

1 **Fire fragility curves for industrial steel pipe-racks integrating demand** 2 **and capacity uncertainties**

3 **Abstract**

4 This paper aims at deriving fire fragility curves for a prototype steel pipe-rack in an industrial plant
5 subjected to localised fires. In particular, starting from a reference case study, uncertainties related to
6 the structural capacity and the size of the localised fires caused by a hole in a tank or a hole in a pipe
7 are included in the analyses. Thus, the influence of uncertainties in the derivation of the fragility
8 functions was highlighted by comparing four sets of analyses in which both demand and capacity
9 uncertainties were progressively introduced. Moreover, alongside the cloud analysis (CA), the
10 suitability of the Multiple Stripe Analysis (MSA) to build relevant probabilistic fire demand models
11 was assessed. Fire fragility curves were derived by considering the interstorey drift ratio (ISDR) as
12 engineering demand parameter (EDP) and by assessing different relevant intensity measures (IMs)
13 that represent the severity of localised fires. It was found that by introducing uncertainties in the steel
14 yield strength, lower probabilities to exceed the life safety and the near collapse limit states with
15 respect to the reference case study were observed. Moreover, the inclusion of further uncertainties,
16 described with continuous physically-based probability functions of the size of the fire diameter,
17 affected the probabilistic models by lowering the probability of exceedance. These functions provide
18 a more realistic description of the fire scenario, enabling a better representation of the structural
19 vulnerability. For this case study, the CA exhibited better suitability for the derivation of fire fragility
20 curves than the MSA. All the analysis results are thoroughly discussed in the paper.

24 **1. Introduction**

25 Fire safety is a fundamental requirement of the design of civil and industrial structures, which
26 according to the current European norms [1] may be satisfied by employing either a prescriptive or a
27 performance-based approach. The prescriptive approach mainly consists in "deemed-to-satisfy"
28 solutions and employs nominal fire curves, e.g., ISO 834 or hydrocarbon curves, that do not represent
29 the real fire behaviour. Instead, Performance-Based Fire Engineering (PBF) provides performance
30 objectives and requirements to be satisfied and exploits more realistic fire curves, that consider the
31 fire characteristics and the environment in which the structure is located. In general, PBF allows for
32 a better description of the actual fire behaviour, an increase in design flexibility and a reduction of
33 the construction costs but, on the other hand, it entails an adequate expertise of the designer and the
34 employment of advanced tools, like numerical software for thermal and structural analyses or
35 probabilistic frameworks for the definition of plausible fire events or for fire risk assessment. Whilst
36 numerical simulation of several types of structures and resisting mechanisms in fire can rely on
37 thoroughly validated software and new developments, suited for the investigation of complex
38 phenomena [2-8], the extension of probabilistic concepts to fire safety engineering requires separate
39 studies addressing specific structural types, fire characteristics and scenarios. In this respect, fragility
40 functions/curves are useful tools for risk assessment, hazard mitigation and expected damage
41 estimation of structures and infrastructures, but their implementation in fire engineering is still at an
42 initial stage, in particular for industrial plants. As performance-based fire engineering and fully
43 probabilistic structural fire engineering approaches are arising in the design practice, the definition
44 of probabilistic fire demand models (PFDMs) and fire fragility curves is becoming important. Indeed,
45 despite meaningful indications of different nature can be obtained by applying the PBF with a
46 deterministic approach [9-14], a probabilistic approach provides more general considerations, as well
47 as useful tools, like fire fragility curves, which show the probability of exceedance of specific limit
48 states, defined according to appropriate engineering demand parameters (EDP), conditioned on a
49 suitable intensity measure (IM) that characterise the fire, such as the fire dimension or the fire load.

50 These curves may be integrated in a fully probabilistic structural fire engineering (PSFE) framework,
51 contributing, for instance, to estimate the expected damage of a structure when combined with
52 probabilities of occurrence of fires in a specific context, e.g. residential or industrial.

53 Though the probabilistic approach has been widely exploited in Performance-Based Earthquake
54 Engineering (PBEE) [15-20], there are only a few works focused on the development of fire fragility
55 curves [21-25]. Among the others, in [22, 23] a methodology for developing fire fragility curves for
56 steel structures exposed to compartment fires, relevant to office and dwelling buildings, was
57 presented. Lange et al. [24] and Shrivastava et al. [25] adapted the probabilistic framework of the
58 Pacific Earthquake Engineering Research Center (PEER) [26] to fire engineering. In addition,
59 methods to compute fragility curves were mainly deployed in the context of PBEE. For instance, the
60 three main methods used to build probabilistic demand models: cloud analysis (CA), incremental
61 dynamic analysis (IDA), and multiple stripe analysis (MSA), were compared in [15]. Shome et al.
62 [16] and Cornell et al. [17] laid the groundwork for the adoption of cloud analysis in seismic
63 applications. Baker [18] instead, investigated incremental dynamic analysis and multiple stripe
64 analysis and developed a fragility functions fitting based on a maximum likelihood estimation. Luco
65 and Cornell [19] described the concepts of efficiency and sufficiency of an IM to assess its suitability
66 for developing seismic fragility functions, while a relative measure between two IMs, i.e., relative
67 sufficiency, was proposed as alternative sufficiency indicator in [20].

68 Probabilistic fire analyses and fragility curves become even more rare when it comes to industrial and
69 petrochemical plants, though their piping systems mainly transport flammable material, liquid or gas
70 fuel. Natural or accidental events may severely damage the structure supporting the piping systems
71 [27-32], usually consisting of steel pipe-racks, and they may cause a release of flammable material
72 from a pipe or a tank. Although in general the probability of occurrence of a fire may be low, the
73 probability of ignition of the spilled flammable material increases in industrial environments and
74 severe consequences are expected, as shown, among the others, by Uehara [33], Chan and Lin [34],
75 Zheng and Chen [35] and Shu and Chong [36]. Therefore, the fire risk cannot be ignored for

76 petrochemical plants, and the definition of specific probabilistic fire demand models (PFDMs) is
77 desirable. For this purpose, plausible fire scenarios, representing pool fires resulting from leakage
78 and loss of containment from a pipe or a tank, should be defined. Methods to quantify the probability
79 of occurrence of a loss of fuel and the characteristics of the arising fires, e.g., the mass flow rate
80 resulting from a fuel leakage through a hole in a tank or in a pipe, were provided in [37-40]. These
81 methods introduce a variability in the fire characteristic, or in general in the fire demand, that should
82 be carefully considered when developing PFDMs. However, uncertainties may affect the capacity of
83 the structures as well. In this respect, Gernay et al. [22, 23] indicated several sources of uncertainties
84 that may influence the structural capacity of residential or office buildings, like the randomness in the
85 material properties and in the magnitude of the loads. Recently, a probabilistic model for the steel
86 properties at elevated temperature was illustrated in [41, 42].

87 In this context, this paper gives a novel contribution to the field by developing fire fragility curves
88 for a prototype steel pipe rack exposed to localised fires, considering both demand and capacity
89 uncertainties, that will be useful to apply in probabilistic frameworks to estimate the expected damage
90 and/or in fire risk assessment analyses. It investigates the effect of including different uncertainties
91 by increasing the number of uncertain parameters and finally provides fragility curves that are
92 representative of a more realistic description of the fire scenario and structural behaviour. In detail,
93 starting from a reference case study presented in [43], additional numerical analyses were performed,
94 first integrating randomness in the steel material properties at elevated temperature, and then
95 introducing variability of fire characteristics for both material loss from a hole in a tank or in a pipe
96 in the model. To evaluate the effects of demand and capacity uncertainties, the four different sets of
97 analyses were compared throughout the whole procedure that brought to the development of fire
98 fragility curves for three relevant IMs. Among the different IM, a scaled distance, based on concepts
99 employed to describe blast or explosion hazard and obtained as a simple function of the fire
100 parameters, is proposed to characterise the fire severity. Efficiency and relative sufficiency concepts
101 were used to determine the most suitable IMs and the employment of not only the CA but also of the

102 MSA for building the fragility curves was investigated. The numerical analyses were carried out with
103 the software SAFIR [2], since it enables both structural and thermal analyses, and includes the
104 LOCAFI model for localised fires. Indeed, numerous works have investigated the thermal radiation
105 emitted from hydrocarbon pool fires to propose fire models [44-50], but only recently an analytical
106 model for localised fire, namely LOCAFI, was developed and integrated in a software [51-55]. This
107 model quantifies the thermal impact of localised fires on vertical structural elements assuming that
108 the flame shape is conical and based on the Heskestad flame length and temperature correlations [46,
109 55].

110 The paper is organised as follows: in Section 2 the prototype steel pipe-rack is described along with
111 the fire scenarios and the uncertain parameters; Section 3 presents the probabilistic fire analysis and
112 the derivation of the fire fragility curves; finally, in Section 4 the conclusions and the future
113 perspectives are drawn.

114 **2. Description of a prototype steel pipe-rack subjected to localised fires**

115 In this section the prototype steel pipe-rack is presented, together with its numerical modelling.
116 Analogously, the pool fire scenarios and the associated localised fire models are described as well.
117 Finally, the probabilistic approach employed to account for uncertainties is outlined and the structure
118 of the numerical analyses is delineated. For comparison purposes, four case studies are defined
119 depending on the source of the uncertainties introduced in numerical simulation. Further details on
120 the structural and fire models adopted in the analyses can be found in [43].

