extremal principles do not apply.

Recently, a new energy-based variational formulation has been developed for a broad class of non-potential problems in rate-independent plasticity [7]. It has been shown that direct incremental energy minimization does not provide a proper solution to the rate-problem posed when the global stiffness matrix for active plastic deformation mechanisms is not symmetric. The correct rate-solution is then generated by a quasi-extremal energy principle in which the minimized function depends on an unknown solution as a parameter.

The aim of the present work is twofold. First, to extend the quasi-extremal energy principle, formulated originally for rate-solutions, to small but finite increments with the end-point values as unknowns in a computational approach. Second, to apply it in numerical simulations of large plastic deformation of a single crystal for automatic selection of the currently active slip systems at each time step, without assuming symmetry of the slip-system interaction matrix.

A QUASI-EXTREMAL ENERGY PRINCIPLE FOR A DISCRETIZED PROBLEM

A *quasi-extremal principle* (QEP) for a discretized plasticity problem takes the form

$$x = \arg\min_{z\in\mathbb{Z}} \mathcal{E}(z,x)\,, \qquad z=(\tilde{q},\tilde{\mu}), \qquad \mathbb{Z}=\mathbb{R}^m\times\mathbb{R}^n_+\,, \tag{1}$$

where the variable $z=(\tilde{q},\tilde{\mu})$ encompasses virtual increments $\tilde{q}=q^{k+1}-q^k\in\mathbb{R}^m$ of generalized displacements and non-negative plastic multipliers $\tilde{\mu}\in\mathbb{R}^n_+$. A characteristic feature of a quasi-extremal principle is that the minimized real-valued function $\mathcal{E}$ depends not only on variable z but also on an unknown solution x as a parameter. Function $\mathcal{E}$ has a particular energy-based form derived in [7]. It is essential that function $\mathcal{E}$ is generally non-convex when evaluated with accuracy to second-order terms. When extended to small but finite increments, it takes a fully analogous form,

$$\mathcal{E}(z,x)=\tilde{E}(z)+z\cdot Cx\,, \qquad C=-C^{\mathrm{T}}\,, \tag{2}$$

where the leading term is the incremental energy function defined for isothermal irreversible processes by

$$\tilde{E}=\tilde{\Phi}+\tilde{\Omega}+\tilde{\mathcal{D}}\,. \tag{3}$$

Here, a tilde over a symbol means an increment, Φ is the Helmholtz free energy, Ω the potential energy of external loads, and $\tilde{\mathcal{D}}$ is the incremental rate-independent dissipation in the case when all components of $\tilde{z}$ vary proportionally in time during a time step $[t^k,t^{k+1}]$. The term $z\cdot Cx$ in Eq. (2) is new and accounts for the loss of potentiality of the incremental problem. It is expressed through the anti-symmetric part $C=\frac{1}{2}(A-A^{\mathrm{T}})$ of a governing matrix A in constitutive equations $(\tilde{Q},\tilde{f})=Ax+o(t^{k+1}-t^k)$ that relate an incremental solution x to increments $\tilde{Q}$ of generalized forces and $\tilde{f}$ of yield functions. It has been shown that a solution x to QEP (1) solves the incremental quasi-static problem so that $\tilde{Q}$ satisfies the equilibrium conditions and $\tilde{f}$ the discrete consistency conditions at the end of a time step.

Moreover, QEP (1) includes also the energy criterion of stability of a solution path in the sense that small perturbing forces make a non-negative scalar product with a deviation δx they induce in the solution. QEP (1) with non-convex $\mathcal{E}$ provides thus a criterion of choice among multiple solutions that is not based on arbitrarily assumed imperfections or random selection but has a physical meaning. For potential problems we have $C=0$, and then QEP (1) reduces to direct minimization of $\tilde{E}(z)$ known as the energy criterion of path stability or as the incremental energy minimization approach.

SELECTION OF ACTIVE SLIP SYSTEMS IN A SINGLE CRYSTAL

Similarly to the incremental energy minimization limited to potential problems, QEP (1) can be used to overcome the difficulty related to non-uniqueness of incremental solutions to non-potential problems for ductile single crystals. In particular, it has been employed to select a non-uniquely defined set of active slip systems in a single crystal for which the energy function $\mathcal{E}$ is non-convex due to latent hardening higher than self-hardening. To solve the problem numerically, the constrained non-convex minimization problem in QEP (1) has been converted to a smooth unconstrained one by using the augmented Lagrangian method [8] in a manner fully analogous to that in [6].