121 The case study is based on an existing petrochemical plant located in Italy, whose seismic behaviour
122 was thoroughly studied [28-31], and it is composed of several steel frames with rigid beam-to-column
123 joints, pinned column-base joints in the transversal direction and vertical braces in the longitudinal
124 direction with repeated modules composed of seven bays and only one equipped with bracings. The
125 structural contribution of the piping system was neglected, and the geometry of the supporting steel
126 pipe rack was simplified, resulting in the case study depicted in Figure 1. A regular portion of the
127 structure was analysed, consisting of a six-bay module frame with a total extension of $L_s=36\text{m}$. The

128 vertical load due to the self-weight of the pipes and their content was assumed equal to $q_v=75\text{kN/m}$,
 129 whilst a horizontal load $q_H=2\text{kN/m}$ was applied to take into account the friction of the pipes.
 130 Moreover, point loads were applied at midspan of the longitudinal beams, i.e., $V=15\text{kN}$ vertical and
 131 $H=7.5\text{kN}$ horizontal loads. As for the fire models later described in this paper, wind effects were
 132 neglected and no wind loads were applied.

133 The numerical model was defined with the thermo-mechanical non-linear finite element software
 134 SAFIR [2]. In detail, the model comprised HEA 340 columns, HEA 200 longitudinal beams, a lower
 135 row of HEA 300 transversal beams and HEB 300 for the remaining transversal beams, all made of
 136 S275 steel. 936 3D Bernoulli beam finite elements, having length of 50 cm each, were employed in
 137 the analyses. Columns were pinned at their base in both principal directions, transversal beams were
 138 end fixed to the columns, whilst the longitudinal beams were pinned to the columns (Figure 1b). Since
 139 the heating of the longitudinal bracing system, based on the investigated fire scenarios, was very
 140 limited and the major thermal impact occurred in the transverse direction, the bracing system was
 141 substituted in the model with horizontal restraints in the longitudinal direction to limit the
 142 computational burden.

143 **Figure 1. Case study**

144 **2.1. Fire scenarios description and localised fire models**

145 Fire scenarios consisting of pool fires resulting from a flammable material leakage or from a burning
 146 tank (Figure 2a) in industrial plants were investigated. A meaningful set of plausible localised fires
 147 impacting the structure with different levels of intensity, that cause from low consequences to the
 148 collapse of the entire structure, was considered. The set of scenarios was defined varying three

149 parameters, i.e., the fuel type, the fire diameter D and the fire-structure distance d , where the latter is
 150 the distance separating the edge of the fire and the structure. As shown in Figure 2b, the fires were
 151 always located in front of the structure, with the fire centre aligned with the central transversal beam
 152 of the structure. The distance between the fire centre and the structure is indicated as L . The analyses
 153 performed in [43], used as reference in this work and referred to as Case Study 0 (CS0), were
 154 performed employing the pool fire parameters reported in Table 1. Such analyses were expanded in
 155 this work as described in Section 2.2.

156 **Table 1.** Set of pool fire scenarios – fuel, fire-structure distance d and fire diameter D values used in the reference analysis - CS0

Pool fire parameters		Number of analyses
Fuels	Pentane, Kerosene, Heptane, Gasoline, Fuel Oil, Benzene, Acetone	7
Distance d [m]	0.5, 1, 2, 3, 4, 5, 6	7
Diameter D [m]	5, 7.5, 10, 12.5, 15, 17.5, 20, 22.5, 25, 27.5, 30	11
Total number of analyses		539

157 In CS0 7 liquid fuels were selected for the definition of the fire scenarios, since petrochemical plants
 158 deal with various flammable products, as well as 7 fire-structure distances. Distances higher than 6
 159 m were not investigated since for $d=6$ m the selected fires were already having a limited impact on
 160 the structure. Eleven equally spaced diameters were considered, assuming a uniform distribution of
 161 diameters in the 5 m to 30 m range, i.e., fires with diameters in the selected range all occur with the
 162 same probability, without distinguishing between leakage from a hole in the tank or from a pipe
 163 (Figure 2a). By varying the three parameters, 539 different localised fires were obtained and for each
 164 of them a thermo-mechanical analysis was performed, considering 60 minutes of thermal exposure.

165 **Figure 2.** a) Liquid outflow through a tank or a pipe; b) Fire-structure distance d and fire diameter D

166 A localised fire model integrated in SAFIR was employed to describe the fire development. Such
 167 model, i.e, LOCAFI model [55], belongs to the category of analytical models that exploit the virtual
 168 solid flame concept and was proven to provide accurate results, without being as demanding as more
 169 refined computational fluid dynamics (CFD) models. The model relies on the existing Heskestad
 170 correlations for localised fires included in Annex C of EN1991-2 [1] and describes a localised fire
 171 with a conical shape. It was validated against experimental data of fires characterised by diameters
 172 up to 50 m [55,56]. Localised fires are obtained in the model by defining the fire diameter D and the
 173 rate of heat release (RHR) Q of the fire. Indeed, additional information as the flame length L_f and
 174 temperature evolution along the flame axis can be derived from these two parameters

$$L_f = 0.0148Q^{0.40} - 1.02D \text{ [m]} \quad (1)$$

$$T(z) = 20 + 0.25Q_c^{\frac{2}{3}}(z - z_0)^{-\frac{5}{3}} \leq 900 \text{ [}^\circ\text{C]}$$

175 with

$$Q_c = 0.8Q \text{ [W]} \text{ and } z_0 = 0.00524Q^{0.40} - 1.02D \text{ [m]} \quad (2)$$

176 Where Q_c is the convective part of the rate of heat release Q and z_0 is the virtual origin of the fire
 177 source. The rate of heat release Q employed in the analyses was obtained as follows

$$Q = \dot{m}_b \Delta H_c \left(\frac{D\pi^2}{4} \right) \text{ [kW]} \quad (3)$$

$$\dot{m}_b = \dot{m}_\infty (1 - e^{-k\beta D}) \left[\frac{\text{kg}}{\text{m}^2\text{s}} \right]$$

178 where the mass burning rate \dot{m}_b was defined by Zabetakis and Burgess [58]. \dot{m}_∞ is the limiting mass
 179 burning rate, $k\beta$ is the empirical constant defined as the product between the extinction coefficient k
 180 and the mean beam length corrector β and ΔH_c is the heat of combustion (kJ/kg). The values
 181 employed in the analyses are reported in Table 2 [59]. For pentane the mass burning rate was taken
 182 as the limiting mass burning rate, and thus, no empirical constant is provided in Table 2. As a
 183 reference value to quantify the fuel intensity, the equivalent RHR density of the fuel q was obtained
 184 as follows

$$q = Q / \left(\frac{D\pi^2}{4} \right) \text{ [MW/m}^2\text{]}, \text{ with } \dot{m}_b = \dot{m}_\infty \quad (4)$$

185

Table 2. Fuel properties

Fuel	Limiting mass burning rate \dot{m}_∞ [kg/m ² s]	Empirical constant $k\beta$ [m ⁻¹]	Heat of combustion ΔH_c [kJ/kg]	Equivalent RHR density q [MW/m ²]
Acetone	0.038	2.24	25800	0.98
Fuel Oil	0.034	1.67	39700	1.35
Gasoline	0.055	1.48	43700	2.40
Kerosene	0.063	1.27	43000	2.71
Benzene	0.085	2.70	40100	3.41
Heptane	0.081	1.39	44600	3.61
Pentane	0.095	–	48800	4.64

186

2.2. Uncertainties in the structural and in the fire models

187 In CS0 [43] the variability of the fire input, or in general of the thermal demand, was accounted for
188 by varying the parameters characterising the fire considering a predetermined set of values. However,
189 a probabilistic approach, accounting also for uncertainties that may have a significant impact on the
190 structural capacity, e.g., steel mechanical and thermal properties and the applied loads [22], should
191 be preferred. In the specific case of the analysed pipe-rack, applied vertical loads are well defined in
192 case of normal service conditions, meaning that no significant variation is foreseen. Conversely, the
193 uncertainty related to the steel properties, and in particular to the mechanical properties, may
194 significantly affect the structural behaviour, as highlighted in [22,23]. Nevertheless, steel thermal
195 properties have relatively low variances and the deterministic values from EN-1993-1-2 [57] can be
196 taken [22]. Based on this discussion, in this work a probabilistic approach was adopted to consider
197 uncertainties affecting both the fire demand and the structural capacity with reference to the yield
198 strength at ambient and at elevated temperature. Starting from the reference case study CS0,
199 uncertainties related to the steel yield strength were implemented in a new set of analyses, namely
200 Case Study 1 (CS1). In detail, in CS0 the properties of steel at elevated temperature were taken as in
201 EN 1993-1-2 [57], whilst the analyses summarised in Table 1 were run in CS1 by considering the
202 logistic EC3-based probabilistic model proposed by Khorasani et al. [41] and Qureshi and al. [42] for
203 the yield strength at elevated temperature, whereas the Young's modulus and the proportional limit

204 were taken as in EN 1993-1-2 [57]. In this model the reduction of the yield strength at elevated
 205 temperature follows a probabilistic distribution, in which the variability of the value of the retention
 206 factor k_y , defined as the yield strength at a given temperature T measured at a 2% strain normalized
 207 by the yield strength at room temperature, is accounted for by means of the following equation

$$k_y = \frac{1.7 \exp[\text{logit}(\hat{k}_y^*) + 0.412 - 0.81 \cdot 10^{-3} \cdot T + 0.58 \cdot 10^{-6} \cdot T^{1.9} + 0.43\varepsilon]}{\exp[\text{logit}(\hat{k}_y^*) + 0.412 - 0.81 \cdot 10^{-3} \cdot T + 0.58 \cdot 10^{-6} \cdot T^{1.9} + 0.43\varepsilon] + 1} \quad (5)$$

208 where

$$\text{logit}(\hat{k}_y^*) = \ln\left(\frac{\hat{k}_y^*}{1-\hat{k}_y^*}\right), \hat{k}_y^* = \frac{k_{y,EN1993-1-2} + 10^{-6}}{1.7} \quad (6)$$

209 $k_{y,EN1993-1-2} = k_{y,EN1993-1-2}(T)$ is the retention factor of the yield strength at elevated temperature
 210 according to EN1993-1-2 [57] and ε is the standard normal distribution. The yield strength at ambient
 211 temperature also varies according to Eqs. (5) and (6) in terms of ε . Hence, the change in the steel
 212 strength with temperature was characterised by a different k_y reduction factor, determined according
 213 to Eq.(5) and values of ε generated with a Latin Hypercube sampling, in each one of the 539 analyses.
 214 Figure 3a illustrates the distributions of the retention factors k_y obtained at different temperatures,
 215 i.e. 20°C, 400°C and 600°C. It can be observed that the probabilistic model allows for higher retention
 216 factors and in turn yield strengths, compared to the EN1993-1-2 until very high temperatures are
 217 reached. In detail, the 0.5 quantile of k_y is always higher than $k_{y,EN1993-1-2}$ for $T < 700^\circ\text{C}$, whilst the
 218 mean of k_y is higher than $k_{y,EN1993-1-2}$ until approximately 900°C. In particular, as reported in [60]
 219 the logistic model described in Eqs. (5) and (6) implicitly includes the effect of strain hardening at
 220 lower temperatures and therefore, k_y can be higher than 1.0 at ambient temperature and consequently
 221 higher than $k_{y,EN1993-1-2}$. In this respect, the characteristic yield strength value was used in order to
 222 avoid too large yield strength values at ambient temperature.

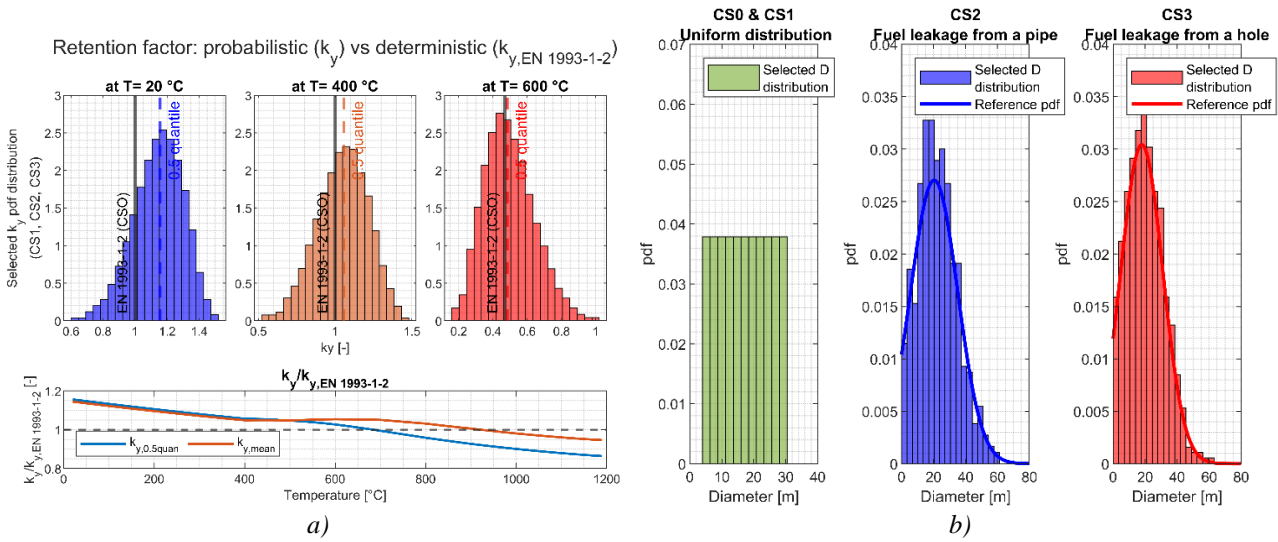

223 Two further set of analyses, namely Case Study 2 (CS2) and Case Study 3 (CS3), were carried out to
 224 propose a more refined thermal demand model for which the fire diameter was computed with
 225 continuous physically-based probability distributions based on the leakage of flammable material

226 from a hole in the tank or from a pipe. Indeed, in [43] the two probability density distributions were
 227 obtained by quantifying the liquid flow from a tank through a hole, or a pipe respectively. They were
 228 derived in order to determine the dimension of the fires that were most likely to occur and to be
 229 enough severe for the structure. For each of the two scenarios, consisting of 1000 different
 230 configurations, the fuels reported in Table 1 were considered and random tank and pipe geometries,
 231 hole dimensions and tank filling degrees varying within realistic ranges were selected. These analyses
 232 resulted in the fire diameter distributions depicted in Figure 3b. The illustrated normal distributions
 233 are defined with a mean of 20.39 m and a standard deviation of 14.75 m for a fuel leakage through a
 234 pipe and with a mean of 17.93 m and a standard deviation of 13.11 m for a fuel leakage through a
 235 hole. Therefore, the analyses of CS2 and CS3 were performed considering the diameter distributions
 236 for a liquid outflow from a pipe and from a hole, respectively. For each of the 49 fuel-distance pairs,
 237 11 diameters D were used from a set of 539 values picked with a Latin Hypercube sampling from the
 238 distributions. In Figure 3b also the distribution of the set of diameters employed in CS0 and CS1 is
 239 reported for comparison purposes. A summary of the quantities differentiating the 4 sets of analyses
 240 is provided in Table 3.

241

Table 3. Features of the investigated sets of analysis

Sets of analysis	Demand parameters	Capacity parameters
	Diameter D [m]	Steel yield strength
CS0	Uniform distribution (Table 1 & Figure 3b)	Deterministic (EN 1993-1-2 [57])
CS1	Uniform distribution (Table 1 & Figure 3b)	Probabilistic (Eq. 1)
CS2	Probabilistic (Figure 3b – pipe)	Probabilistic (Eq. 1)
CS3	Probabilistic (Figure 3b – hole)	Probabilistic (Eq. 1)

242 **Figure 3.** a) Probabilistic (Qureshi and al. [42]) vs deterministic retention factor model; b) Diameters distributions in
 243 CS0&CS1, CS2 and CS3

244 **3. Probabilistic fire analysis**

245 In this work, the results of numerical analyses are used to define a probabilistic fire demand model,
 246 with the aim to develop fire fragility curves, by providing a useful tool for practitioners that want to
 247 probabilistically assess or design a steel pipe-rack structure subjected to localised fires. Such curves
 248 describe the probability that an engineering demand parameter (EDP) exceeds a structural limit state
 249 (LS) conditioned on an intensity measure (IM).

$$P(\text{EDP} > \text{LS} | \text{IM}) \quad (7)$$

250 It is evident, that the selection of appropriate engineering demand parameters (EDP) and intensity
 251 measures (IMs) is crucial to propose fire fragility curves that accurately describe the structural
 252 response and the severity of the action. In this context, a significant data elaboration process had to
 253 be performed in order to only present the outcomes that provide a valuable information in terms of
 254 the selected EDPs and IMs. Therefore, in Section 3.1 and 3.2 suitable relevant IMs and EDPs are
 255 described.

256 **3.1. Intensity measures**

257 A good IM for a PFDM should be able to properly represent the severity of the fire scenario. In the
 258 literature several IMs have been proposed for compartment fires, but their ability to characterise

259 localised fires is not guaranteed. Therefore, the 8 IMs reported in Table 4 are investigated. The first
 260 7 were proposed by Randaxhe et al. [43], whereas the last one has been added in this work. Three
 261 obvious choices for the IMs consisted in the 3 parameters characterising the fire scenarios, i.e., the
 262 fire diameter D , the structure-fire distance d and the equivalent RHR density q . The latter is obtained
 263 assuming that $\dot{m}_\infty = \dot{m}_b$, which is a good approximation for $D > 1$ m. The remaining IMs were
 264 selected as functions of D , d and q . The fire position-diameter ratio was computed by considering the
 265 distance between the structure and the fire centre L as $D/2+d$. Instead, Eq.(1) was employed in the
 266 definition of the flame length L_f and the structure fire distance-flame length ratio d/L_f . HF_{avg} was
 267 obtained by means of a weighted average of the heat fluxes HF on the four sides of the cross section
 268 when it was impinged by the maximum radiative heat flux obtained with the LOCAFI model [55].
 269 The RHR density q is typically employed as IM in applications for compartment fires [22-25], since
 270 it provides an accurate estimate of the fire severity when a uniform fire distribution is assumed in an
 271 entire compartment. However, the RHR density q cannot accurately describe the severity of fires
 272 developing in a limited zone that might be far from the structure, i.e. localised fires. In particular, the
 273 fire dimensions and the distance separating the structure and the fire might influence the heat flux
 274 received from the structure and the number of critical elements that are severely heated.
 275 In order to provide an indicator that considers these aspects and more accurately characterises the
 276 severity of a localised fire, a further IM was defined, namely the scaled distance $d/A_{b,PE,eq}$ (Table 4).
 277 As shown later in this paper, the scaled distance is one of the best IM candidates yet being much
 278 simpler to derive than HF_{avg} and is obtained as the ratio between the structure-fire distance d and the
 279 equivalent pentane surface $A_{b,PE,eq}$, computed as

$$A_{PE,eq} = \frac{Q}{\dot{m}_{b,PE} \Delta H_{c,PE}} = \frac{q(1 - e^{-k\beta D}) \left(\frac{\pi D^2}{4} \right)}{\dot{m}_{b,PE} \Delta H_{c,PE}} \quad [m^2] \quad (8)$$

280 Where $\dot{m}_{b,PE}$ and $\Delta H_{c,PE}$ are the mass burning rate and the heat of combustion of pentane, respectively
 281 (Table 2). $A_{b,PE,eq}$ represents the equivalent surface of pentane to obtain the same RHR of the actual
 282 localised fire. Thus, the lower the scaled distance $d/A_{b,PE,eq}$ the higher the severity of the fire. It is

worth to point out that in the development of fragility curves related to the blast or explosion hazard, a scaled distance is widely employed as IM, e.g. in [61-63], which is defined as the structure-explosion distance over a fractional power of an equivalent TNT mass M_{TNT} . Analogously to $A_{b,PE,eq}$ (Eq. (8)), M_{TNT} is obtained as the mass of TNT that is necessary to obtain the same energy released by the actual explosion.