The algorithm developed in [6] has been applied after modifying the incremental work expression by adding an extra term corresponding to the last term in Eq. $(2)_1$. Effectiveness of the algorithm for large plastic deformation is demonstrated by an example of simple shear λ relative to a fixed laboratory frame $\bar{X}_i$ initially aligned with crystallographic lattice direction [100] and plane (001) of an fcc single crystal with the full set of crystallographic slip systems. The results reported here have been obtained for the step size in λ equal to 0.01. The predicted material response and the changes of active slip systems caused by rotation of the crystallographic lattice are illustrated in Fig. 1.

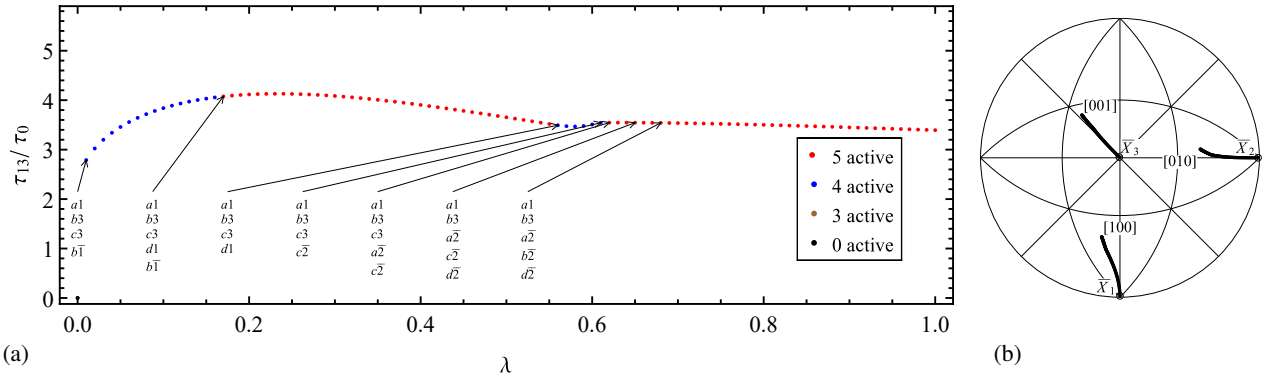

Figure 1: (a) Normalized shear stress vs shear strain for simple shear of a Cu single crystal, and (b) accompanying changes in the orientation of crystallographic axes.

The results are qualitatively similar to those obtained earlier in [6]. However, there are also quantitative differences due to the selective symmetrization of the slip-system interaction matrix used in [6] and absent here. The points marked by arrows in Fig. 1a correspond to unloading of some slip system and/or loading of some other system that reaches the current threshold value of the resolved shear stress. It is remarkable that the number of simultaneously active slip systems does not exceed five, which is in accord with experimental observations of polycrystals and results here from the energy criterion of path stability that is embedded in QEP (1).

Further work on non-unique deformation patterns computed with the help of the quasi-extremal energy principle is currently in progress.

CONCLUSION

- The recently proposed [7] quasi-extremal energy principle (QEP) for non-potential problems in rate-independent plasticity has been extended to small but finite increments with the end-point values as unknowns in a computational approach.
- Applicability of the QEP has been illustrated by the example of selection of active slip systems in a Cu single crystal under large plastic shear, without assuming symmetry of the slip-system interaction matrix.

THEORETICAL AND COMPUTATIONAL RESULTS ON MATERIAL CONSTRAINTS IN ANISOTROPIC ELASTICITY

Michele Marino*[1] and Peter Wriggers[2]
[1]Department of Civil Engineering and Computer Science, University of Rome Tor Vergata, Rome, Italy
[2]Institute of Continuum Mechanics, Leibniz University, Hannover, Germany

Summary Incompressibility conditions and/or strong anisotropies introduce internal constraints in material deformation. Numerical simulations comprising "constrained" materials show an overstiff structural response, referred to as element locking. Implementations based on mixed variational methods can heal locking but several solutions adopted in the state-of-the-art are still non-optimal for anisotropic materials. This paper addresses this issue by proposing a novel decomposition of anisotropic deformation modes on the basis of kinematic and energy requirements. Theoretical results exploit the Walpole's formalism. A low-order mixed finite element formulation for dealing with quasi-inextensibility and/or quasi-incompressibility constraints is thus derived and analysed.