Table 4. Investigated Intensity Measures (IM)

IM	Name	Function/Formula
D [m]	Fire diameter	f(D)
d [m]	Structure fire distance	f(d)
q [MW/m ²]	Equivalent RHR density of the fuel	f(q) = $\dot{m}_{\infty}\Delta H_c$
L/D	Fire position-Diameter ratio	f(D, d) = (D/2 + d)/D
L _f [m]	Flame length	f(D, q) = Eq. (1)
HF _{avg} [kW/m ²]	Maximum average heat flux impinging the structure	f(D, d, q) see [26]
d/L _f	Structure fire distance-Flame length ratio	f(D, d, q) = d/Eq. (1)
d/A _{b,PE,eq} [m ⁻¹]	Scaled distance	f(D, d, q) = d/Eq. (8)

3.2. Engineering demand parameters

The EDP should be a good indicator of the structural response, but an EDP suited for a particular case might not be the best choice for a different structure or for a different action (e.g., fire, seismic, impact, etc.). For instance, the maximum temperature and the vertical deflections of the structural members may be identified as relevant EDPs for steel buildings exposed to compartment fires but are not suited for the proposed case study. Indeed, since the structural members are not engulfed in fire, limited vertical deflections were registered and a single temperature measure cannot adequately represent the complex thermal distribution inside and along the structural members. Therefore, in [43] the numerical results were examined thoroughly to identify an adequate EDP among different candidates, e.g., the inter-storey drift ratio, the axial load and the bending moment in the structural elements, the maximum average temperature within the whole structure and the average temperature within the most stressed structural elements. Finally, the inter-storey drift ratio (ISDR) was selected as EDP since it accurately represents the structural state regardless from the fire scenario and is widely employed for other types of structures and actions, e.g., seismic actions. Indeed, despite in general

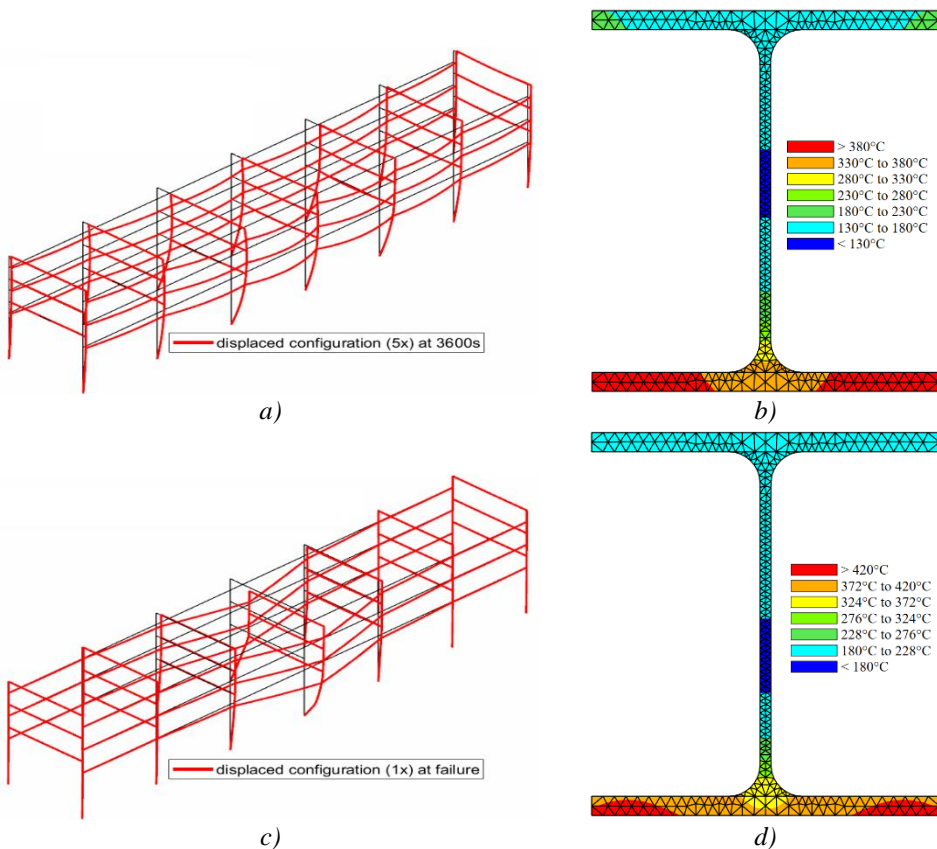

304 thermally induced drifts are not directly correlated to damage, in the investigated case study large
305 drifts were the major contributing cause of structural failure. Moreover, though localised fires may
306 induce differential ISDR at the same floor, numerical results showed that in this work the ISDR could
307 be associated with the damage of a significant part of the structure and thus, could be taken as an
308 indicator of the global structural response.

309 Detailed information on the values of ISDR associated to specific structural damage states (LS in Eq.
310 (7)) is available in literature. In this study, the ISDR values of 5% and 2.5% were adopted for near
311 collapse limit state and life safety limit state respectively, according to the indications for steel
312 moment resisting frames of the American seismic rehabilitation prestandard [64]. The selected limit
313 states refer to a situation in which a small increase of thermal and/or mechanical loads would lead the
314 structure to failure, i.e. near collapse, or to a situation in which the structure is in a significant
315 deformative state, but still has a margin of bearing capacity to support additional thermal and/or
316 mechanical loads, i.e., life safety.

317 **3.3. Results of the numerical analyses**

318 The results of the 2156 numerical analyses performed for the four case studies (i.e., 4 x 539 analyses)
319 are reported. If failure was not attained earlier, the analyses were stopped at 60 min, since by
320 preliminary checks it was found that thermal equilibrium was reached in the steel members after that
321 time. Figure 4a and Figure 4c show the typical deformed shape of the structure at failure and after 60
322 minutes, respectively. Figure 4 refers to CS3 and Figure 4a and Figure 4b depict the structure exposed
323 to a heptane fire at a distance of 2 m and a diameter of 25.4 m, whereas Figure 4c and Figure 4d show
324 the case with a heptane fire but diameter equal to 11.0 m. As depicted, the typical failure mechanism
325 of the structure consisted in the loss of stability of the central frame, which in most of the cases
326 experienced the largest transversal deformations. Despite the maximum displacements occurred at
327 the top of the structure, the highest inter-storey drift ratios (ISDR) were registered in the transverse
328 direction at the first level of the columns, i.e, at a height of 5m. Since no load increments were applied,

329 the progressive increase of the transversal displacements was related to the effects of the fire
 330 exposure. Indeed, strength and stiffness degradation of steel occurred and consequently the load-
 331 bearing capacity of the structural members decreased. In addition, the structural members were
 332 partially restrained; thus, axial dilatation and thermal bowing of the members induced variations of
 333 the internal forces. In particular, thermal bowing in the columns was substantial due to the significant
 334 non-uniform temperature distributions in the cross sections and entailed an increase in second order
 335 effect importance, as depicted in Figure 4b and Figure 4d for the central column of the closest row to
 336 fire at a height of 5m.

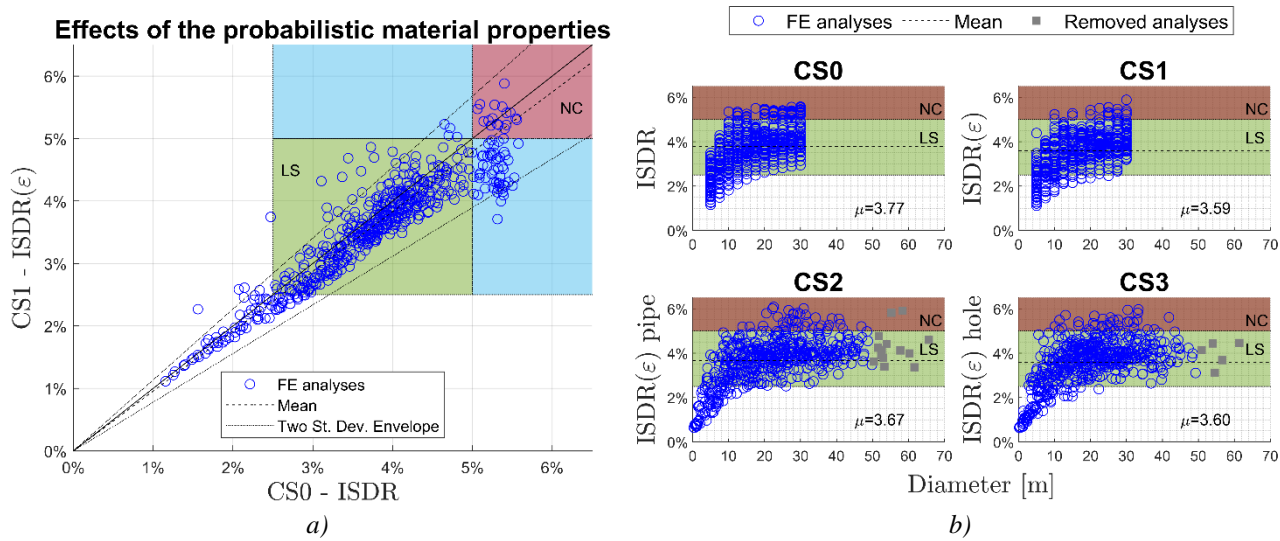

337 **Figure 4.** CS3 – Fuel=Heptane, d=2m: a) D=25.4m, deformed shape at failure; b) D=25.4m, temperatures of the front
 338 row central column at 5m at failure; c) D=11.0m, deformed shape after 60 minutes; d) D=11.0m, temperatures of the
 339 front row central column at 5m after 60 minutes

340 The maximum inter-storey drifts obtained in the analyses are represented in Figure 5 and Figure 6
 341 and they are denoted as ISDR for CS0, and as ISDR(ϵ) for CS1-CS3, where the steel yield strength
 342 at elevated temperature varied in accordance with the standard normal distribution ϵ in Eq.(5). The
 343 regions relevant to the life safety limit state and the near collapse limit states are indicated in green
 344 ($2.5\% \leq \text{ISDR} < 5\%$) and in red ($\text{ISDR} \geq 5\%$).