INTRODUCTION

Many engineering applications comprise materials with an anisotropic response [1]. For instance, in civil, aerospace and automative industries, fibrous or fiber-reinforced materials are widely employed since they gather lightweight properties with excellent strength behaviors and complex target responses. In the design of fiber-reinforced composite materials, structural requirements or production restrictions might lead to the use of highly-stiff fiber materials or matrix properties with small/negligible volumetric deformations. This occurs, for instance, in applications like soft actuators, textiles, rubberized concretes or laminates, but also in the domain of biological tissues [2]. Stiff responses along particular directions and/or in the volumetric behavior can be regarded as internal constraints in material response.

Numerical simulations are widely employed in technical applications to analyze material and/or structural behavior for design and verification purposes. Nevertheless, the robustness and accuracy of numerical simulations are highly affected by the presence of internal constraints in material response. Traditional finite element formulations exhibit poor convergence rates in the basic variables and the element response is overstiff. These phenomena are generally referred to as locking and they have been widely explored in the literature, for instance, for the case of incompressibility [3], fiber inextensibility or intra-ply fiber shear [4, 5, 6]. Clearly, when material constraints couple each other, like when inextensble fiber are embedded in an incompressible material, locking effects severly amplify. This work explores Hu-Washizu-like mixed formulations introduced for overcoming element locking in the case of anisotropic materials [7]. The analysis is restricted to linear elasticity with transversely isotropic material symmetries.

MIXED FORMULATIONS IN ANISOTROPIC ELASTICITY

Within a variational principle for mixed formulations, the internal energy density is enriched by means of Lagrange (stress-like) multipliers and deformation-like (energy-conjugate) variables. In order to deal with material constraints, the strain tensor is generally split in two contributions: a penalized contribution, associated with the material constraint, and the complementary part. Apart from mechanical equilibrium (i.e., the balance of linear momentum), stationary of the enriched potential energy leads to two additional (set of) equations. One is associated with kinematic compatibility, where the penalized strain (i.e., the displacement field) is controlled in terms of the introduced deformation-like variables. The other one is associated with the constitutive relationship, where the deformation-like variables are related to the Lagrange multipliers through the material constitutive response associated with the overstiff behavior (e.g., the bulk modulus for incompressibility or fiber stiffness for inextensibility). This rationale is here referred to as penalized-kinematics. If the introduced decomposition of the strain tensor respects energetically-orthogonality, the balance of linear momentum will not explicitly depend on the deformation mode associated with the material constraint, being fully replaced in its stress response by the introduced Lagrange multipliers. As a consequence, the material constants associated with the overstiff behaviour will also not explicitly appear. In this case, the associated mixed variational formulation is referred to as energetically-decoupled, since the penalized "constrained" deformation mode is decoupled in energy from the complementary "unconstrained" one.

In isotropic elasticity, the classical volumetric-deviatoric split leads to energetically-decoupled mixed variational formulations where the bulk modulus does not explicitly appear in the static equilibrium [3]. Anisotropy introduces relevant issues in the kinematic decomposition of material response for dealing with internal constraints. For instance, the classical volumetric-deviatoric split for treating incompressibility in the presence of anisotropic elasticity looses its significance (since it assumes an isotropic response). Moreover, in the presence of fiber inextensibility, existing mixed formulations for anisotropic materials are generally built exclusively upon a kinematic rationale (like the removal of the unidirectional elongation of fibers), hence violating energy-orthogonality requirements [4, 5]. A general constraint manifold theory which