345 The effects of the introduction of the variability in the steel material properties can be discussed
346 observing the comparison between ISDR from CS0 and CS1 proposed in Figure 5a. A good
347 correlation is found between the results of the two analyses (mean and standard deviation of the ISDR
348 are 0.96% and 0.09% respectively), but accounting for the steel yield strength uncertainties tends to
349 reduce the ISDR in CS1. The points inside the green and red shaded areas represent the analyses
350 exceeding both the life safety and the near collapse limit state for each single analysis of the two sets,
351 i.e. CS0 and CS1. Instead, the points lying inside the blue areas are associated with the analyses for
352 which the near collapse limit state was exceeded in one CS, but only the life safety limit state was
353 reached for the other CS. In this respect, the CS0 deterministic material property assumptions appear
354 more severe since analyses that exceed the near collapse for CS0 are, conversely, in many cases still
355 only exceeding the life safety limit state for CS1. Indeed, in CS1 the steel retention factors of the
356 yield strength are on average larger than the one prescribed in the EN 1993-1-2 and used in CS0 (see
357 the 0.5 quantile and the mean of the picked k_y factors in Figure 3). Thus, higher strength is exhibited
358 in the CS1 analyses. This holds true when the ISDR of CS0 are compared to the ones of CS2 and CS3
359 as also in these cases the probabilistic material model was considered, as shown in Figure 5b. In
360 addition, the mean ISDRs of CS1, CS2 and CS3, i.e., 3.59%, 3.67%, 3.60%, reflect the mean of the
361 diameter distributions employed in such analyses, i.e., 17.5m, 20.39m, 17.93m. Larger diameters
362 entail more severe fires, leading to higher values of ISDR.

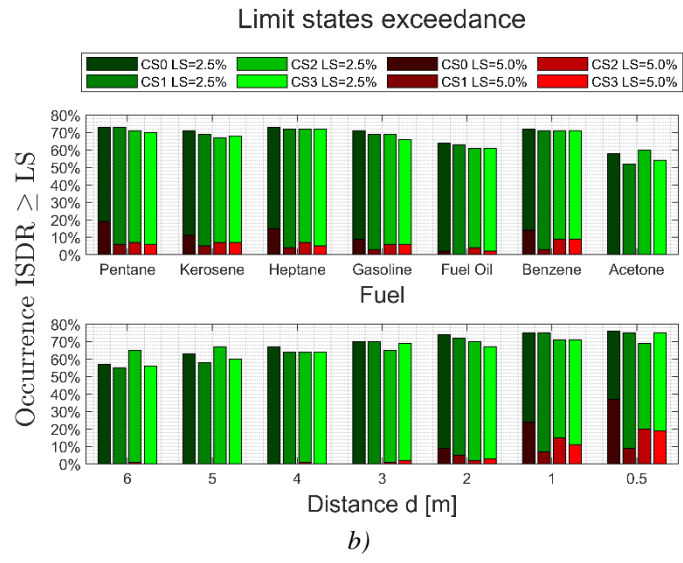

363 To better understand the effects of uncertainties, the results of each of the analyses performed for
364 CS2 and CS3 were examined. As mentioned before, since the LOCAFI model was not extensively
365 investigated for fire diameters larger than 50 m ($D > 50$ m) [55,56], the analyses obtained for diameters
366 larger than 50 m in CS2 (14 analyses) and in CS3 (5 analyses) are explicitly indicated in Figure 5b
367 with grey squares and are not considered later in the development of the PFDMs. Besides, it has to
368 be observed that some analyses experienced $ISDR > 5\%$ without showing structural failure owing to
369 lack of numerical convergence caused mainly by material fracture occurred in a highly deformed
370 configuration, that also determined runaway in some analyses. Therefore, the analyses run until the

371 end (60 minutes). For such analyses it was checked that by slightly increasing the loads, failure was
 372 reached to confirm that they were in a near collapse state.

373 **Figure 5.** Influence on the ISDR: a) of the uncertainties in the material properties; b) of the uncertainties in the material
 374 properties and the diameter distribution

375 Finally, as shown in Figure 6, the near collapse limit state threshold (5%) was exceeded more
 376 frequently in CS0, whilst the 2.5% threshold exceedance occurred for all four case studies in a
 377 comparable number of analyses for a given fuel or structure-fire distance. Again, the trend of the
 378 results indicates that higher ISDR may be reached for the same fire scenario when the deterministic
 379 material properties are employed (CS0), for which plasticity and load redistribution occur for lower
 380 load levels or fire intensity ISDR compared to the case studies with the probabilistic material model (CS1-
 381 CS3).

382 **Figure 6.** a) LS thresholds exceedance for type of fuel and for distance d

383 **3.4.Cloud analysis and Multiple stripe analysis**

384 Though numerous probabilistic seismic demand models (PSDM) are available, the literature is
385 currently lacking extensive applications in the fire context and only few probabilistic fire demand
386 models (PFDM) can be found [21-25]. With respect to PSDM, incremental dynamic analysis (IDA),
387 Cloud analysis (CA) and Multiple stripe analysis (MSA) are usually employed to obtain fragility
388 curves. PSDMs are obtained with IDA by incrementing an IM in dynamic analyses until the EDP
389 exceeds a certain limit state (LS). However, scaling fire IMs, such as fire load or heat flux, can rapidly
390 lead to unrealistic fire scenarios and thus, IDA is not well suited for a PFDM and is not applied in
391 this work. Instead, both CA, also employed in [43] and MSA are proposed to develop the PFDM.

392 **3.4.1. Cloud Analysis (CA)**

393 Cloud analysis (CA) is suited to build a PSDM from EDP-IM pairs arranged in a data cloud. This
394 procedure is particularly convenient as it does not require to perform several analyses for discrete
395 quantities of IM as in MSA and thus, it is not necessary to determine the IM to be employed in the
396 PSDM model a priori. This allows for the selection of the most suitable IM a posteriori, i.e., in light
397 of the results of the numerical analyses and of the CA.

398 The CA method assumes that an EDP follows a lognormal distribution when conditioned on an IM.
399 Hence, the probabilistic demand model can be characterised as follows

$$\begin{aligned} \widehat{\text{EDP}} &= a\text{IM}^b \\ \ln(\widehat{\text{EDP}}) &= A + B \ln(\text{IM}) \end{aligned} \tag{9}$$

400 where $\widehat{\text{EDP}}$ is the median of the EDP, and the parameters $a = \exp(A)$ and $b = B$ are identified by
401 means of a linear regression. Indeed, the conditional median of the EDP given the IM is linear in the
402 log–log space, whereas the conditional dispersion of the EDP given the IM is constant. Such
403 dispersion, referred to as $\beta_{\text{EDP}|\text{IM}}$, can be determined as the standard deviation of the linear regression

$$404 \sigma_{\ln(\text{EDP})|\text{IM}}$$

$$\beta_{\text{EDP}|\text{IM}} = \sigma_{\ln(\text{EDP})|\text{IM}} = \sqrt{\frac{\sum_{i=1}^n [\ln(\text{EDP}_i) - \ln(\widehat{\text{EDP}}_i)]^2}{n-2}} \quad (10)$$

405 Finally, the fragility function can be defined in the form of a lognormal cumulative distribution
 406 function [42]

$$P(\text{EDP} > \text{LS}|\text{IM}) = 1 - \Phi\left(\frac{\ln\left(\frac{\text{LS}}{a\text{IM}^b}\right)}{\beta_{\text{EDP}|\text{IM}}}\right) \quad (11)$$

407 **3.4.2. Multi Stripe Analysis (MSA)**

408 MSA can be applied to build a demand model by considering a discrete set of IMs, so that EDP-IM
 409 pairs are arranged in a stripe for each IM level. However, a minimum number of analyses should be
 410 performed for each level of IMs to obtain meaningful models [15]. In the framework of this work,
 411 MSA analysis was employed for IMs and CSs that allowed for stripes with at least 7 occurrences, i.e.,
 412 at least 7 analyses were performed for each value of the IM. Though at least 10 instances per stripe
 413 are usually suggested [15], the threshold was lowered to 7 to test the ability of MSA to provide
 414 efficient PFDMs with only few results for each IM level.