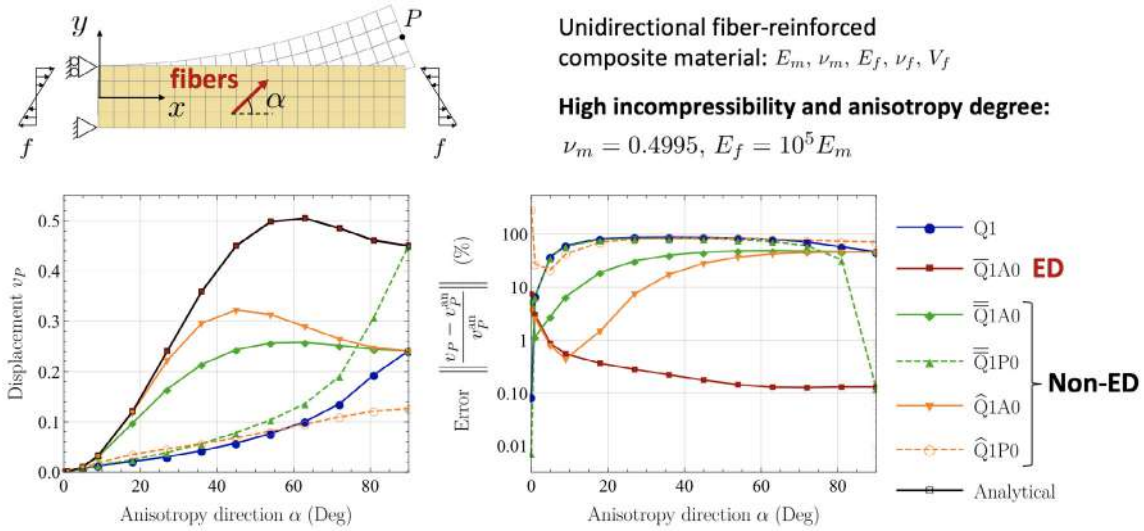

Figure 1: Vertical displacement v_P (left) and relative error (right) obtained in a pure bending test: comparison between the proposed energetically-decoupled (ED) Hu-Washizu formulation using the Walpole's formalism for strong transverse isotropy and high incompressibility with different non-energetically-decoupled (Non-ED) mixed potentials. Results are shown for different anisotropy direction (i.e., fiber angle α) on a structured mesh with element density $n_{el} = 10$.

introduces energetically-consistent Hu-Washizu formulations for incompressibility, inextensibility and inshearability has been recently discussed by Zdunek in Ref. [6].

The present work presents novel theoretical and computational results on transversely isotropic elasticity for different degrees of incompressibility and/or anisotropy. Results are built exploiting the convenient basis offered by the Walpole's formalism [8, 9]. A projector operator is built on the basis of kinematic and energy requirements and its effectiveness in terms of numerical results analysed.

NUMERICAL RESULTS

A low-order mixed finite element formulation based on the proposed kinematic split is introduced and tested on a number of benchmark tests and engineering case studies. Firstly, in order to investigate on the engineering relevance of the obtained theoretical results, the ineffectiveness of the classical volumetric-deviatoric split in anisotropic elasticity is investigated from the numerical point of view, showing that accuracy is lost even in the presence of mild anisotropy degrees. Moreover, the drawbacks of employing a non-energetically-decoupled formulation based only on a penalized-kinematics rationale are clearly shown in terms of accuracy, convergence properties and robustness with respect to material properties (see Fig. 1).

CONCLUSIONS

In this work, the theoretical derivation of energetically-orthogonal deformation modes in transversely isotropic linear elasticity was developed by exploiting the convenient representation offered by the Walpole's basis. A projector operator on the deformation field has been designed in order to satisfy kinematic and energy requirements. It has been proven that the projected strain contains the full volumetric deformation at hand. Accordingly, the proposed formulation allows to effectively deal with the presence of material constraints associated with quasi-inextensibility and/or quasi-incompressibility. Energetically-decoupled mixed variational formulations were introduced and implemented in low-order finite element models, investigating their numerical effectiveness.

Summary The aim of the work is to study the overall mechanical response of periodic composite characterized by constituents with a nonlinear response. In particular, a plasticity material model with isotropic hardening is considered at the microscale. A representative volume element of the heterogeneous material is studied. The micromechanical problem is solved considering two different reduced order models, one based on Hashin-Shtrikmann homogenization scheme and the other one on the Transformation Field Analyses. Some numerical applications are carried out comparing the two presented techniques.