415 MSA is based on the definition of fraction of collapses for a predefined LS and for each i-th level of
 416 IM, i.e., for each stripe. Such fraction is obtained dividing the number k_i of analyses in which $\text{EDP} >$
 417 LS by the total number of analyses performed. Assuming that observations of “collapse” or “no-
 418 collapse” are independent for the different fire scenarios, a binomial distribution can be used to
 419 express the probability of observing k_i collapses among n_i fire scenarios given an IM_i

$$P(k_i \text{ collapses in } n_i \text{ fire scenarios}) = \binom{n_i}{k_i} p_i^{k_i} (1 - p_i)^{n_i - k_i} \quad (12)$$

420 where p_i is the probability to observe a collapse C given an IM_i . Such probability can be defined with
 421 a lognormal cumulative distribution function [18]

$$p_i = P_i(C|\text{IM}_i) = \Phi\left(\frac{\ln\left(\frac{\text{IM}_i}{\theta}\right)}{\beta}\right) \quad (13)$$

422 The function $\Phi(\)$ is the standard normal cumulative distribution function, while θ and β define the
423 shape of the fragility function and are the median of the fragility function, i.e., the IM level generating
424 a probability of exceedance of 50%, and the standard deviation of $\ln(\text{IM})$, respectively. The parameter
425 β is the dispersion of the fragility function and must not be confused with the term $\beta_{\text{EDP}|\text{IM}}$ in Eq.
426 (10), which is the dispersion of the EDP conditioned on IM. In this work the fragility function is built
427 with the maximum likelihood method, which aims at finding the probability distribution with the
428 highest likelihood of having produced the fraction of collapse observed for each IM_i . The likelihood
429 is defined as the product of the binomial probabilities

$$\begin{aligned} \text{Likelihood} &= \prod_{i=1}^m \binom{n_i}{k_i} p_i^{k_i} (1 - p_i)^{n_i - k_i} \\ \text{Likelihood} &= \prod_{i=1}^m \binom{n_i}{k_i} \Phi\left(\frac{\ln(\frac{\text{IM}_i}{\theta})}{\beta}\right)^{k_i} \left(1 - \Phi\left(\frac{\ln(\frac{\text{IM}_i}{\theta})}{\beta}\right)\right)^{n_i - k_i} \end{aligned} \quad (14)$$

430 where m is the number of IM levels or stripes. The optimal parameters $\hat{\theta}$ and $\hat{\beta}$ of the fragility function
431 are obtained by maximising the likelihood as follows

$$\{\hat{\theta}, \hat{\beta}\} = \max_{\theta, \beta} \sum_{i=1}^m \left[\ln \binom{n_i}{k_i} + k_i \ln \Phi\left(\frac{\ln(\frac{\text{IM}_i}{\theta})}{\beta}\right) + (n_i - k_i) \ln \left(1 - \Phi\left(\frac{\ln(\frac{\text{IM}_i}{\theta})}{\beta}\right)\right) \right] \quad (15)$$

432 Once the optimal parameters are defined, the fragility function can be obtained employing the
433 distribution assumed earlier (Eq.(13))

$$P(\text{EDP} > \text{LS}|\text{IM}) = \Phi\left(\frac{\ln\left(\frac{\text{IM}}{\hat{\theta}}\right)}{\hat{\beta}}\right) \quad (16)$$

434 The dispersion of the EDP conditioned on the IM for the i -th stripe $\beta_{\text{EDP}_i|\text{IM}_i}$ can be taken as in [25].

$$\begin{aligned} \beta_{\text{EDP}_i|\text{IM}_i} &= \frac{\sigma_{\text{EDP}_i|\text{IM}_i}}{\mu_{\text{EDP}_i|\text{IM}_i}} \\ \sigma_{\text{EDP}_i|\text{IM}_i} &= \sqrt{\frac{\sum_{i=1}^o [\text{EDP}_{i,o} - \mu_{\text{EDP}_i|\text{IM}_i}]^2}{n}} \quad \mu_{\text{EDP}_i|\text{IM}_i} = \frac{\sum_{i=1}^o \text{EDP}_{i,o}}{n} \quad \text{with } o = \text{occurrences at } \text{IM}_i \end{aligned} \quad (17)$$

3.5. CA and MSA results

In order to derive the fire fragility curves, the results of the four case studies were analysed by means of CA and MSA. The ISDR was used as unique EDP and the IMs given in Table 4 were exploited. The CA was applied to all cases and all IMs, as mentioned in Section 3.4, whilst the MSA was employed only when at least 7 instances per stripe were available. As a result, the MSA was applied to CS0 and CS1 for IMs consisting of single fire parameters or simple functions of them, i.e., D, d, q, L/D and L_f ; while, due to the variability of the diameters D introduced in the analyses, MSA was used only for d and q in CS2 and CS3. Indeed, it appears that obtaining well-defined stripes is not trivial when uncertainties are included into the demand model as continuous probabilistic density functions. The obtained PFDMs are shown against the numerical results in an EDP-IM space in Figure 7. The CA regression is represented as a continuous line, while single points are used for each stripe of the MSA. A log-log space representation is preferred to better show the linear regression fit when only the CA is available. The parameters of the CA and the MSA defined in Sections 3.4.1 and 3.4.2 are reported in Table 5 and Table 6, respectively.

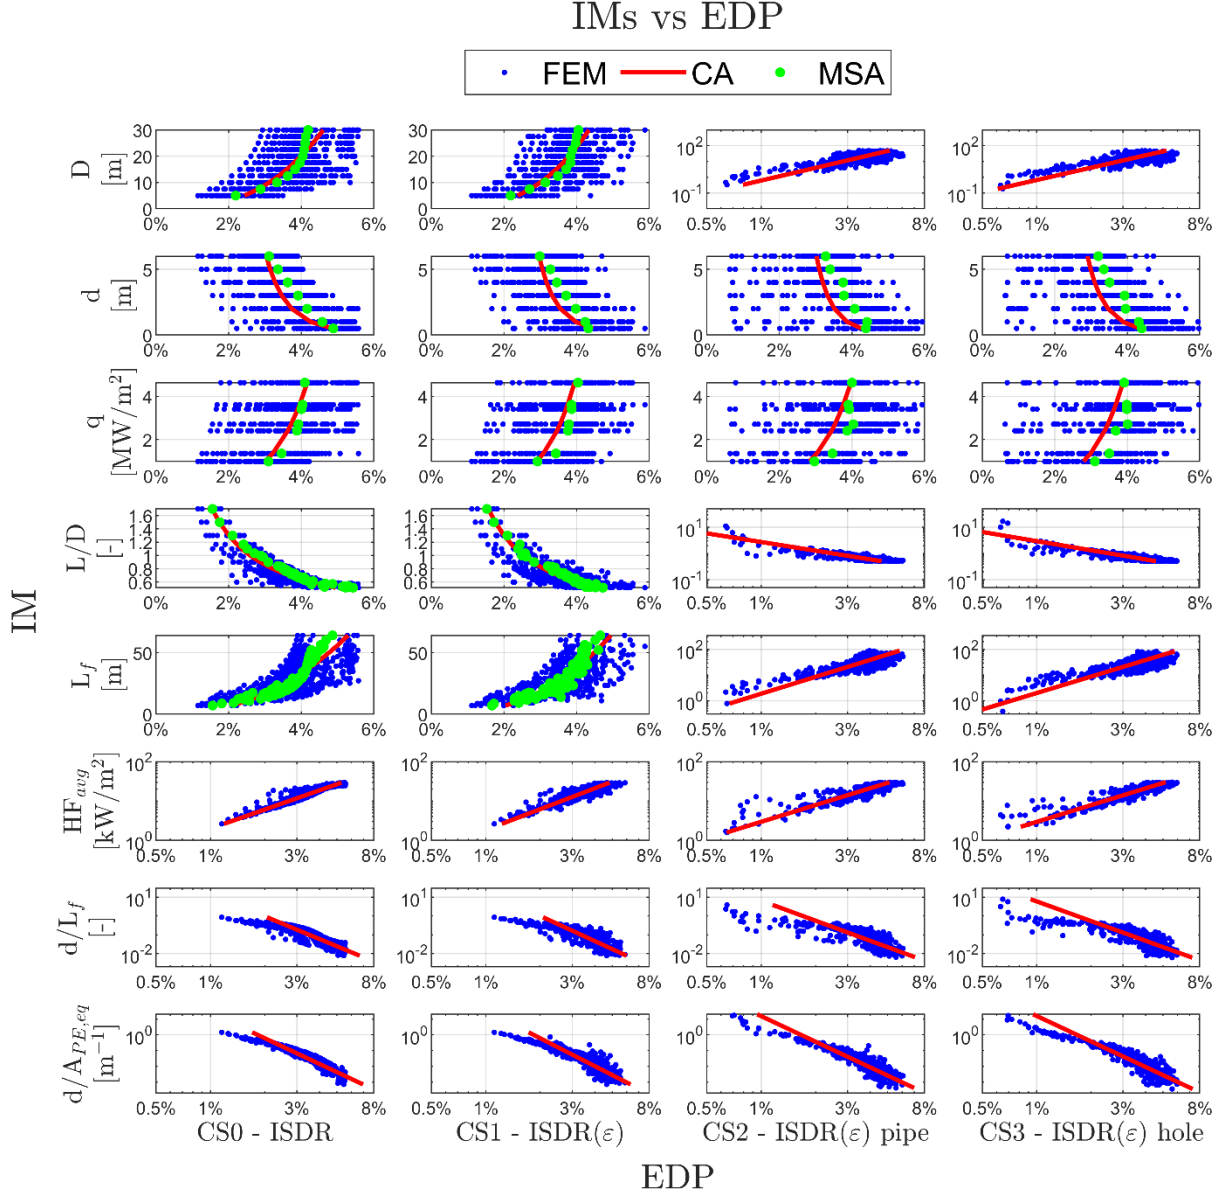

Table 5. Cloud analysis parameters

CA parameters								
IM	CS0		CS1		CS2		CS3

451 **Figure 7.** Cloud and multi-stripe analysis fit models
 452 Not all IMs allow for equally well-defined PFDMs and the dispersion of the EDP conditioned on IM
 453 $\beta_{EDP|IM}$ provides a quantitative measure of the variations between the actual and the predicted EDP
 454 values for a given IM. Such dispersions are summarised in Figure 8 for all the derived PFDMs. When
 455 the MSA was used, dispersion values were determined according to Eq. (17) at each IM level. As

456 expected, the MSA applied with L/D and L_f as IMs, showed the highest variability in the dispersion
 457 because only 7 analyses per stripe were used, confirming that at least 10 analyses for each IM level
 458 [15] are probably necessary to obtain efficient demand models.