INTRODUCTION

Composite materials are used in several fields of structural engineering. Their heterogeneous and complex microstructure have to be considered in order to predict the macroscopic response of the composite material, taking into account the possible nonlinear response of the components. In this case, the study becomes more complex as the nonlinear effect occurring in the material has also be modeled. A large class of composite media are made of constituents that exhibit plastic behavior that requires the use of nonlinear elastoplastic material models.
One possibility to evaluate the overall mechanical response of these composite materials, which have complex microstructures and plastic effects in its constituents, is to adopt micromechanical procedures, that study a representative volume element (RVE), determining the behavior of the homogenized equivalent material. To this end, nonlinear finite element analyses can be developed to solve the micromechanical problem, requiring expensive computations, due to the large number of history variables and micromechanical unknowns, in view of multiscale analyses.
Thus, efficient tools able to determine the overall response of the material, taking into account its microstructure and the nonlinear phenomena occurring, are needed. For this reason, model order reduction techniques have been proposed in the literature.
The aim of this work is to study and compare two reduced order models (ROM) in order to underline advantages and disadvantages of these techniques. In particular, the study investigates the performances of the Hashin-Shtrikmann (HS) homogenization scheme, proposed in [1] and based on the Hashin and Shtrikman approach [2], and of the Piecewise Uniform Transformation Field Analysis homogenization technique, presented in [3] and based on Transformation Field Analysis proposed by Dvorak [4]. In particular, the HS technique is herein extended to plasticity with isotropic hardening adopting the Von Mises yield criterion.

REDUCED ORDER MODELS

Periodic composites are considered and a unit (UC), repetitive cell is studied. Indeed, composites with constituents characterized by a plastic behaviour are studied and, in particular, a plastic model based on the introduction of Mises yield function and isotropic hardening is considered.
The micromechanical problem of the UC is solved adopting two different reduced order models. In both the approaches the UC is divided in elastic and plastic clusters where constant plastic strains are considered.
The Piecewise Uniform Hashin-Shtrikman (PWUHS) is derived from the Hashin-Shtrikman variational formulation, which is based on the introduction of a linear-elastic reference medium characterized by an elastic tensor $\mathbf{C}_0$. A common choice is to consider the isotropic stiffness matrix according to the homogenization theory by Voigt, which assumes homogeneous strain throughout the composite material components. An alternative is provided by the overall elasticity matrix $\bar{\mathbf{C}}$ evaluated on the real composite. A constant eigenstress is introduced in each cluster to take into account the actual elastic properties of the cluster with respect to the linear-elastic reference medium and the plastic phenomena. The micromechanical problem is formulated considering the average strains in each cluster as primary unknowns and the uniform inelastic strain as internal variables. To improve the results of the procedure the elastic properties of the reference medium can be updated during the loading history according to the *secant modulus approach,* in order to take into account the plastic phenomena occurring in the heterogeneous material. The second approach is based on the Transformation Field Analysis in which the inelastic strain, assumed as internal variable, is considered uniform in each cluster (PWUTFA) and its evolution is governed by the average stress in the cluster. In both the approaches the numerical procedure is developed to solve the micromechanical problem in two dimensional framework. The unit cell is studied applying loading histories in terms of overall average strains. The two presented homogenization techniques are able to determine the overall stress in the UC taking into account the nonlinear phenomena.

NUMERICAL APPLICATIONS

Different numerical applications are carried out in order to study the convergence of the two approaches and the efficiency in evaluating the mechanical response of composites characterized by plastic matrix and elastic inclusions. The results

obtained by the homogenization techniques are compared with the one recovered solving the micromechanical problem by nonlinear finite element analysis.

A convergence study for the PWUHS is herein reported. In Figure 1(a) a UC characterized by a plastic matrix and an elastic inclusion with a volume fraction equal to 0.54, is represented (UC-1). Both the matrix and the inclusion are characterized by the same elastic properties (Young modulus equal to 210 GPa and Poisson coefficient equal to 0.3). The yield stress of the matrix is 300 MPa and the isotropic hardening modulus is 100 MPa. The reference elastic matrix is considered constant during the analysis or updating its properties. An increasing monotonic loading history is considered for the horizontal average strain. Several analyses are carried out for two possible scenarios considering only one cluster for the inclusion and an increasing number of clusters for the matrix or a completely refined inclusion (60 clusters) and an increasing number of clusters for the matrix. The method converges to the FE solution as reported in Figure 1(b) and (c) where the value of the overall stress at the end of the analysis is plotted versus the number of clusters in the matrix.