459 **Figure 8.** Cloud vs multi-stripe analysis dispersions
 460 In fact, the dispersion is a good indicator to evaluate the efficiency of an IMs. An IM is efficient if it
 461 generates low $\beta_{EDP|IM}$ values, usually below 0.3 [15]. Therefore, the dispersion of the CA was
 462 employed to select the best IM candidates for developing the fire fragility curves. Dispersions were
 463 compared in the efficiency plot of Figure 9a, from which it can be observed that for CS2 and CS3 q
 464 and d , which are the only IMs completely independent from the diameter D (Table 4), cannot be
 465 deemed efficient. This is due to the fact that the fire diameter D is a fundamental parameter to
 466 characterise the fire severity and this is even more true when a probabilistic distribution of D is
 467 assumed as in CS2 and CS3. Nevertheless, even though for CS0 and CS1 q and d can be considered
 468 efficient, they show the highest dispersion values among the different IM. Based on this discussion,
 469 q and d were discarded and among the remaining IM candidates, the three with the highest efficiency
 470 were selected, namely L/D , HF_{avg} and $d/A_{b,PE,eq}$.

471 Besides, the sufficiency of the IMs was investigated to ensure an accurate estimate of the probability
 472 of a structural response given an IM, i.e., $P(EDP|IM)$. According to Luco and Cornell [19], IMs are
 473 sufficient when the structural response to a demand shows no trend in the correlation with the

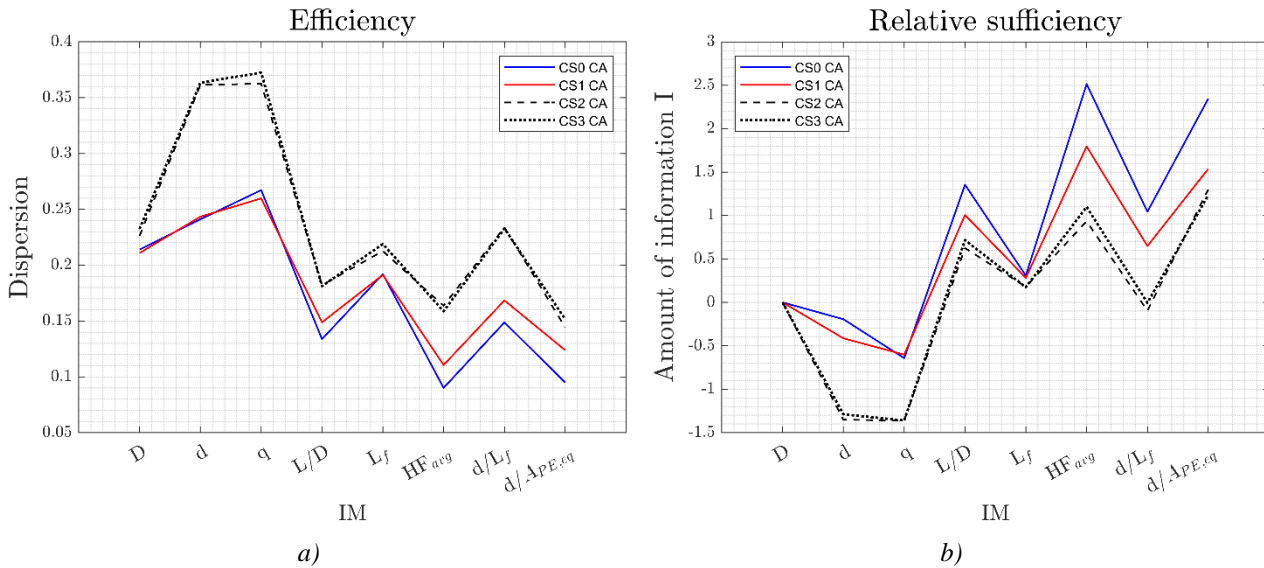

474 parameters defining such demand. However, the IMs candidates employed in this work were defined
 475 as functions of the fire parameters, i.e., D , d and q , and correlation was always observed between the
 476 residuals of EDP and these parameters. In this situation, a more appropriate sufficiency measure is
 477 the relative sufficiency, which compares the sufficiency of IMs by evaluating the amount of
 478 information gained on average about the structural response. The amount of information I gained by
 479 IM_2 with respect to IM_1 can be evaluated according to [20]

$$I(\text{EDP}|IM_2|IM_1) \approx \frac{1}{n} \sum_{i=1}^n \log_2 \frac{p[\text{EDP} = \text{EDP}_i|IM_2]}{p[\text{EDP} = \text{EDP}_i|IM_1]}$$

$$P(\text{EDP} = \text{EDP}_i|IM) = \frac{1}{\beta_{\text{EDP}|IM} \text{EDP}_i} \Phi \left(\frac{\ln \left(\frac{\text{EDP}_i}{aIM_i^b} \right)}{\beta_{\text{EDP}|IM}} \right) \quad (18)$$

480 and is expressed in unit of bits of information. EDP_i is the parameter evaluating the structural response
 481 (ISDR) for each of the n fire scenarios, $P(\text{EDP}|IM)$ is the probability of a structural response given
 482 the IM and $\Phi(\cdot)$ is the standard gaussian probability density function. An IM is more sufficient than
 483 another if it provides more information on the structural response. It follows that IM_2 is more
 484 sufficient than IM_1 for positive values of $I(\text{EDP}|IM_2|IM_1)$. The higher the value of $I(\text{EDP}|IM_i|IM_1)$,
 485 the more sufficient the IM_i is. A relative sufficiency plot is depicted in Figure 9b, by comparing the
 486 amount of information I of the candidates IMs with respect to the diameter ($IM_1=D$). The choice of
 487 the reference IM is arbitrary, since selecting a different IM the relative sufficiency plot translates
 488 vertically, but the difference between the values of I for each IM remain unchanged. The three best
 489 IMs in terms of relative sufficiency are the same as for the efficiency and thus, no further
 490 consideration was necessary to choose the IMs for developing the fragility curves. For all the four
 491 sets of analyses $d/A_{b,PE,eq}$ permits for dispersions and amounts of information comparable with the
 492 ones obtained considering HF_{avg} as IM. However, $d/A_{b,PE,eq}$ has the advantage of being much more
 493 straightforward to calculate than HF_{avg} . As expected, Figure 9 shows that IMs are less efficient and
 494 less sufficient when uncertainties are introduced, but their ranking remains unchanged. Moreover,

495 being d and q completely independent from the diameter D , their relative sufficiency is significantly
 496 worse when probabilistic distributions of the diameter are used (CS2 and CS3) and the diameter
 497 provides more relevant information to characterise the fire severity, and in turn the structural
 498 response.

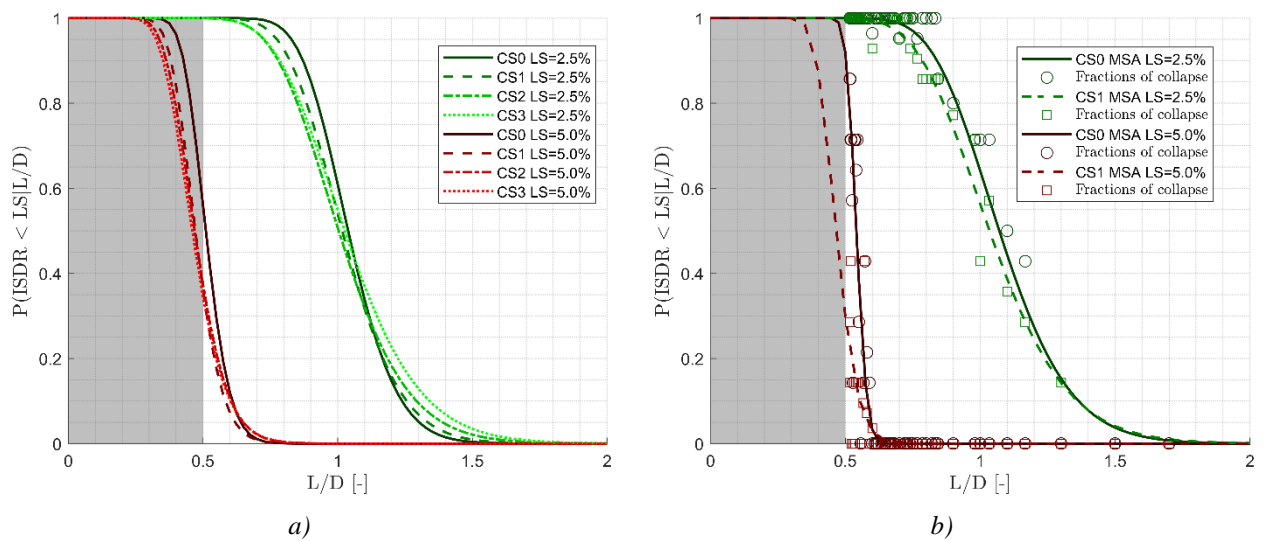

499 **Figure 9.** a) Efficiency and b) relative sufficiency of IMs

500 3.6. Fire fragility curves

501 Fire fragility curves were derived from the PFDMs obtained for each of the IM candidates given in
 502 Table 4. However, only the fragility curves obtained for the three most efficient and sufficient IMs
 503 are shown and discussed. The proposed curves can be used to quantify the probability that a steel
 504 pipe-rack exposed to a localised fire exceeds a predetermined limit state. The curves are developed
 505 for two limit states, namely the near collapse limit state and life safety limit state, for which a 5% and
 506 a 2.5% threshold is set on the ISDR. Fragility curves were derived for all the case studies, i.e. CS0,
 507 CS1, CS2 and CS3.

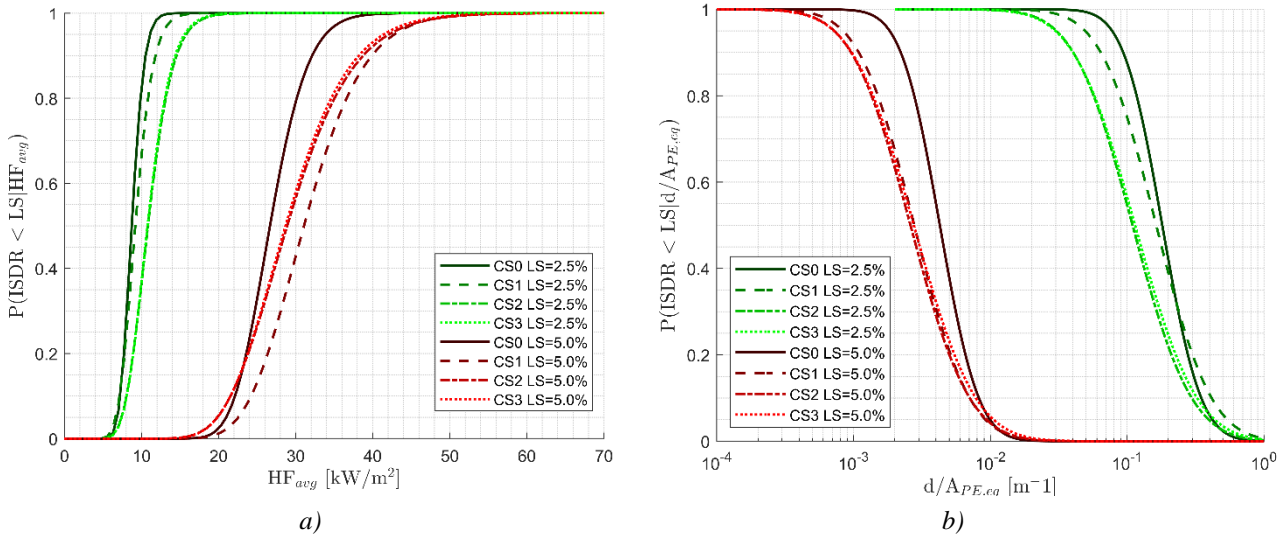

508 Figure 10 shows the fragility curves for the PFDM based on L/D as IM. A limitation should be applied
 509 to this model since for $L/D < 0.5$ part of the structure would be engulfed into the localised fire and a
 510 different structural response is expected, with the ISDR no longer being the most appropriate EDP.
 511 Therefore, these curves may not be suited for the range shaded in grey. All the fragility curves for a
 512 given limit state attain the median of the probability distribution, i.e., $P(\text{ISDR} > \text{LS} | L/D) = 50\%$ at

513 similar ISDR values. For the life safety limit state the 50% probability is exceeded for
514 $0.45 < L/D < 0.52$, while for the near collapse limit state this occurs for $1.03 < L/D < 1.06$. As expected,
515 here and in all the subsequent figures, the fragility curves show a higher dispersion when the
516 parameter uncertainties are incorporated, i.e. CS1, CS2, CS3.
517 For L/D fire fragility curves for CS0 and CS1 are obtained also from the MSA, as illustrated in Figure
518 10b. The fragility curves based on the MSA fit the fraction of collapses, intended as the ratio between
519 the cases in which a limit state was exceeded over the total number of fire scenarios (539) given an
520 IM_i . Though the IM ranges relevant to collapses are similar to the ones from CA, different values of
521 probabilities of exceedance are found. For instance, a higher curve is derived for the near collapse in
522 CS0, for which at $L/D=0.5$ the probability of exceedance is higher than 90%. Conversely, by
523 comparing the CS1 case study at the near collapse limit state the MSA and the CA provide similar
524 fragility curves. This was also observed at the life safety limit state for which good agreement between
525 the two methods to derive fragility curves is shown in Figure 10. However, since only few data were
526 available for each stripe (7 or 14) and the curve fit rather disperse fraction of collapses, the MSA
527 based fragility curves are deemed less reliable and the use of CA is suggested when less than 10 data
528 are available for each IM level, as recommended in [15].

529 **Figure 10** fragility curves for near collapse and life safety preventions with L/D as IM. a) CA; b) MSA
530 A significant improvement in efficiency and relative sufficiency was obtained by employing HF_{avg}
531 and $d/A_{b,PE,eq}$, whose associated CA based fragility curves are depicted in Figure 11a and Figure

532 11b, respectively. In Figure 11a, the probability of exceeding the life safety and the near collapse
 533 limit states surpasses the 50% for $8.7 < HF_{avg} < 10.8 \text{ kW/m}^2$ and $26.6 < HF_{avg} < 31.1 \text{ kW/m}^2$ respectively.
 534 For $IM = d/A_{b,PE,eq}$, the probability of exceeding the life safety and the near collapse limit states
 535 attains the 50% for $0.13 < d/A_{b,PE,eq} < 0.21 \text{ m}^{-1}$ and for $3.1 \cdot 10^{-3} < d/A_{b,PE,eq} < 4.9 \cdot 10^{-3} \text{ m}^{-1}$ respectively,
 536 as illustrated in Figure 11b.

537 **Figure 11.** CA based fragility curves for near collapse and life safety preventions with: a) HF_{avg} as IM; b) $d/A_{b,PE,eq}$ as
 538 IM

539 It is interesting to note that in general, the fragility curves show lower probabilities of exceedance for
 540 a given value of IM when the probabilistic model for the steel strength at elevated temperature is
 541 considered (CS1-CS3 in Figure 10 and Figure 11). However, this may not be true for low probabilities
 542 of exceedance owing to the higher dispersions found in CS1 to CS3. This is a typical effect when
 543 considering parameter uncertainties, as the introduction of further uncertainties inflates the tails of
 544 the probability distributions, causing their cumulative distributions, i.e., the fragility functions, to
 545 span over larger IM ranges. Nevertheless, the medians of the probability distributions, i.e., the values
 546 of IM for which a probability of exceedance of 50% is reached, are always less demanding for CS1-
 547 CS3. Therefore, it can be concluded that in general less severe fragility curves are obtained when the
 548 probabilistic model for the steel strength is considered. This was expected because the retention
 549 factors at elevated temperature included in Eurocode are for design purposes and thus, inherently

550 conservative. Indeed, in the probabilistic model the retention factor k_y of the steel yield strength f_y
551 in CS1 - CS3 is higher than the nominal one $k_{y,EN1993-1-2}$ used in CS0 (see Figure 3a).
552 In addition, the employment of probabilistic fire diameter distributions rather than a uniform one may
553 have a significant influence on the fragility curves (CS1 vs CS2 and CS3), whilst very similar curves
554 are always found for two normal diameter distributions with different mean and standard deviation
555 because of the different type of leakage, i.e. CS2 vs CS3. Hence, the fragility curves seem more
556 sensitive to the fact that a discrete diameter distribution is employed, rather than to the variation of
557 the mean and standard deviation of the diameter of continuous density probability distributions. It
558 should be noted that the difference in the mean and standard deviations of the normal distributions
559 between leakage from a hole and from a pipe is in the order of about 12%. Moreover, it cannot be
560 concluded that discrete diameter distributions always provide more severe fragility functions. Indeed,
561 as shown in Figure 11, CS2 and CS3 fragility curves may be more or less severe than the ones from
562 CS1 depending on the limit state and on the IM. Nevertheless, the definition of fire demand models
563 based on probabilistic distributions is desirable and should be preferred since they provide more
564 realistic fire scenarios based on leakage from a hole in the tank (CS2) or from a pipe (CS3).

565 **4. Conclusions**

566 The paper presented the development of probabilistic fire demand models for a prototype steel pipe-
567 rack exposed to localised fires by adding uncertainties related to the structural capacity, i.e. yield
568 strength, and to the fire diameter that is caused by a hole in a tank or by a hole in a pipe. PFDMs were
569 defined for each case study by means of the Cloud analysis (CA) and, when suitable, also through the
570 Multiple stripe analysis (MSA). It is shown that the CA is a viable method to derive PFDMs and fire
571 fragility curves, whilst in order to benefit from the application of MSA, suitable IMs should be
572 identified before performing the analyses so as to obtain stripes with at least 10 instances by scaling
573 the severity of the fire based on such IMs. As expected, by allowing for the uncertainty of the steel
574 yield strength, lower values of ISDR with respect to the reference case study CS0 were observed

575 because the retention factors, and in turn the yield strength values at elevated temperature were, on
576 average, larger than the ones prescribed in EN 1993-1-2. Indeed, the steel structural members
577 plasticized later with the probabilistic material model (CS1, CS2 and CS3), allowing for both a delay
578 in load redistribution and smaller displacements, therefore resulting in less severe fragility curves.
579 The fire fragility curves were derived for different EDP-IM candidates. In this respect, the most
580 suitable IMs for steel pipe-racks, with similar characteristics with the prototype one, exposed to
581 localised fires were identified as the ones that maximise the efficiency (lowest dispersion of the EDP
582 given the IM) and the relative sufficiency (highest amount of information on the structural response).
583 Three suitable IMs were identified: i) the fire position-diameter ratio L/D , which is easy to use for
584 practitioners, but has lower efficiency and relative sufficiency indicators among the three proposed
585 IMs; ii) the maximum average heat flux impinging the structure HF_{avg} and iii) the scaled distance
586 $d/A_{b,PE,eq}$, which consists of a simple function of the fire parameters q , d and D , derived in similar
587 fashion for explosion hazard as the structure-explosion distance over a fractional power of an
588 equivalent TNT mass. The HF_{avg} and the $d/A_{b,PE,eq}$ are more efficient and more relatively sufficient
589 IMs, but the maximum average heat flux impinging the structure HF_{avg} is not as straightforward to
590 calculate as the scaled distance $d/A_{b,PE,eq}$, that showed comparable efficiency and sufficiency with
591 HF_{avg} and accounts for the effects of the distance of the fire from the structure and the extension of
592 the fire. MSA based fragility curves with L/D as IM were developed for the CS0 and CS1, but only
593 7 analyses were available for some stripes and thus, the CA fragility functions are deemed more
594 reliable. Furthermore, probabilistic diameter distributions in CS2 and CS3 had influence on the
595 fragility curves by lowering the probability of exceedance of the limit states for same values of IM
596 and should be considered since they provide more realistic fire scenarios. In general, the definition of
597 fire demand models based on probabilistic distributions for demand and capacity is desirable and
598 should be preferred since they provide more realistic fire scenarios. Future perspectives will focus on
599 considering multiple burning pool fires and the presence of the wind.
